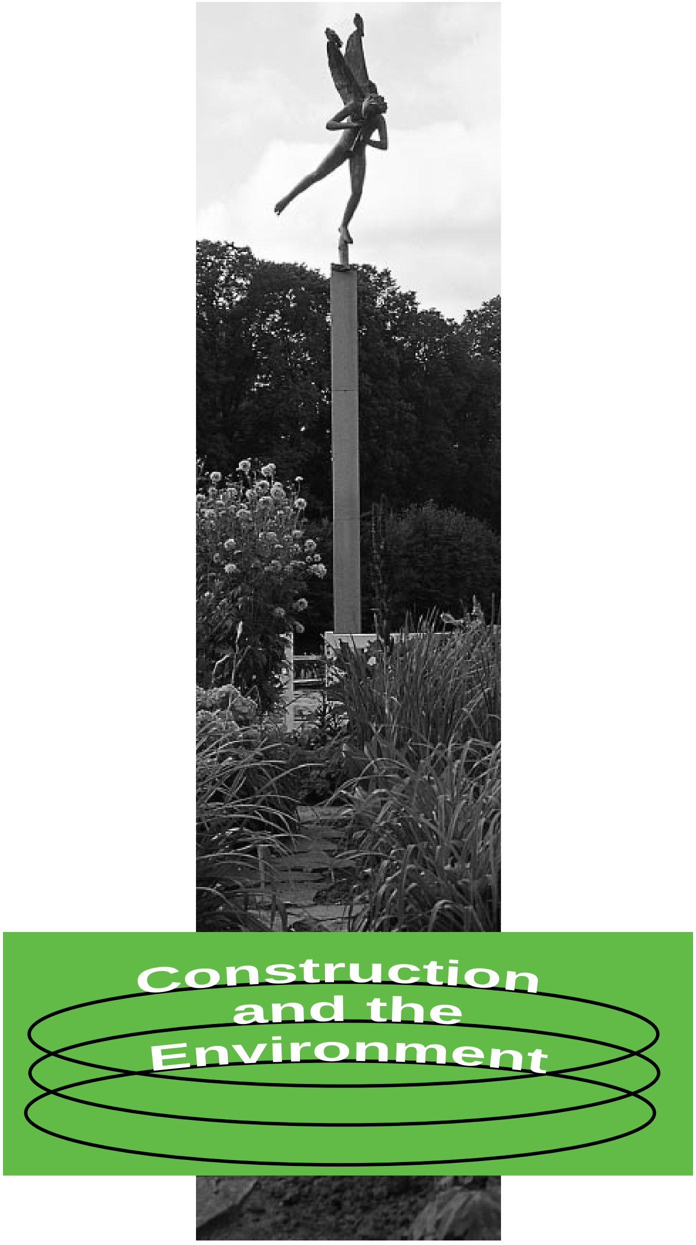
Proceedings on CD-ROM and Abstract Folder



CIB World Building Congress 1998

Gävle, Sweden 7 – 12 June

International Council for Building Research Studies and Documentation
Conseil International du Bâtiment pour la Recherche l´Etude et la Documentation

CIB 98

Contents

Materials and Technologies for Sustainable Construction

Service Life and Durability

Autoclaved aerated concrete for construction in hot regions **A98**
H. Almudhaf, F.A. Al-Ragom

Durability and reliability, alternative approaches to 17 assessment of component performance over time **A204**
E.V. Bartlett, S. Simpson

The effects of mineral fines on thermal properties of wood composites **A110**
M.L. Benmalek, A. Bouguerra, A. Ledhem, R.M. Dheilly, M. Quéneudec

Prediction of durability for performance-based codes **A223**
A.F. Bennett

Durability of elastomeric building sealants - results from a five year programme **A268**
T. Boettger, H. Bolte

Lightweight clay-based concretes formulated with wood aggregates: hygrothermal behaviour **A111**
A. Bouguerra, A. t´Kint de Roodenbeke, R.M. Dheilly, M. Quéneudec

A proposed standard for service life of buildings: Part 3 Auditing systems **A351**
K. Bourke, G. Soronis

The interrelationship between performance and service life of building products **A213**
E. Brandt

Alternatives to plasticized PVC for flooring tiles **A155**
J. Campanelli, M. Bani-Hani, D. Banu, D. Feldman

Upgrading the use of recycled aggregates **A41**
R.J. Collins

Moisture monitoring system based on a remote moisture sensor **A100**
G. Dai, K. Ahmet

Methodology and experimental programme to evaluate building components service life **A163**
B. Daniotti, T. Poli, F. Re Cecconi, G. Rigamonti

Durability of cracked fibre reinforced concrete exposed to freeze-thaw and deicing salt **A39**
E.J. de Place Hansen

More sustainable construction using building systems based on pre-stressed concrete elements **A303**
F. De Troyer

Moisture migration in building walls: numerical modelling of transient water movement during a rainfall **A120**
M.L. Deangelis, A. Piovani

Analysis of the performances of concrete components made with recycled aggregates **A96**
P. Dessy, C. Badalucco, L. Bignami, F. Cantoni, L. Morfini, L. Nironi,S. Palmieri, A. Strini

Development of the lattice model and it´s application for the shear failure mechanism **A267**
F.M. El-Behairy, T. Tanabe

Development and validation of the Wetcorr Inwood method **A226**
B. Eriksson, P. Norberg, J. Norén, U. Elvedal, J.F. Henriksen

Action of gypsum on recycled aggregate concrete **A89**
J.L. Gallias

Recycled waste clinker X-ray structural analysis **A9**
V.S. Gryslov, A.I. Fomenko

Service life and safety prediction of concrete slabs at filling stations **A27**
S. Gunnarsson, J-D. Wörner

Service life planning in building design **A172**
G. Hed

Application of aggregates out of construction- and demolition waste in road constructions and concrete **A158**
Ch.F. Hendriks

Evaluation of the Factor Method to estimate the service life of building components **A193**
P.J. Hovde

Quantitative measurement and estimation of driving rain on a building facade **A3**
A. Högberg

Earth as a wall material and its impact on pollution **A13**
B. Isik

A RC filler slab with non-autoclaved cellular concrete blocks for sustainable construction **A12**
M.P. Jaisingh, L. Jaisingh, B. Singh

Efficient hydrophobation of concrete with novel silicone products **A331**
W. Keller, R. Hager

Quantitative evaluation of the effect of pollutants on the atmospheric corrosion of structural metals **A125**
D. Knotkova, K. Kreislova, P. Boschek

Design guidelines and life-cycle-cost analysis for the use of recycled plastic lumber (RPL) in structures **A180**
P. Krishnaswamy

Studies of hydrophobised plastered autoclaved aerated concrete **A338**
H. Kus, G. Kalmar

The influence of finely ground ceramic waste materials on the properties of new mortars **A321**
M. Levy, P. Helene

A discrete stochastic model for performance prediction of roofing systems **A352**
Z. Lounis, D.J. Vanier, M.A. Lacasse

Further steps towards a quantitative approach to durability design **A280**
Z. Lounis, M.A. Lacasse, A.J.M. Siemes, K. Moser

Improving building operators contribution towards sustainability **A283**
A. Lucchini, N. Maiellaro

Functional analysis as a method to design new building components **A152**
P.N. Maggi, M. Rejna, F. Ravetta

Experimental program to evaluate building components service life: an application **A251**
P.N. Maggi, F. Ravetta, F. Re Cecconi

Degradation of Portland cement and Portland ash cement concrete **A29**
S. Miletic, M. Ilic, M. Djuric, J. Ranogajec, R. Marinkovic-Neducin

Durability evaluation of newly developed fluoropolymer emulsion paints **A34**
K. Motohashi, T. Hirono, N. Miyazaki, M. Yamauchi

"Green concrete" is as simple as ABC **A161**
L.C. Muszynski

Non-destructive tests and computer methods applied to the conservation of historical buildings **A376**
A. Nappi

Service life prediction of buildings and the need for environmental characterisation and mapping **A362**
J. Norén, K. Westberg, P. Jernberg, S.E. Haagenrud, Ch. Sjöström

Longtime performance of plastered external walls made from autoclaved aerated concrete **A222**
K. Nygren

Life cycle impact of floor coverings: A model for the contribution of the usage phase **A97**
J. Paulsen

Technological complex for utilization of high-calcium ash and slag for Abakan thermal power plant **A164**
S. Pavlenko, A. Shishkanov, A. Soin, V. Malyshkin

Release and flows of metals from building materials due to corrosion and degradation **A217**

D. Persson, V. Kucera

Performance of concrete with recycled aggregates **A159**
H.S. Pietersen, L.A. Fraay

A lightening process of clay-cement pastes by recycled oxblood **A112**
M. Ruzicka, A. t´Kint de Roodenbeke, R.M. Dheilly, M. Quéneudec

Properties of concrete incorporating fly ash and recycled demolition waste **A133**
K. Sagoe-Crentsil, A. Taylor, T. Brown

Performance requirements of building products derived from construction and demolition waste **A132**
K. Sagoe-Crentsil, T. Brown

Weather-induced degradation of PVC profiles in Indian climate **A188**
B. Singh, M. Gupta, A. Verma

Towards a new integrated ISO - standard for sustainable building **A11**
G. Soronis, A.R. Makenya

Durability of building materials and components in agricultural environment **A40**
B. Svennerstedt

Effect of latex paint compositions on the water transport mechanism **A318**
K.L. Uemoto, N.M.N. Sato, V. Agopyan, J.M. Silva

The performance of surface treatments for the conservation of historic brick masonry **A375**
R.P.J. van Hess

Hydraulic conductivity of combiliners in solid-waste landfills **A4**
R. Willocx, D. Van Gemert, J. Maertens

Climatic variability and climate change - implications for design and construction **A300**
T.J.S. Yates

Materials and Technologies for Sustainable Construction

Information Technologies

Structuring of data for LCA of buildings **A68**
T. Björklund, R. Carlsson, A.C. Pålsson

Information technologies and data formatting for the design life of buildings **A184**
L.S. Burn, I.S. Cole, S.N. Tucker

Data collection and handling for environmental assessment of building materials by architects and specifiers **A122**
S. Edwards, S. Hobbs

The product's milieu - Towards an effective information domain to deliver sustainable building **A19**
S. Emmitt, D.P. Wyatt

Information system for maintenance of 2500 buildings: A case history **A189**
W.C. Greer, Jr., W.C. Malek

Wood-Assess - Systems and methods for assessing the conservation state of wooden cultural buildings **A239**
S.E. Haagenrud, J.F. Henriksen, J. Veit, B. Eriksson

Wood-Assess - Mapping environmental risk factors on the macro local and micro scale **A228**
J.F. Henriksen, S.E. Haagenrud, U. Elvedal, J. Häusler,P. Norberg, J. Veit

Recycling waste as building materials: An internet database **A313**
V.M. John, J.A. Tinker

Presentation of Eco-Quantum, the LCA based computer tool for the quantitative determination of the environmental impact of buildings **A335**
J. Kortman, H. van Ewijk, J. Mak, D. Anink, M. Knapen

The life cycle simulation method EQUER applied to building components **A212**
B. Peuportier

The programming of plaster surface maintenance by the 'evolution scheme' approach **A233**
M.R. Pinto, S. De Medici, M. Palumbo, G. Carotenuto

Environmental relevant product information in the Dutch building industry **A66**
A. Schuurmans-Stehmann, J.P.R Meijer

Visualisation of 3-D city model on the Internet A151
J. Shan, M. Schmitz

Scientific tools for assessment of the degradation of historic brick masonry A374
K. van Balen

Life Cycle Analysis

The problems of phosphogypsum utilization in Lithuania A48
E. Blazevicius, R. Kaminskas, A.V. Raginis

Repair of environmental constructions with the high-performance concrete SIFCON A49
R. Breitenbücher

"Recoverability" of building elements in recovery intervention A154
E. Dal Zio, F. Vergine, R. Paparella

Necessary measures to reduce construction waste in Egypt. A model for developing countries A2
O.E.K. Daoud

Life cycle design and ecomaterials technology of building structural composite components for sustainable construction A1
T. Fukushima

From theory into practice. Subarctic ecological building in Östersund A30
K. Hagberg, H. Hällstrand, Å. Ulfsdotter Kjellman

The potential for solar powered desiccant cooling A147
S.P. Halliday, C.B. Beggs

Ecological water reservoir A81
A.A. Hess, M.B. Natalini

Ecological building design A28
T. Häkkinen, M. Saari

Stratified layer building systems A364
M. Imperadori

Building Physics - No way around it A191
G. Jóhannesson, P. Levin

Life cycle assessment and indoor environmental assessment A54
Å. Jönsson

Investigations of mass and energy flow in the existing building stock A23
H. Kloft, J-D. Wörner

Ultrasonic bridge inspection using 3D-SAFT A87
M. Krause, H. Wiggenhauser, W. Müller, J. Kostka, K.J. Langenberg

Building for Environmental and Economic Sustainability (BEES) A26
B. Lippiatt

The construction industry and sustainable housing for the next 21st century: The eastern Africa case A128
A.R. Makenya, P.D. Rwelamila, L.A. Chobya

Changeable internal surfaces for seasonal flexibility A43
P.J. Martin

Energy implications of the transportation of building materials A75
A.J. Miller

Recycling of concrete in Sweden A279
C. Molin

Application of Life Cycle Assessment (LCA) to urban renewal projects A50
K. Sakai, T. Nakahara, T. Fujita, T. Morioka, N. Yoshida, N. Urushizaki, K. Takemoto

Integrated life cycle design of materials and structures A57
A. Sarja

Methodology to evaluate used foundry sand as concrete aggregate A330
C. Sbrighi Neto, C.E.S. Tango, F. Lotti, V.A. Quarcioni

Environmentally-sound building technologies A104

P. Schmid

Socio-economic changes and sustainable construction **A88**
G. Seaden, A. Manseau

Material flows in the construction and heavy engineering sector **A210**
N. Tolstoy, C. Björklund, P.O. Carlson

Returnable packaging for non-specific building materials **A35**
F.J.M. van Gassel

Experiences from life-cycle assessments on steel and concrete composite bridges **A123**
J. Widman

Waste management in the construction industry **A200**
O.D. Wilson, R.M. Skitmore, A. Seydel

Environmental Technologies and Processes

A causal path model to evaluate the environmental impact of frame materials **A319**
S.J. Allwinkle, A.W. Brown

Analytical comparison of buildings in terms of environmental impact criteria **A63**
M. Aygün

The effect of panelized single family residential construction on the environment **A165**
G.Z. Brown, T.E. Peffer

Environmental assessment method adapted to buildings **A238**
M. Erlandsson

Ecological aspects of using concretes with large-tonnage waste **A242**
B.V. Gusev, A. Malinina, T.P. Shcheblykina

Assessment of the environmental compatibility of concrete admixtures **A99**
R. Gälli, M. Ochs, U. Mäder

The use of earth in the construction of ecological dwellings **A82**
D. Klees, M.B. Natalini

Recycling excavated soil to back-filling material with liquefied stabilized soil method **A190**
G. Kuno, S. Okamoto, J. Iwabuchi, Y. Shibata, F. Irishima,T. Taniguchi

Ecological, Low Energy and Low Cost Housing Possibilities for Latvia **A174**
V.A. Lapsa

INIES - A framework to compile information on building products´ environmental quality **A201**
J.F. Le Téno, J.L. Chevalier, M. Rubaud

Environmental evaluation of external clay brick masonry **A153**
I. Oberti, A. Ratti, L. Roveda, S. Piardi, L. Morfini

Energy related environmental impact of buildings - IEA Annex-31 **A186**
P.A.G. Russell

New information service - Environmental declaration of building materials and products **A93**
M. Salmi

Multicomponent cementitious binder from industrial by-products **A361**
M. Singh, M. Garg

An assessment protocol for historic wooden buildings **A218**
J. Veit

System applied in Poland for assessment of products and technologies for sustainable construction **A173**
S.M. Wierzbicki

Life cycle assessment for the evaluation of environmental impacts of construction materials **A332**
M. Öberg

Indoor Environment and Sustainable Development - Are They Compatible?

Methods for Reduction of Load, Source Characterisation and Control

Assessment of energy conservation measures suitable for retrofitting residential buildings in Kuwait **B52**
F.A. Al-Ragom, F. Al-Ghimlas

Moisture performance of retrofitted exterior walls of multi storey residential buildings in Istanbul **B78**
M.C. Altun

New function for indoor air quality evaluation **B269**
Q. Chen

ISIAQ Guideline moisture control in cold climates **B281**
T. Follin

Moisture control in buildings - How can varying outdoor climate be allowed for when designing the structure? **B31**
E. Harderup, P.I. Sandberg

The human olfactory system - Implications on hormones concerning perception of VOC **B368**
E. Lövgren

Egg tempera or water based paint? An epidemiological study **B262**
D. Norbäck, G. Wieslander

The effects of fenestration characteristics on the thermal performance of retrofitted residential buildings in Istanbul **B79**
A. Tavil, E. Özkan

Energy and IAQ assessment of the Swedish housing stock **B53**
T. Waller

Health Effects, Productivity and Total Economy

Indoor environment and sustainable development - Toward a more ascetic way of living **B108**
G. Blachère

Design for health. Healthy building project **B328**
R. Corner

Is it advisable to remediate a sick building solely by a HVAC-system? **B265**
B. Wessén, G. Eckerbom, L-O. Åkerlind

Value of indoor air quality to productivity **B181**
G. Flatheim

Reported health problems and indoor environment in single-family houses **B135**
H. Högberg

Indoor environment and sustainable development: A crucial "Buildings partnership" **B95**
C.O. Magnell, D.S. Barno

Sustainable development also means healthy building **B183**
A. Maugard, L. Bourdeau, C. Cochet

Moisture, mold and health in apartment homes **B327**
A. Nevalainen, M. Vahteristo, J. Koivisto, T. Meklin, A. Hyvärinen,J. Keski-Karhu, T. Husman

Guidelines for indoor climate investigations in residential buildings **B348**
J. Palonen, O. Seppänen, K. Jokiranta, R. Ruotsalainen

Health effects of installing a new ventilation system in school buildings **B277**
G. Smedje, D. Norbäck, C. Edling

Aspects on Ventilation and Air Conditioning Systems and Recycling of Air Conditioning Equipme

The opportunity of indoor environment performances improvement - component of the sustainable development **B360**
I. Bliuc, A. Radu, I. Baran

Natural night ventilation and thermal inertia **B67**
O. Douzane, J-M. Roucoult, T. Langlet

Glazing analysis in a cristal palace **B196**
J. Gallostra, M. Casals, M. Etxeberria

Thermotropic layers to provide shading for outside walls **B140**
H. Goedeke

Adsorption of air contaminants on indoor surfaces **B235**

P. Hansson, H. Stymne

Solar thermal storage with phase change materials in domestic buildings **B74**
K.C.W. Ip

Environmental and energetic advantages of solar-collector **B357**
L. Kajtár, I. Erdõsi, Zs. Bakó-Biró

Projecting energy saving from daylighting in partitioned open plan spaces **B309**
G. Kim

Assessment of a hybride heating system with ventilated concrete ceiling **B141**
N. König, D. Oswald

Three green buildings from Venezuela: proposals for climate sensitive design **B293**
P. La Roche, F. Mustieles, M. Machado, I. de Oteiza

Natural convection within a rectangular enclosure in a window construction - A numerical study **B136**
U. Larsson, B. Moshfegh, M. Sandberg

Computer-based performance modelling tools for natural ventilation **B371**
Y. Li, J. Symons, A. Delsante, L. Chen

The self-contained dwelling **B312**
M. Machado, F. Mustieles, P. La Roche, I. de Oteiza

Healthy and environmentally compatible building materials, report on a German project **B44**
E. Mayer, K. Breuer

Subjective indoor air quality in geriatric hospitals **B264**
K. Nordström, D. Norbäck, G. Wieslander, R. Wålinder

A graphic method to evaluate shading effectiveness in windows and facades **B317**
C. Quirós

Cost efficiency and financial feasibility of retrofitting with heat insulation of existing residential buildings in Istanbul **B64**
N. Sahal, E. Özkan

Selection of a contractor - Evaluation of bids **B276**
A. Seeger Meriaux, B. Hansson

Classification of indoor climate, construction, and finishing materials **B347**
O. Seppänen

Guidelines for indoor air quality in schools: Creation of healthy indoor environment **B229**
I. Sävenstrand Rådö, M. Hult, E. Falck, J.V. Bakke

Case study on the thermal comfort in a series of stores **B354**
G. Verbeeck, H. Hens

Classification of finishing materials '95 **B114**
K. Vikström

Legal and Procurement Practices - Right for the Environment

Aligning procurement methods toward innovative solutions to environmental and economic needs **C231**
J.B. Miller

Building an environmentally sound future: the construction industry and sustainable development **C373**
J. Whitelegg

Minimising Environmental Degradation

Planning techniques and environmental issues in procurement **C121**
A. Ciribini, G. Rigamonti

Environmental concerns V's commercial reality - Who really pays for construction waste? **C287**
S. Emmitt, C. A. Gorse

Exploring the cultural dimensions of construction procurement - dealing with difference to achieve sustainable development **C246**
A. Gilham, I. Cooper

Collaborative performance-based purchasing for sustainable innovation **C51**
H. Westling

Enhancing Technology Transfer

Environmental risk assessment of private finance initiative projects C270
A.S. Akintoye

Construction projects: the culture of joint venturing C344
R.F. Fellows

Understandings of environmentally conscious procurement arrangements in culturally diverse circumstances C70
M.A. Hall, D.M. Jaggar

Procurement methods and contractual provisions for sustainability in construction C296
G. Ofori, P. Chan

Risk management for sino-foreign joint ventures in the Chinese construction C10
L.Y. Shen, W.C. Wu, S.K. Ng

Building procurement and organisational learning - Missed opportunities C325
D.H.T. Walker, B.M. Lloyd-Walker

Case Studies of Procurement Systems

Design and management practice for a safe working environment C234
A.T. Baxendale, O. Jones

Attitudes to UK construction procurement systems for refurbishment work C256
C.O. Egbu

The direction of policies and systems for the development of sustainable human settlements in Korea C162
K.I. Lee

Contractual systems for construction refurbishment projects C221
I.G. Okorji, S.G. Naoum

Procurement sustainable building practice C105
P. Schmid

Health and safety and the environment as project parameters C247
J.J. Smallwood

The role of procurement practices in occupational health and safety and the environment C241
J.J. Smallwood

Matching contract procurement systems to particular construction environments in developing countries C308
W.H.E. Suite

Examples of Legal and Technological Innovations

Land planning evaluation: The new Tuscan Planning Act N. 5/1995 C182
V. Bentivegna

Identification of environmental risks and their impact on procurement of construction works C326
R.W. Craig

Procurement and sustainability in the construction industry: Tendering for durable relationships with process and projects C175
W. Tijhuis

Conflict Management and Dispute Resolution

Project performance and conflict avoidance: A front-end approach C249
T. Abdel Meguid, C. Davidson

Contract provisions for effective dispute resolution C94
R.M. Entwistle

The adjudication of construction disputes - New dawn or false hope? C289
P. Newman

Dispute Review Boards 1998: The need to stay on track C359
R.J. Smith

Alternative dispute resolution: The Queensland Building Tribunal **C199**
O.D. Wilson, R.M. Skitmore, P.A. Davies

Managing Sustainability - Endurance Through Change

Sustainable development: A challenge to the construction industry **D369**
G. Ashworth

Sustainability in management and organisation: The key issues? **D292**
P.S. Brandon

Management and Organisation

Sustainable design construction and the performance concept **D62**
G.K.I. Ang

Project management - the agent of sustainable production? **D33**
D. Baldry

Sustainability through integration **D145**
P. Barrett, M. Sexton, M. Curado

Intelligent environmental modelling of building performance for sustainable design **D15**
K. Beattie, I. Molloy, I. Ward

Research for sustainable development in the construction processes **D203**
J. Borgbrant

Sustainable constructions´ strategies from the technological/biological perspective **D137**
A. Cobzaru

Environmental cost, a decision support model **D205**
M. Dewever

Fragile networks and robust gates - A view on managing for sustainability **D20**
S. Emmitt

Strategies for change - understanding sustainable development from a construction industry perspective **D245**
A. Gilham

Cultural change in construction: Generic or gendered? **D353**
C. Greed

The TWIN-model, an environmental calculation method as performance concept **D22**
M. Haas

What do we mean by sustainable construction? **D146**
S.P. Halliday

A simulation of the urban environment in Salford **D171**
A. Hamilton, S. Curwell, T. Davies

Promoting BEQUEST: Building Environmental Quality Evaluation for Sustainability through Time **D286**
S. Curwell, A. Hamilton, I. Cooper

Sustainable building maintenance **D365**
M.H. Hermans

Sustainable maintenance in transition economies **D102**
M. Katavic, A. Ceric, I. Završki

Environmental management in Denmark from revelopment programmes to practice **D148**
I.S. Olsen

Sustainable building organisation **D106**
P. Schmid

Collecting systems for waste return in the building industry: combining political, logistical, economical and environmental aspects **D65**
A.M. Schuurmans-Stehmann, J.M.J.M. Bijen

Managing construction projects within emerging information driven business environments **D61**
A. Thorpe, F.T. Edum-Fotwe, S.P. Mead

Management of construction & demolition waste streams **D252**
M. Torring

A 3D CAD model of embodied energy for assessment of sustainable construction **D215**
S.N. Tucker, M.D. Ambrose, C. Mackley

Sustainable development in construction **D288**
T.E. Uher, W. Lawson

Methodologies and Regulations

Sustainable development building design and construction - twenty-four criteria facing the facts **D240**
R. Angioletti, C. Gobin, M. Weckstein

Towards a more sustainable development: A model for the building sector production **D109**
J. Baillon, C. Lipari

Productivity and quality in renewal of buildings **D92**
N.H. Bertelsen

Tentative application of the ECE Compendium of model provisions for building regulations **D107**
G. Blachère

New classification system for easy identification of the content and use of standards by standards users **D284**
P. Boltri, B. Daniotti, G. Turchini, A. Lucchini, M. Sanvito

Sustainable development and the future of construction, a CIB W82 project **D253**
L. Bourdeau, P. Huovila, R. Lanting

Difficulties into application of the sustainable concepts on construction in Spain **D197**
M. Casals, D. Giménez, P. Alavedra

Modelling sustainable community development in Edinburgh's South East Wedge **D14**
M. Deakin, J. Hine

Sustainability & regional planning: Barcelona´s area case study **D195**
D. Giménez, P. Alavedra, M. Casals

The South African public sector, proposed legislation and the application of sustainability in the construction industry **D366**
R.D. Hindle

Taking into account environmental values in building construction **D350**
J.-A. Kaivonen

Horizon 2020: Design-build **D295**
C.J. Katsanis, C.H. Davidson

A regionally adapted system for assessing building performance **D46**
N.K. Larsson

Managing sustainability in urban planning evaluation **D90**
P.L. Lombardi

Scenarios and visions as tools for endurable changes in sustainability in society, organisations and the built environment **D116**
G. Molin

Environmental book of specifications and qualitative assessment method for green secondary schools **D355**
S. Nibel, Ph. Duchêne-Marullaz, G. Olive

The energy barometer - A new system for monitoring energy use in the housing stock **D37**
K-E. Westergren, H. Högberg, U. Norlén

Sustainable building - a Swedish national research program **D298**
A.-M. Wilhelmsen

Feedback and Evaluation

Necessity of common understanding of sustainability in construction in Asia **D349**
K. Baba

Environmental seal of quality for buildings - European experience **D324**
A. Blum, C. Deilmann, F.-S. Neubauer

Persistence of energy savings of the UK´s Energy Efficiency Best Practice Programme for buildings **D156**
S.P. Boyle

The influence of the use-efficiency on the resource-efficiency of housing **D323**
C. Deilmann

Environmental concerns for construction growth in Gaza Strip **D6**
A. Enshassi

Challenges and opportunities in UK housing into the next century **D17**
P. Evans

Basic approach methodologies for buildings´ management in mountain environment. Case study **D209**
A. Frattari, I. Garofolo

Life cycle assessment of building components - concentration on the phase of use **D322**
K. Gruhler

Transport environmental implications of buildings **D192**
N.P. Howard, A. Gilham, S. Rao, M. Thomas

Sustainable construction in Finland: Approach and best practices **D301**
P. Huovila, T. Häkkinen, I. Aho

The limits to sustainability **D160**
C.J. Kibert

The concept and context of sustainable development in the Caribbean **D315**
T.M. Lewis

Education of construction engineers for sustainability **D314**
T.M. Lewis

Changing consumption patterns to achieve sustainable development: Role of construction **D297**
G. Ofori

A practical approach to life-cycle economy **D149**
I.S. Olsen

An environmental perspective on UK construction materials **D16**
L. Parrott

Modelling cash flow in construction projects in countries in transition **D47**
M. Radujkovic

The need for the implementation of Quality Management Systems in South African construction **D248**
J.J Smallwood, P.D. Rwelamila

Striving for harmony between contemporary construction and values of natural and cultural heritage in protected areas **D150**
V. Stauskas

An attempt to measure the unsustainability **D341**
J. Suler

Analysis of the primary process for efficient use of building components **D334**
H. Tempelmans Plat

An assessment and optimization model of environmental influence about city construction planning in China Three Gorges Reservoir Area **D17**
Y. Yang, Y. Yang, N. Yang

Environmental assessment of buildings, building operations and urban areas **D101**
A. Yates, R. Baldwin

Sustainable Design and Production

Design for adaptability - a hierarchical decision process for adaptability **D278**
S.H. Blakstad

Designing for sustainability: Ideal and practical increments of change **D130**
R.J. Cole

Open building implementation. Matching demand and supply for flexibility **D255**
R.P. Geraedts

Open building: Balancing stability and change **D38**
S.H. Kendall

Technologies of family house construction **D356**
J. Petrovic, D. Vidakovic, Z. Dolacek

Open industrialisation: State of the art and future perspectives **D58**
A. Sarja

A centre for sustainable housing technologies in Brazil **D259**
M.A. Sattler

Validation of multilateral building product design by the QFD method **D142**

KEYWORDS
Symposium A, Volume 1

Materials and Technologies for Sustainable Construction
Service Life and Durability

Autoclaved aerated concrete for construction in hot regions **A98**
H. Almudhaf, F. Al-Ragom
Building performance, Autoclaved aerated concrete, Energy consumption, Hot regions

Durability and reliability, alternative approaches to assessment of component performance over time **A204**
E.V. Bartlett, S. Simpson
Building fabric, Building services, Durability, Reliability, Life-cycle, Weibull, Maintenance, Function, Sustainability, Service life, Statistical analysis

The effects of mineral fines on thermal properties of wood composites **A110**
M.L. Benmalek, A. Bouguerra, A. Ledhem, R.M. Dheilly, M. Quéneudec
Thermal properties, Waste, Wood concretes

Prediction of durability for performance-based codes **A223**
A.F. Bennett
Durability, Codes, Test methods, Prediction, Performance

Durability of elastomeric building sealants - results from a five year programme **A268**
T. Boettger, H. Bolte
Accelerated ageing, Chemical spectroscopy, Correlation, Cyclic movement, Elastomeric sealants, Free films, Joint models, Natural weathering, Thermo-analytical

Lightweight clay-based concretes formulated with wood aggregates: hygrothermal behaviour **A111**
A. Bouguerra, A. t´Kint de Roodenbeke, R.M. Dheilly, M. Quéneudec
Lightweight concrete, Thermal conductivity, Thermohygrometric conditons

A proposed standard for service life of buildings: Part 3 Auditing systems **A351**
K. Bourke, G. Soronis
Durability, Service life, Standards, Auditing systems

The interrelationship between performance and service life of building products **A213**
E. Brandt
Performance concept, Durability data, Service life, Performance data

Alternatives to plasticized PVC for flooring tiles **A155**
J. Campanelli, M. Bani-Hani, D. Banu, D. Feldman
Polyolefin plastomer, Poly(vinyl chloride), Flooring tiles, Plasticizer, Recycled high density polyethylene

Upgrading the use of recycled aggregates **A41**
R.J. Collins
Cement, Concrete blocks, Demolition, Flooring, Internet, Precast, Quality control, Readymix, Recycled aggregates

Moisture monitoring system based on a remote moisture sensor **A100**
G. Dai, K. Ahmet
Moisture sensors, Timber, Instrumentation

Methodology and experimental programme to evaluate building components service life **A163**
B. Daniotti, T. Poli, F. Re Cecconi, G. Rigamonti
Service life, Durability test, Building components, Maintainability, Sustainable construction

Durability of cracked fibre reinforced concrete exposed to freeze-thaw and deicing salt **A39**
E.J. de Place Hansen
Capillary water uptake, Cracks, Deicing salt, Degradation mechanisms, Durability, Fibre reinforced concrete, Frost resistance, Air entrainment

More sustainable construction using building systems based on pre-stressed concrete elements **A303**
F. De Troyer
Pre-stressed concrete elements, System building, Sustainability

Moisture migration in building walls: numerical modelling of transient water movement during a rainfall **A120**
M.L. Deangelis, A. Piovani
Moisture migration, Numerical modelling, Saturation time, Diffusivity parameter, Brick, Rainfall

Analysis of the performances of concrete components made with recycled aggregates **A96**
P. Dessy, C. Badalucco, L. Bignami, F. Cantoni, L. Morfini, L. Nironi,S. Palmieri
Characterization, Concrete performance, Recycled aggregates

Development of the lattice model and it´s application for the shear failure mechanism **A267**
F.M. El-Behairy, T. Tanabe
Arch elements, Modified lattice model, Shear-resisting mechanism, Subdiagonal element, Total potential energy

Development and validation of the Wetcorr Inwood method **A226**
B. Eriksson, P. Norberg, J. Norén, U. Elvedal, J.F. Henriksen
Time of wetness, Moisture content, Wood, Microclimate, Wetcorr

Action of gypsum on recycled aggregate concrete **A89**
J.L. Gallias
Recycled aggregate, Gypsum, Sulphate content, Concrete, Mortar expansion, Mechanical strengths

Recycled waste clinker X-ray structural analysis **A9**
V.S. Gryslov, A.I. Fomenko
X-ray method, Phase composition, Diffractography, Solid waste of production, Portland cement

Service life and safety prediction of concrete slabs at filling stations **A27**
S. Gunnarsson, J-D. Wörner
Life expectancy, Penetration fuels in concrete, Filling stations

Service life planning in building design **A172**
G. Hed
Service life planning, Building design

Application of aggregates out of construction- and demolition waste in road constructions and concrete **A158**
Ch.F. Hendriks
Summary of certification, Environment, Recycled aggregates

Evaluation of the Factor Method to estimate the service life of building components **A193**
P.J. Hovde
Service life, Estimation, Factor method, Building materials, Building components

Quantitative measurement and estimation of driving rain on a building facade **A3**
A. Högberg
Driving rain, Micro climate, Wind around a building, Climatological measurement, Simulation of wind

Earth as a wall material and its impact on pollution **A13**
B. Isik
Adobe construction, Construction technology, Earth construction technology, Energy consideration, Mechanization, Pollution reduction, Stabilization, Wall material

A RC filler slab with non-autoclaved cellular concrete blocks for sustainable construction **A12**
M.P. Jaisingh, L. Jaisingh, B. Singh
Filler slab, Flyash, Non-autoclaved cellular concrete blocks, Construction

Efficient hydrophobation of concrete with novel silicone products **A331**
W. Keller, R. Hager
Concrete protection, Hydrophobation, Silicones, Creme, Silanes, Siloxanes, Masonry water repellents

Quantitative evaluation of the effect of pollutants on the atmospheric corrosion of structural metals **A125**
D. Knotkova, K. Kreislova, P. Boschek
Atmospheric corrosion, Structural metals, Effects of pollution, Regression function, Logaritmic model

Design guidelines and life-cycle-cost analysis for the use of recycled plastic lumber (RPL) in structures **A180**
P. Krishnaswamy
Recycled Plastic Lumber, Life-cycle cost, Design guidelines, Shipping pallets

Studies of hydrophobed plastered autoclaved aerated concrete **A338**
H. Kus, G. Kalmar
Autoclaved aerated concrete, Surface treatments, Water repellants, Degradation, Moisture properties

The influence of finely ground ceramic waste materials on the properties of new mortars **A321**
M. Levy, P. Helene
Mortars, Waste material, Recycling

Further steps towards a quantitative approach to durability design **A280**
Z. Lounis, M.A. Lacasse, A.J.M. Siemes, K. Moser
Time-dependent reliability, Crossing problem, Deterioration, Durability, Performance, Random variable, Semi-probabilistic, Service life, Stochastic process

A discrete stochastic model for performance prediction of roofing systems **A352**
Z. Lounis, D.J. Vanier, M.A. Lacasse
Condition rating, Deterioration, Markov chain, Performance, Roof system, Roof components, Service life, Stochastic process

Improving building operators contribution towards sustainability **A283**
A. Lucchini, N. Maiellaro
Sustainable building, Building design, Design for durability, Internet

Experimental program to evaluate building components service life: an application **A251**
P.N. Maggi, F. Ravetta, F. Re Cecconi
Building products, Coil coated steel sheet, Exposure test, Service life, Survey

Functional analysis as a method to design new building components **A152**
P.N. Maggi, M. Rejna, F. Ravetta
Building components, Performances, Service life, Maintainability, Durability, Functional analysis, Sustainable construction

Degradation of Portland cement and Portland ash cement concrete **A29**
S. Miletic, M. Ilic, M. Djuric, J. Ranogajec, R. Marinkovic-Neducin
Degradation, Portland cement, Fly ash, Concrete

Durability evaluation of newly developed fluoropolymer emulsion paints **A34**
K. Motohashi, T. Hirono, N. Miyazaki, M. Yamauchi
Fluoropolymer, Water-based emulsion, Durability, Paint, Repaint, Standard specification, Air pollution

"Green concrete" is as simple as ABC **A161**
L.C. Muszynski
Cement, Concrete, Construction materials, Fly ash, Recycled materials

Non-destructive tests and computer methods applied to the conservation of historical buildings **A376**
A. Nappi
Cultural heritage, Diagnostics, Monitoring, Non-destructive tests, Numerical models, Pseudodynamic tests, System identification

Service life prediction of buildings and the need for environmental characterisation and mapping **A362**
J. Norén, K. Westberg, P. Jernberg, S.E. Haagenrud, Ch. Sjöström
Buildings, Environmental characterisation and mapping, Service life predictions

Longtime performance of plastered external walls made from autoclaved aerated concrete **A222**
K. Nygren
Durability, Plasters, Autoclaved aerated concrete

Life cycle impact of floor coverings: A model for the contribution of the usage phase **A97**
J. Paulsen
LCA, Service life, Environmental impacts, Floor coverings, Usage phase

Technological complex for utilization of high-calcium ash and slag for Abakan thermal power plant **A164**
S. Pavlenko, A. Shishkanov, A. Soin, V. Malyshkin
High-calcium fly ash, Slag sand, Silica fume, Cementless binder, Technological complex

Release and flows of metals from building materials due to corrosion and degradation **A217**
D. Persson, V. Kucera
Heavy metals, Runoff, Corrosion, Degradation, Building materials

Performance of concrete with recycled aggregates **A159**
H.S. Pietersen, L.A. Fraay

A lightening process of clay-cement pastes by recycled oxblood **A112**
M. Ruzicka, A. t´Kint de Roodenbeke, R.M. Dheilly, M. Quéneudec
Air entraining agent, Lightweight concrete, Insulating materials

Performance requirements of building products derived from construction and demolition waste **A132**
K. Sagoe-Crentsil, T. Brown
Recycling, C&D waste, Concrete, Specifications, Concrete aggregate, Contaminants

Properties of concrete incorporating fly ash and recycled demolition waste **A133**
K. Sagoe-Crentsil, A. Taylor, T. Brown
Aggregate, Concrete, Recycling, Fly ash, Durability, Compressive strength, Fines

Weather-induced degradation of PVC profiles in Indian climate **A188**
B. Singh, M. Gupta, A. Verma
PVC, Weathering, Elongation, UV exposure, Degradation

Towards a new integrated ISO - standard for sustainable building **A11**
G. Soronis, A.R. Makenya
Standards, Durability, Service life, Sustainable building

Durability of building materials and components in agricultural environment **A40**
B. Svennerstedt
Durability, Farm buildings, Agricultural environment, Concrete material, Wood material, Steel material

Effect of latex paint compositions on the water transport mechanism **A318**
K.L. Uemoto, N.M.N. Sato, V. Agopyan, J.M. Silva
Humidity, Latex paints, Mould growth, Permeability, Service life, Maintenance costs, Degradation factors, Time of wetness

The performance of surface treatments for the conservation of historic brick masonry **A375**
R.P.J. van Hess
Historic brick masonry, Water repellents

Hydraulic conductivity of combiliners in solid-waste landfills **A4**
R. Willocx, D. van Gemert, J. Maertens
Geomembrane, Clayliner, Hydraulic conductivity, Pollution, Geosynthetic composite

Climatic variability and climate change - implications for design and construction **A300**
T.J.S. Yates

Materials and Technologies for Sustainable Construction
Information Technologies

Structuring of data for LCA of buildings **A68**
T. Björklund, R. Carlsson, A.C. Pålsson
LCA, Building, Environmental assessment, Database, LCA-data, Data structure

Information technologies and data formatting for the design life of buildings **A184**
L.S. Burn, I.S. Cole, S.N. Tucker
Design life, Data exchange, Information technologies, IAI, STEP, Object orientation, CAD, Life cycle costing

Data collection and handling for environmental assessment of building materials by architects and specifiers **A122**
S. Edwards, S. Hobbs
Environmental assessment, LCA, Materials, Specifiers

The product's milieu - Towards an effective information domain to deliver sustainable building **A19**
S. Emmitt, D.P. Wyatt
Information domain, Supply chain, Sustainability, Asset management, Disassembly, Expert knowledge systems, Service life planning

Information system for maintenance of 2500 buildings: A case history **A189**
W.C. Greer, Jr., W.C. Malek
Cost estimates, Database, Maintenance, Management system, Rehabilitation, Repair, Replacement, Service life

Wood-Assess - Systems and methods for assessing the conservation state of wooden cultural buildings **A239**
S.E. Haagenrud, J.F. Henriksen, J. Veit, B. Eriksson

Wooden buildings, Condition survey, Assessment protocol, Mapping environmental risk factors and -areas, Geographical information systems (GIS)

Wood-Assess - Mapping environmental risk factors on the macro local and micro scale **A228**
J.F. Henriksen, S.E. Haagenrud, U. Elvedal, J. Häusler, P. Norberg, J. Veit
Wooden buildings, Rotting, Moisture, Mapping of risk factors, Geographical information system (GIS)

Recycling waste as building materials: An internet database **A313**
V.M. John, J.A. Tinker
Recycling, Methodology, Database, Internet, Sustainable development

Presentation of Eco-Quantum, the LCA based computer tool for the quantitative determination of the environmental impact of buildings **A335**
J. Kortman, H. van Ewijk, J. Mak, D. Anink, M. Knapen
Eco-Quantum, Computer tool, Building design, Life cycle assessment, Quantitative, Environmental impact

The life cycle simulation method EQUER applied to building components **A212**
B. Peuportier
Life cycle assessment, Simulation, Building materials, Environmental impacts

The programming of plaster surface maintenance by the 'evolution scheme' approach **A233**
M.R. Pinto, S. De Medici, M. Palumbo, G. Carotenuto
Historical building life-cycle, Maintenance program, Plaster alterations

Environmental relevant product information in the Dutch building industry **A66**
A. Schuurmans-Stehmann, J.P.R Meijer
Building industry, Environment, LCA, MRPI, Product information

Visualisation of 3-D city model on the Internet **A151**
J. Shan, M. Schmitz
Visualisation, IT, 3-D city model, GIS

Scientific tools for assessment of the degradation of historic brick masonry **A374**
K. van Balen
Masonry damage diagnostic system, Expert system, Historic brick structures, Masonry, Damage atlas

Life Cycle Analysis

The problems of phosphogypsum utilization in Lithuania **A48**
E. Blazevicius, R. Kaminskas, A.V. Raginis
Phosphogypsum, Utilization, Waste, Lithuania

Repair of environmental constructions with the high-performance concrete SIFCON **A49**
R. Breitenbücher
Environmental constructions, Covering layer, High-performance steel fibre concrete, Ductility, High strength, Impact, Abrasion

"Recoverability" of building elements in recovery intervention **A154**
E. Dal Zio, F. Vergine, R. Paparella
Building recovery, Recycling of construction materials

Necessary measures to reduce construction waste in Egypt. A model for developing countries **A2**
O.E.K. Daoud
Construction waste, Design, Building materials, Concrete, Environment protection, Training, Recycling, Developing countries

Life cycle design and ecomaterials technology of building structural composite components for sustainable construction **A1**
T. Fukushima
Continuous fiber reinforced concrete (FRPRC), Continuous fiber reinforced thermoplastic (FRTP), Cascade recycling, Ecomaterials design, Elemental technology, Life cycle design, Long service life, Recyclability

From theory into practice. Subarctic ecological building in Östersund **A30**
K. Hagberg, H. Hällstrand, Å. Ulfsdotter Kjellman
Earth walls, Ecological building centre, Ecological planning and building engineering, Green room, Sedum plants, Straw clay walls

The potential for solar powered desiccant cooling **A147**
S.P. Halliday, C.B. Beggs
Desiccant cooling, Heat driven cooling, Heat powered cycles, Solar

Ecological water reservoir **A81**
A.A. Hess, M.B. Natalini
Water reservoir, Vegetal fibres, Cement asbestos

Ecological building design **A28**
T. Häkkinen, M. Saari
Ecological building design, Environmental building

Stratified layer building systems **A364**
M. Imperadori
Lightweight buildings, Stratified layer systems, Dry assemblies, Building quality, Life cycle planning

Building Physics - No way around it **A191**
G. Jóhannesson, P. Levin
Durability, Embodied energy, Emissions, Energy use, Performance, Service life

Life cycle assessment and indoor environmental assessment **A54**
Å. Jönsson
Building materials, Buildings, Floorings, LCA, Life cycle assessment, Indoor climate, SBS, VOC

Investigations of mass and energy flow in the existing building stock **A23**
H. Kloft, J-D. Wörner
Mass and energy flow, Material composition, Primary energy input

Ultrasonic bridge inspection using 3D-SAFT **A87**
M. Krause, H. Wiggenhauser, W. Müller, J. Kostka, K.J. Langenberg
Injection faults, Modelling utrasonic wave propagation (EFIT), Prestressed concrete, Reconstruction calculation (3D-SAFT), Scanning laser vibrometer, Tendon ducts, Ultrasonic testing

Building for Environmental and Economic Sustainability (BEES) **A26**
B. Lippiatt
Building products, Economic performance, Environmental performance, Green buildings, Life-cycle assessment, Life-cycle costing, Multiattribute decision analysis, Sustainable development

The construction industry and sustainable housing for the next 21st century: The eastern Africa case **A128**
A.R. Makenya, P.D. Rwelamila, L.A. Chobya
Building technology, Building methods, Construction industry, Eastern Africa, Government policy, Materials technology, Sustainable housing

Changeable internal surfaces for seasonal flexibility **A43**
P.J. Martin
Sustainable surface finishes, Thermal admittance, Tapestries

Energy implications of the transportation of building materials **A75**
A.J. Miller
Embodied energy, Transportation

Recycling of concrete in Sweden **A279**
C. Molin
Concrete recycling, Demolition

Application of Life Cycle Assessment (LCA) to urban renewal projects **A50**
K. Sakai, T. Nakahara, T. Fujita, T. Morioka, N. Yoshida, N. Urushizaki,K. Takemoto
Global warming, LCA, Urban renewal

Integrated life cycle design of materials and structures **A57**
A. Sarja

Design, Life cycle, Requirements, Environment, Integrated design, Ecology, Service life, Durability

Methodology to evaluate used foundry sand as concrete aggregate **A330**
C. Sbrighi Neto, C.E.S. Tango, F. Lotti, V.A. Quarcioni
Waste materials, Used foundry sand, Inertization, Evaluation methodology

Environmentally-sound building technologies **A104**
P. Schmid
Life Cycle, Use and reuse, Recycling

Socio-economic changes and sustainable construction **A88**
G. Seaden, A. Manseau
Evolving socio-economic forces, New business opportunities, Sustainable construction, Technology and regulatory challenges

Material flows in the construction and heavy engineering sector **A210**
N. Tolstoy, C. Björklund, P.O. Carlson
Building materials, Dump, Energy-production, Material flow, Recycle,Re-use

Returnable packaging for non-specific building materials **A35**
F.J.M. van Gassel
Environment technology, Packaging, Waste prevention, Return systems, Transport equipment

Experiences from life-cycle assessments on steel and concrete composite bridges **A123**
J. Widman
Construction, Environment, Steel, Concrete, Bridge, EPS, LCA, Zink

Waste management in the construction industry **A200**
O.D. Wilson, R.M. Skitmore, A. Seydel
Waste management, Landfill, Recycle, Reuse, Waste disposal

Environmental Technologies and Processes

A causal path model to evaluate the environmental impact of frame materials **A319**
S.J. Allwinkle, A.W. Brown
Frame material, Environmental assessment, Causal path modelling

Analytical comparison of buildings in terms of environmental impact criteria **A63**
M. Aygün
Building performance evaluation, Environmental impact criteria, Life cycle assessment

The effect of panelized single family residential construction on the environment **A165**
G.Z. Brown, T.E. Peffer
Industrialized housing, Panels, Material use, Energy, Environment

Environmental assessment method adapted to buildings **A238**
M. Erlandsson
Life cycle assessment, Impact assessment, Buildings, Indoor air quality, Safequards, Evaluation

Ecological aspects of using concretes with large-tonnage waste **A242**
B.V. Gusev, A. Malinina, T.P. Shcheblykina
Concretes, Large-tonnage waste, Heavy metals, Toxicity, Ecology

Assessment of the environmental compatibility of concrete admixtures **A99**
R. Gälli, M. Ochs, U. Mäder
Environment, Concrete admixtures, Leaching, Superplasticizers, Concrete demolition material

The use of earth in the construction of ecological dwellings **A82**
D. Klees, M.B. Natalini
Construction material, Earth, Ecological dwellings, Modular elements of soil cement

Recycling excavated soil to back-filling material with liquefied stabilized soil method **A190**
G. Kuno, S. Okamoto, J. Iwabuchi, Y. Shibata, F. Irishima, T. Taniguchi

Recycling excavated soil, Clay with high water contents, Liquefied stabilized soil, back-filling, Narrow space, No compaction

Ecological, Low Energy and Low Cost Housing Possibilities for Latvia **A174**
V.A. Lapsa
Ecology, External walls and roofs, Heat losses, Industrial pollutants, Load-bearing capacity, Thermal resistence, Low-cost housebuilding, Middle class, Structural optimization

INIES - A framework to compile information on building products´ environmental quality **A201**
J.F. Le Téno, J.L. Chevalier, M. Rubaud
Life cycle analysis, Risk analysis, Qualitative, Environmental quality, INIES

Environmental evaluation of external clay brick masonry **A153**
I. Oberti, A. Ratti, L. Roveda, S. Piardi, L. Morfini
Comparison among technical alternatives, Clay brick masonry, Design, Environmental profiles, Low impact building techniques, Sustainable construction

Energy related environmental impact of buildings - IEA Annex-31 **A186**
P.A.G. Russell
Buildings, Environmental impact, Energy

New information service - Environmental declaration of building materials and products **A93**
M. Salmi
Ecology, Sustainable development, Product information

Multicomponent cementitious binder from industrial by-products **A361**
M. Singh, M. Garg
Binder, Flyash, Phosphogypsum, Ettringite, Durability

An assessment protocol for historic wooden buildings **A218**
J. Veit
Historic wooden construction, Inspection, Documentation, Maintenance

System applied in Poland for assessment of products and technologies for sustainable construction **A173**
S.M. Wierzbicki
Assessment, Buildings, Products, Sustainable construction

Life cycle assessment for the evaluation of environmental impacts of construction materials **A332**
M. Öberg
Life Cycle Assessment, LCA, Sustainable buildings

Symposium B
Indoor Environment and Sustainable Development- Are They Compatible?

Methods for Reduction of Load, Source

Characterisation and Control

Assessment of energy conservation measures suitable for retrofitting residential buildings in Kuwait **B52**
F.A. Al-Ragom, F. Al-Ghimlas
Energy conservation, Exterior insulaton and finish system, Retrofitting

Moisture performance of retrofitted exterior walls of multi storey residential buildings in Istanbul **B78**
M.C. Altun
Water vapor diffusion, Retrofitting, Exterior wall, Residential building, Moisture performance

New function for indoor air quality evaluation **B269**
Q. Chen
Air quality evaluation, Fanger's olf method, German VDI method, Theoretical calculation method, Olf function

ISIAQ Guideline moisture control in cold climates **B281**
T. Follin
Moisture, Guideline, Contamination, SBS, Damages

Moisture control in buildings - How can varying outdoor climate be allowed for when designing the structure? **B31**
E. Harderup, P.I. Sandberg
Moisture, Calculation, Climate, Design, Random, Safety

The human olfactory system - Implications on hormones concerning perception of VOC **B368**
E. Lövgren
Olfactory, Hormones, Volatile organic compound VOC, Sick building syndrome SBS, Humidity, Smell, Signal molecule images

Egg tempera or water based paint? An epidemiological study **B262**
D. Norbäck, G. Wieslander
Asthma, Sick building syndrome, Egg tempera, Water based paint, Microbial volatile organic compounds (MVOC)

The effects of fenestration characteristics on the thermal performance of retrofitted residential buildings in Istanbul **B79**
A. Tavil, E. Özkan
Fenestration characteristics, Thermal performance, Residential building, Retrofitting, Computer simulation, Energy analysis

Energy and IAQ assessment of the Swedish housing stock **B53**
T. Waller
Microanalytic simulation , Density estimation, Energy efficiency, Indoor climate

Health Effects, Productivity and Total Economy

Indoor environment and sustainable development - Toward a more ascetic way of living **B108**
G. Blachère

Design for health. Healthy building project **B328**
R. Corner
Building design, Materials and construction, Moisture control, Guidelines for health and environment, Quality control, Housing estate

Value of indoor air quality to productivity **B181**
G. Flatheim
Clean building philosophy, Environmental plan, Indoor air quality, Productivity, Total costs

Reported health problems and indoor environment in single-family houses **B135**
H. Högberg
Complaints, Building characteristics, Indoor climate, Health problems, Moisture, Single-family houses

Indoor environment and sustainable development: A crucial "Buildings partnership" **B95**
C.O. Magnell, D.S. Barno
Indoor air quality, Indoor environment, Air cleaning technologies

Sustainable development also means healthy building **B183**
A. Maugard, L. Bourdeau, C. Cochet
Building, Environment, Sustainable development, Health, Comfort, Risk assessment

Moisture, mold and health in apartment homes **B327**
A. Nevalainen, M. Vahteristo, J. Koivisto, T. Meklin, A. Hyvärinen, J. Keski-Karhu, T. Husman
Moisture, Mold, Health effects, Exposure, Apartement house

Guidelines for indoor climate investigations in residential buildings **B348**
J. Palonen, O. Seppänen, K. Jokiranta, R. Ruotsalainen
Indoor climate, Dwellings, Investigation method, Diagnostics

Health effects of installing a new ventilation system in school buildings **B277**
G. Smedje, D. Norbäck, C. Edling
Schools, Pupils, Sick building syndrome, Ventilation system, Exposures

Is it advisable to remediate a sick building solely by a HVAC-system? **B265**
B. Wessén, L-O. Åkerlind, G. Eckerbom
Molds, Bacteria, Microorganisms, Ventilation, SBS

Aspects on Ventilation and Air Conditioning Systems and Recycling of Air Conditioning Equipme

The opportunity of indoor environment performances improvement - component of the sustainable development **B360**
I. Bliuc, A. Radu, I. Baran
Requirements performances, Sustainable development, Thermal rehabilitation

Natural night ventilation and thermal inertia **B67**
O. Douzane, J-M. Roucoult, T. Langlet
Night cooling ventilation, Thermal inertia, Time-constant, Pilot study, Rapid dynamics, Summer refreshment

Glazing analysis in a cristal palace **B196**
J. Gallostra, M. Casals, M. Etxeberria
Geographic aspects in sustainability, Solar radiation, Sustainable indoor environment, Use of existing buildings

Thermotropic layers to provide shading for outside walls **B140**
H. Goedeke
Adaptive shading, Overheating, Solar protection system, Thermotropic glazing, TOPAS

Adsorption and desorption of air contaminants on indoor surfaces **B235**
P. Hansson, H. Stymne
Adsorption, Building materials, IAQ, Sinks, VOC

Solar thermal storage with phase change materials in domestic buildings **B74**
K.C.W. Ip
Phase change materials, Thermal storage, Solar space heating, Computer simulation

Environmental and energetic advantages of solar-collector **B357**
L. Kajtár, I. Erdõsi, Zs. Bakó-Biró
Efficiency, Energy saving, Solar-collector

Projecting energy saving from daylighting in partitioned open plan spaces **B309**
G. Kim
Daylighting, Electric lighting, Energy, Layout, Partition

Assessment of a hybride heating system with ventilated concrete ceiling **B141**
N. König, D. Oswald
Energy consumption, Hybride air heating system, Mould risk, Solar collector, System costs, Thermal behaviour (IAQ), Ventilated concrete slab

Three green buildings from Venezuela: proposals for climate sensitive design **B293**
P. La Roche, F. Mustieles, M. Machado, I. de Oteiza
Sustainable design, Bioclimatical design, Passive cooling and heating, Housing

Natural convection within a rectangular enclosure in a window construction - A numerical study **B136**
U. Larsson, B. Moshfegh, M. Sandberg
Well-insulated windows, Natural convection, Heat transfer, Numerical analysis, Enclosed cavity

Computer-based performance modelling tools for natural ventilation **B371**
Y. Li, J. Symons, A. Delsante, L. Chen
Natural ventilation, Design tool, Modelling, Application, Flow pattern

The self-contained dwelling **B312**
M. Machado, F. Mustieles, P. La Roche, I. de Oteiza
Bioclimatic container design, Natural ventilation, Solar radiation

Healthy and environmentally compatible building materials, report on a German project **B44**
E. Mayer, K. Breuer
Building materials of low emission, Chemical measurements, Sensory measurements, Toxicological measurements

Subjective indoor air quality in geriatric hospitals **B264**
K. Nordström, D. Norbäck, G. Wieslander, R. Wålinder
Damp buildings, Indoor air quality, "Ecological building", Geriatric hospital, 2-etyl-1-hexanol, Dry air, Stuffy air

A graphic method to evaluate shading effectiveness in windows and facades **B317**
C. Quirós
Solar control, Energy in buildings, Thermal comfort, Design tools, Building envelope

Cost efficiency and financial feasibility of retrofitting with heat insulation of existing residential buildings in Istanbul **B64**
N. Sahal, E. Özkan
Insulation cost, Financial feasibility, Retrofitting, Heat insulation, Life-cycle costing, Existing residential building, Household savings, Income distribution

Selection of a contractor - Evaluation of bids **B276**
A. Seeger Meriaux, B. Hansson
Tender evaluation, Evaluation models, Contractor selection

Classification of indoor climate, construction, and finishing materials **B347**
O. Seppänen
Air quality, Cleanliness, Design values, Healthy buildings, Indoor climate, Material emissions, Ventilation

Guidelines for indoor air quality in schools: Creation of healthy indoor environment **B229**
I. Sävenstrand Rådö, M. Hult, E. Falck, J.V. Bakke
Schools, Indoor environment, Allergy, Guidelines, Renovation, Management, Maintenance

Case study on the thermal comfort in a series of stores **B354**
G. Verbeeck, H. Hens
Comfort measurements, Cooling, Draught, Overheating, Store, Survey, Thermal comfort, Ventilation

Classification of finishing materials '95 **B114**
K. Vikström
Indoor air, Emissions, Finishing materials, Classification, Odours

Legal and Procurement Practices - Right for the Environment

Aligning procurement methods toward innovative solutions to environmental and economic needs **C231**
J.B. Miller
Public infrastructure, Project portfolios, Project delivery and finance, Design-Build, Design-bid-build, Design-build-operate, Build-operate-transfer, Discounted life cycle cash flow

Building an environmentally sound future: the construction industry and sustainable development **C373**
J. Whitelegg

Minimising Environmental Degradation

Planning techniques and environmental issues in procurement **C121**
A. Ciribini, G. Rigamonti
Health and safety planning, Environmental management, Project management

Environmental concerns V's commercial reality - Who really pays for construction waste? **C287**
S. Emmitt, C. A. Gorse
Communication, Individual responsibility, Land fill tax, Temporary procurement networks, Waste management

Exploring the cultural dimensions of construction procurement - dealing with difference to achieve sustainable development **C246**
A. Gilham, I. Cooper
Procurement, Culture, Change, Environmental improvement

Collaborative performance-based purchasing for sustainable innovation **C51**
H. Westling
Performance contracting, Technology procurement, Innovation, Collaborative purchasing

Enhancing Technology Transfer

Environmental risk assessment of private finance initiative projects **C270**
A.S. Akintoye
Risk analysis techniques, Environmental risk, Environmental risk impact, Private finance initiative, Sustainable development, Environmental legislation

Construction projects: the culture of joint venturing **C344**
R.F. Fellows
Culture, Goals, Joint ventures, Participant satisfaction, Procurement, Transaction costs

Understandings of environmentally conscious procurement arrangements in culturally diverse circumstances **C70**
M.A. Hall, D.M. Jaggar
Environmental considerations, International procurement arrangements, Cultural diversity

Procurement methods and contractual provisions for sustainability in construction **C296**
G. Ofori, P. Chan
Sustainability, Client´s role, Procurement methods, Contractual provisions, Singapore

Risk management for sino-foreign joint ventures in the Chinese construction **C10**
L.Y. Shen, W.C. Wu, S.K. Ng
China, Construction Market, Joint Venture, Competitive procurement, Risk, Risk Management

Building procurement and organisational learning - Missed opportunities **C325**
D.H.T. Walker, B.M. Lloyd-Walker
Procurement, Organisational Learning, Construction time performance, Competitive advantage

Case Studies of Procurement Systems

Design and management practice for a safe working environment **C234**
A.T. Baxendale, O. Jones
Construction, Design, Health, Regulations, Management, Safety

Attitudes to UK construction procurement systems for refurbishment work **C256**
C.O. Egbu
Contract, Construction procurement system, Professional attitudes, Refurbishment works

The direction of policies and systems for the development of sustainable human settlements in Korea **C162**
K.I. Lee
Sustainable human settlement, Habitat II, Indicator, Housing, Policy

Contractual systems for construction refurbishment projects **C221**
I.G. Okorji, S.G. Naoum
Construction contract, Procurement selection, Artificial intelligence, Construction refurbishment

Procurement sustainable building practice **C105**
P. Schmid
Method, Holistic, Participation, Care-taking

The role of procurement practices in occupational health and safety and the environment **C241**
J.J. Smallwood
Procurement practices, Health and safety, Environment, Cost

Health and safety and the environment as project parameters **C247**
J.J. Smallwood
Project parameters, Health and safety, Environment

Matching contract procurement systems to particular construction environments in developing countries **C308**
W.H.E. Suite
Contract procurement, Measurement, Payment monitoring, Scheduling, Quality and satisfaction, Payment

Examples of Legal and Technoligcal Innovations

Land planning evaluation: The new Tuscan Planning Act N. 5/1995 **C182**
V. Bentivegna
Evaluation, Environment, Land planning, Planning law

Identification of environmental risks and their impact on procurement of construction works **C326**
R.W. Craig
Common law, Damages, Development, Environment, Liability, Negligence, Nuisance, Rylands v Fletcher

Procurement and sustainability in the construction industry: Tendering for durable relationships with process and projects **C175**
W. Tijhuis
Construction process, Sustainability, Governments, Relationships, Contractors, Clients, Architects, Regulations

Conflict Management and Dispute Resolution

Project performance and conflict avoidance: A front-end approach **C249**
T. Abdel Meguid, C. Davidson
Claims, Delays, Building procurement strategies, Project environment, Project performance

Contract provisions for effective dispute resolution **C94**
R.M. Entwistle

The adjudication of construction disputes - New dawn or false hope? **C289**
P. Newman
Adjudication, Arbitration, Arbitration Act 1996, Conflict, Decision, Enforcement, Final and binding, Housing grants, Construction Regeneration Act 1996, Litigation, Natural justice, Sir Michael Latham

Dispute Review Boards 1998: The need to stay on track **C359**
R.J. Smith
Dispute resolution, Dispute review boards

Alternative dispute resolution: The Queensland Building Tribunal **C199**
O.D. Wilson, R.M. Skitmore, P.A. Davies
Arbitration, Dispute resolution, Mediation, Queensland Building Tribunal, Questionnaire survey

Managing Sustainability - Endurance Through Change

Sustainable development: a challenge to the construction industry **D369**
G. Ashworth

Sustainability in management and organisation: The key issues? **D292**
P.S. Brandon
Evaluation methods, Framework, Management, Philosophy, Research, Sustainability

Management and Organisation

Sustainable design construction and the performance concept **D62**
G.K.I. Ang
Sustainability, Fitness for use, Design-build, Comprehensive, Approach, Assessment models, Performance concept, Intellectual challenge, Total quality management

Project management - the agent of sustainable production? **D33**
D. Baldry
Project management, Construction, Project manager, Risk, Sustainability

Sustainability through integration **D145**
P. Barrett, M. Sexton, M. Curado
Environmental management, Integration, Improvement, Strategy

Intelligent environmental modelling of building performance for sustainable design **D15**

K. Beattie, I. Molloy, I. Ward
Sustainable design, Environmental performance assessment, Simulation modelling, Intelligent environmental modelling, Dynamic building simulation software

Research for sustainable development in the construction processes **D203**
J. Borgbrant
Change, Design, Development, Evaluation, Process, Research, Research methods, Scientific society

Sustainable constructions´ strategies from the technological/biological perspective **D137**
A. Cobzaru
Affordable, Comfortable, Healthy living, Future perspective

Promoting BEQUEST: Building Environmental Quality Evaluation for Sustainability through Time **D286**
S. Curwell, A. Hamilton, I. Cooper
Sustainability, Internet, Environment, Urban, Built, City, Extranet, Intranet

Environmental cost, a decision support model **D205**
M. Dewever
Environmental costs, Environmental budget, Environmental Economy, Cost control

Fragile networks and robust gates - A view on managing for sustainability **D20**
S. Emmitt
Change agent, Diffusion of innovations, Gatekeepers, Risk management, Specification, Environmentally responsible building, New product adoption

Strategies for change - understanding sustainable development from a construction industry perspective **D245**
A. Gilham
Sustainable development, Strategies, Components and drivers of change

Cultural change in construction: Generic or gendered? **D353**
C. Greed
Access, Change, Culture, Disability, Ethnicity, Ethnography, Professions, Women

The TWIN-model, an environmental calculation method as performance concept **D22**
M. Haas
Environmental impact, LCA, Quantitative-qualitative, Performance standards, Environmental costs, Health, Computer programme

What do we mean by sustainable construction? **D146**
S.P. Halliday
Sustainable construction, Culture shift, Case studies, Inter-generational, Construction process, Subsidiarity

A simulation of the urban environment in Salford **D171**
A. Hamilton, S. Curwell, T. Davies
Environment, Sustainability, City, Model, Simulation, Urban, Virtual reality

Sustainable building maintenance **D365**
M.H. Hermans
Building maintenance, Building process, Durability, Life spans, Management and organisation of maintenance, Sustainability

Sustainable maintenance in transition economies **D102**
M. Katavic, A. Ceric, I. Zavrski
Sustainable maintenance, Buildings, Transition economies, Heritage

Environmental management in Denmark from development programmes to practice **D148**
I.S. Olsen
Sustainability, Environmental management, Design, Construction, Operation

Sustainable building organisation **D106**
P. Schmid
Methods, Models, Optimising, Invention, Consensus

Collecting systems for waste return in the building industry: combining political, logistical, economical and environmental

aspects **D65**
A.M. Schuurmans-Stehmann, J.M.J.M. Bijen
Building waste, Economy, Life Cycle Analysis (LCA), Logistics, Policy, Returning system, TRESPA, EPS

Managing construction projects within emerging information driven business environments **D61**
A. Thorpe, F.T. Edum-Fotwe, S.P. Mead
Information, Construction, Processes, Organisation

Management of construction & demolition waste streams **D252**
M. Torring
Demolition, Management, Recycling, Waste, Construction, Cost-benefit

A 3D CAD model of embodied energy for assessment of sustainable construction **D215**
S.N. Tucker, M.D. Ambrose, C. Mackley
Sustainable construction, Embodied energy, 3D CAD, Life cycle energy

Sustainable development in construction **D288**
T.E. Uher, W. Lawson
Sustainability, Sustainable construction, Sustainability criteria, Indicators

Methodologies and Regulations

Sustainable development building design and construction - twenty-four criteria facing the facts **D240**
R. Angioletti, C. Gobin, M. Weckstein
Sustainable development, Research and development

Towards a more sustainable development: A model for the building sector production **D109**
J. Baillon, C. Lipari
Sustainable development, Building sector, Modelling

Productivity and quality in renewal of buildings **D92**
N.H. Bertelsen
Renewal, Productivity, Quality, Roof, Labour, Cost

Tentative application of the ECE Compendium of model provisions for building regulations **D107**
G. Blachère

New classification system for easy identification of the content and use of standards by standards users **D284**
P. Boltri, B. Daniotti, G. Turchini, A. Lucchini, M. Sanvito
Information classification system, Building standards´ data bank, Sustainable building practices

Sustainable development and the future of construction, a CIB W82 project **D253**
L. Bourdeau, P. Huovila, R. Lanting
Building, Sustainable development, Future studies, Environment

Difficulties into application of the sustainable concepts on construction in Spain **D197**
M. Casals, D. Giménez, P. Alavedra
Barriers to application of practical concepts on sustainable construction, Difficulties in practical application of sustainable construction, Geographic points of view, Problems in application of sustainability concepts

Life Cycle Design and Ecomaterials Technology of Building Structural Composite Components for Sustainable Construction

Toshio Fukushima
Building Research Institute, Ministry of Construction, Japan

Abstract
Concept of life cycle design of building structural composite components (such as steel reinforced concrete (RC) and fiber reinforced plastic reinforced concrete (FRPRC)) is proposed, considering the total life cycle processes of production, in service, demolition, recycling and/or reuse, and taking in advance into account the easiness of demolition, recycling. Hybrid structural systems composed of steel reinforced concrete (RC) columns and fiber reinforced plastic reinforced concrete (FRPRC) beams, connected with steel fasteners are the recommended. Ecomaterials design and elemental technology satisfying both the long service life and the recyclability of building structural composite materials and/or components is discussed, in order to try to reduce the environmental burdens of mass of waste building materials which partly cause the dominant environmental problem, as a basis for establishment of the sustainable construction considering the harmony among the environment, economy and safety. Recyclable precast lightweight high strength concrete components reinforced with recyclable continuous fiber reinforced thermoplastic (FRTP) rebars and various effective demolition and recycling methods are considered.

The following experimental results as part of elemental technology establishing this ecomaterials design are reported : 1) Reuse methods of waste thermosetting FRP by pulverizing into powders as fine aggregate and cement-replacing binder in repeated partly recycled (cascade recycled) concrete. 2) Dynamic tensile behavious of continuous carbon and glass fiber reinforced recyclable thermoplastic reinforcements applicable enough for lightweight precast concrete newly developed as ecomaterials gentle to the global environment. 3) Accelerated carbonation test of concrete by step response method as a new method of prediction of the service life of RC and FRPRC corresponding to the increase in the concentration of atmospheric CO_2 as one of the global environmental problems.
Keywords: Continuous fiber reinforced thermoplastic (FRTP), Continuous fiber reinforced concrete (FRPRC), Cascade Recycling, Ecomaterials design, Elemental Technology, Life cycle design, Long service life, Recyclability,

1. Introduction

Development of new building materials have been done so far from the viewpoint of pursuit of the frontier characteristics of lightweight, high strength and high durability in the case of such structural materials as steel, concrete and wood, and the amenity characteristics of high function and flexible design in the case of such non-structural materials as finishing polymer and glass. However, the characteristics of harmony with the global environment are becoming more and more required also for building materials and components as well as the characteristics of high performance and high function. In order to realize the sustainable construction, we have to consider the harmony among the environment, economy and safety. In this paper environment-conscious materials (ecomaterials) design aiming at the conversion of building structural composite materials, components and elements into eco-materials, eco-components, and eco-systems is discussed, paying attention to the establishment of fundamental technology as a basis for the sustainable construction. The concept of environment-conscious materials (ecomaterials) is newly proposed one to try to make an effective approach from materials side for the preservation of the global environment [1-2].

With the recent remarkable development of many types of advanced fibers with excellent material properties like: lightweight, high strength and elasticity, and high corrosion resistance such as carbon, aramid, glass fibers, there has been an increasing innovation in construction technology by effective application of fiber reinforced plastics and/or fiber reinforced cement and concrete as advanced composite materials. Many fruitful research results have been accumulated about fundamental and applicable properties of FRP reinforcements and concrete reinforced with these FRP reinforcements (FRPRC) [3-4]. In spite of many useful properties in service, however, many existing FRP reinforcements have been made of thermosetting resins such as epoxy and vinyl ester which are hard to be chemically resolved in time of demolition and recycling, and have too poor recyclability.

This paper deals with life cycle design of lightweight high strength precast concrete combined with continuous fiber reinforced plastic reinforcement as an example of ecomaterials design considering the compatibility of long service life with recyclability, because concrete and FRP are two main building structural composite materials most difficult to be recycled for the present [5].

2. Research Methods

Existing building structural composite materials and components such as steel reinforced concrete (RC) and FRP reinforced concrete (FRPRC) have many excellent characteristics. Extreme orientation for high performance such as high strength and high corrosion resistance, however, becomes obstacles when we recycle these structural composite materials and components in demolition after designed service life. We try to convert these structural composite materials and components into new recycling-oriented ones, taking into account the harmony of the long service life and recyclability. Figure 1 shows the comparison of concepts of new reinforced concrete with CFRP reinforcements with ordinary steel reinforced concrete, considering the compatibility of recyclability with long service life. As to steel reinforced concrete as one of the main building structural components in building field, for the present, we freshly remember a serious deterioration problem as “concrete crisis”. In order to solve this problem, new approach has been made of durability design for making longer the service life of steel reinforced concrete buildings, and further a new active movement has rapidly gained ground to use various types of new continuous fiber reinforced plastic (FRP) reinforcement replacing steel reinforcement liable to corrode. FRPRC using thermoset resins, however, are difficult to be recycled in demolition after designed service life. If we use FRP reinforcements made of chemically resolved resins, we can expect to convert FRPRC into ecomaterials gentle to the global environment. We aim to systematize such life cycle design and ecomaterials technology.

3. Research results

3.1 Ecomaterials Design of Concrete Composite Materials and Systems [5], [6]

Life cycle processes of ecomaterials design of building structural composite materials and components are shown in Figure 2. How to establish the harmony of long service life with recyclability is an important point of this ecomaterials design.

3.1 Three Research Results as Part of Elementary Technology

The following research results were obtained :

1) Reuse methods of waste thermosetting FRP by pulverizing into powders as fine aggregate and cement-replacing binder. [7],

Table 1 shows the experimental results of concrete mixed with pulverized FRP powder, and Table 2 shows the experimental results of fluidized concrete mixed with pulverized powder. It was found from these experimental results that concrete mixed with FRP powders show the material characteristics comparable to plain concrete.

2) Dynamic tensile behavious of continuous carbon and glass fiber reinforced recyclable thermoplastic reinforcements [8], [9].

Table 3 shows the materials properties and test methods of newly-developed recyclable continuous carbon and glass fiber reinforced thermoplastics (FRTP). Dynamic behavious of these FRTP was exmined by repeated tensile loding test. It was found that these newly developed FRTP are applicable for non-metallic reinforcements, having the characters of the harmony with the environment as well as satisfactory dynamic characteristics necessary for reinforcements for precast concrete.

3) Accelerated carbonation test of concrete by step response method as a new method of prediction of the service life of RC and FRPRC [10].

Accelerated carbonation test was done based upon the step response method by setting the environmental CO_2 concentration as shown in Figure 3 modeling the

4. Conclusion

In order to convert building structural composite materials and component and/or elements into environment-conscious ones, ecomaterials design is proposed, paying special attention to the harmony of long service life with recyclability. Some elemental techniques to establish this ecomaterials design have been developed.

Lightweight high strength concrete components reinforced with recyclable continuous fiber reinforced plastic (FRP) rebars with thermally, photo-chemically and biochemically resolvable resins and fibers are recommended as ecomaterials design satisfying both the long service- life and recyclability of building materials and/or components.

Further, both repeated partial recycling (cascade recycling) of concrete, and reuse of thermosetting FRP rebars by pulverization as fine aggregate and cement-replacing binder in recycled concrete are considered.

In order to apply for recyclable non-metallic reinforcement for concrete structures, continuous carbon and glass fiber reinforced thermoplastics (CFRP and GFRP) have been newly developed. It was found that these recyclable FRP made of thermoplastics show completely elastic tensile behavious just as ordinary FRP (made of thermosets) reinforcement, and that in these thermoplastic FRP, stress concentration occurs dynamically in the fiber part as reinforcing materials for resins as well as in the environing parts of circular holes.

New predictive methods of the progress of carbonation of concrete and accelerated carbonation test methods have been established, considering the tendency of the increase in the concentration of atmospheric CO_2.

This ecomaterials design and elemental techniques will greatly contribute to establish the sustainable eco-construction, and eco-buildings, eco-cities and eco-societies in the future.

Moisture monitoring system based on a remote moisture sensor

G. Dai, K. Ahmet
Faculty of Science, Technology and Design, University of Luton, Luton, UK

Abstract
The moisture monitoring system being developed provides a network of monitoring cells, centrally monitored, to give early warning of potentially damaging failures of building components, generating high and persistent moisture levels, which are known to cause decay and damage to timber and masonry. The most critical aspect of system design is the useful range of the sensors, and their performance and reliability are crucial to a low maintenance installation and long-term customer satisfaction.

The paper describes the development of a new moisture sensor to meet the requirements with respect to accuracy; no species calibration is needed. The sensor consists of two pairs of parallel electrodes, equivalent to a network of six resistances, providing the potential for measuring moisture gradients. Electrodes are embedded with a cylindrical, high durability wood buffer. Several existing measurement techniques are evaluated. Performance of a prototype used in connection with a datalogging system is described. Results demonstrate the possible benefit to the construction industry in all situations where there is the need for an accurate long term measurement of the moisture content (MC) of timber, for example, in purchase, treatment, construction and surveying.
Key words: Moisture sensors, timber, instrumentation

1 Introduction

Moisture is associated with a range of problems in timber. For example, warping, shrinkage and distortion in service can occur where substantial variations exist between the installation and final moisture content (MC) [1]. The resistance to decay is severely affected by the MC of timber as the colonisation of fungi is strongly dependent on the MC. For example, if the MC is above around 25% the probability of fungal decay increases dramatically, especially where the timber is classed as "non-durable" [2]. Hand-held moisture meters are frequently employed for monitoring MC, where individual readings are taken at selected points, these being limited to surface or near surface measurements. For resistance type instruments, if species and temperature corrections, grain orientation and possible moisture gradients are ignored the measured values could suffer large errors.

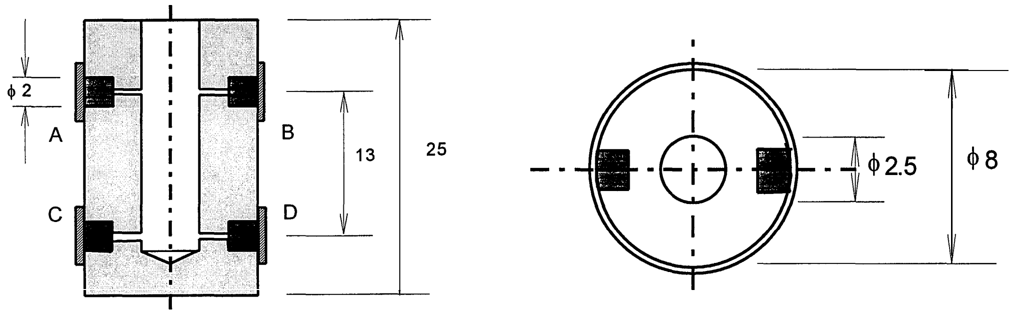
For large and/or inaccessible regions, moisture sensors with long term reliability, small enough to minimise disruption are needed for continuous monitoring. Extensive literature searches reveal that various types of sensor are in existence. [3] and [4] describe small wood sensors (approximate 4×4×15 mm). These are low-cost and easy to produce. In trials with similar sensors, the authors of this paper found that the main problem is in ensuring long-term reliable contact between the conductors and the wood surface. Inter-sensor variations have also been observed to be substantial. [5] describes a composite sensing probe able to measure resistance using stainless-steel rings at various depths in wood. However, the construction of these sensors appears to be involved and the probes are probably not inexpensive.

Sensors designed and produced by the authors' have the following characteristics: durable, low-cost, easy to produce and have small inter-sensor variability although individual sensors can be easily calibrated against oven-dried moisture contents. Small screw-type conductors ensure efficient long-term contact with the wood. Screw-type electrodes were employed very effectively in a previous project [1].

2 Moisture Monitoring System

2.1 Sensor Structure

Sensors employ wood buffers made from several species to ensure long term durability, 8 mm in diameter and 25 mm long. Two pairs of silver painted brass screw-type electrodes are inserted into the wood buffer 13 mm apart along the buffer grain (see Figure 1). A hole, 2.5 mm in diameter, allows the insertion of wires for connection to the electrodes. The 7-gauge shielded leads carry the signals over 4 m to the amplifiers. The isolating material (1 mm width) covers the electrodes to ensure that the electrodes do not touch the sample tested. The majority of the buffer is exposed inside the monitoring material in order that the buffer can reach equilibrium quickly. This sensor is referred to as GD1 hereinafter. In use, although the buffer maybe contact the test sample, this does not noticeably affect the final readings because the resistance of timber strongly depends on the contact of electrodes and buffer. For equilibrium moisture condition, the resistance of the buffer (R_b in Figure 2) is very much less than that of the sample tested (i.e. R_s in Figure 2), that is, $R_b << R_s$, therefore, overall the resistance $R = R_b // R_s \cong R_b$.



(a) Side Section (b) Top view

Figure 1 Sensor model; dimension in mm

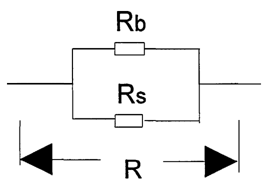


Figure 2 Resistance relation between buffer and sample tested

A range of wood species for the buffer have been carefully selected based on the application purpose. Buffer species are selected based on the permeability, durability and resistivity. Generally, the priority factors chosen are high permeability and low resistivity of buffer species. But for long-term monitoring of MC, durability is high priority.

2.2 General description of the circuit

The block diagram of the circuit is shown schematically in Figure 3. Unlike the commonly used full and half bridge methods, this approach requires no intermediary (and well-characterised) high-resistance standards to bootstrap up the resistance scale. Because the moisture meter should be able to operate over a wide range of moisture contents, a logic seeking strategy to find the appropriate range has been used. In

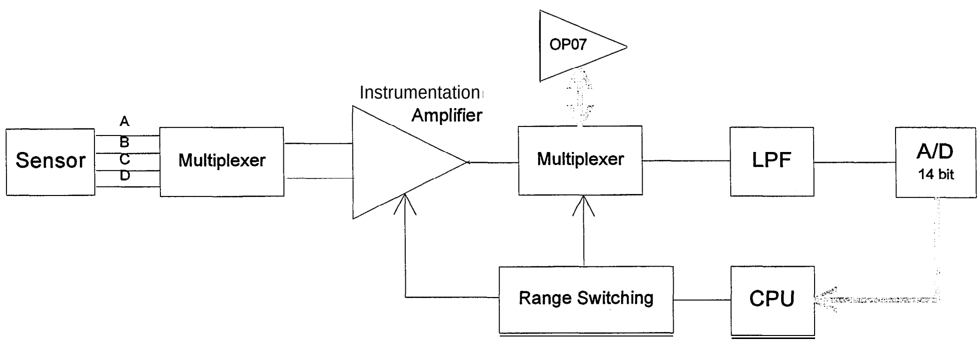

Figure 3 Schematic diagram of the moisture meter. (A/D: analog to digital converter; CPU: central processing unit; LPF: low pass filter)

Figure 3, the instrumentation amplifier has variable gain from 1 to 1 0^4. A high accuracy operational amplifier (OP07) is reserved as second-stage amplifier. These realise a practical operating range between 1kΩ and 100GΩ. Under simulated conditions, the meter measures accurately from 8 to 75 percent moisture content; in practice, however, the readings above the wood fibre saturation point should be considered only as "useful" as a resistance varies slowly with MC in this region.

2.3 Detailed considerations for improved performance

1. Species compensation

Since the wood species for the buffer in GD1 is fixed, relating resistance to wood MC can be determined in the laboratory based on oven-dried measurements of virtually identical samples. For this reason, no species correction are needed for measurements in varying samples. The final MC readings for samples tested can be determined from the relationship established in [6]. This database will be included in the microprocessor firmware, and the reading can be transformed automatically.

2. Polarisation consideration

This system solves the problem of polarisation by using an alternating polarity test sequence. Each sequence consists of the application of a positive polarity voltage, and after an appropriate delay, measures the current; the voltage polarity is then reversed and the current measurement again after the same delay time. This is repeated for a number of cycles (usually about seven) until the user observes stable readings. The instrument then calculates the resistance based on a weighted average of the last four readings.

3. Accuracy improvement

Current moisture meters only measure MC at the point of test. The test data in next section reflects that in some circumstances there are different MC readings from two pairs of electrodes in different depth of test sample. To understand the resistance variation in different directions within the buffer, it is essential to appreciate the electrical equivalent circuit of the measurement process; this is shown in Figure 4. Refer to Figure 1 for the equivalent points on the sensor. Because both R_3 and R_4 are resistances along the buffer grain, and R_5 and R_6 are resistances between two pairs of diagonal electrodes, the following assumptions can be made: $R_3 = R_4 = R_a$; $R_5 = R_6 = R_d$. Figure 4(a) can then be further simplified, Figure 4(b). If all of resistances can be measured, the final values calculated from these resistances will be more accurate measure of MC than that from a single resistance.

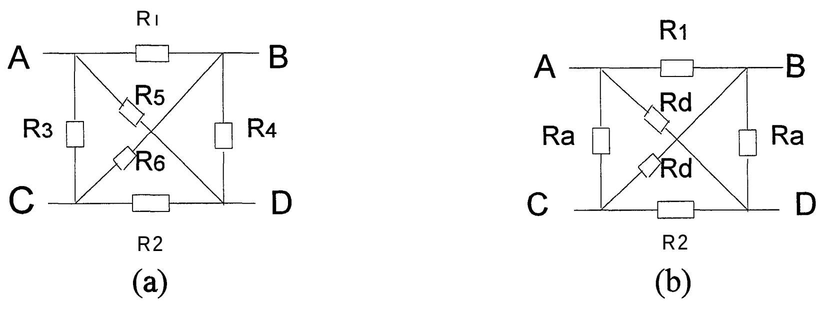

Figure 4 (a) Equivalent circuit diagram of GD1 sensor
(b) Simplified resistance network

4. Noise reduction

Numerous sources of error relating specifically to high resistance measurements (equivalent to low moisture content) have been analysed in [7]. Results of these analyses are still germane to our present work. The two leading limiting factors for obtaining a high accuracy are leakage currents and noise. In order to limit these factors, extensive attention should be paid to correct shielding and guarding, especially of the input terminals, i.e., from electrodes to circuit. Currently, screened cable has been used to transmit the signal. Input cables are shielded throughout. PTFE substrates substitute ordinary PVC for the circuit boards, effectively reducing the leakage current through the printed tracks. Guard pins adjacent to both input connections of the instrumentation amplifier have been used to drive circuit board and input cable guards to maintain extremely low input bias current.

3 Calibration and results

At present, most moisture meters use empirical equations, for example,

$$\log[\log(R)-4]=1.009-0.0322M$$

to relate resistance, R in Ω, along the sample grain to the percentage moisture content M, at temperature 20°C [8].

Figure 5 shows the variation in the electric resistance with moisture content. The shaded area shows the region in which 90% of commercially available species fall [8]. Carl1 [3] and Skaar [8] have well explained the electrical properties of wood, and here we mainly concentrate on the behaviour of the GD1 sensor.

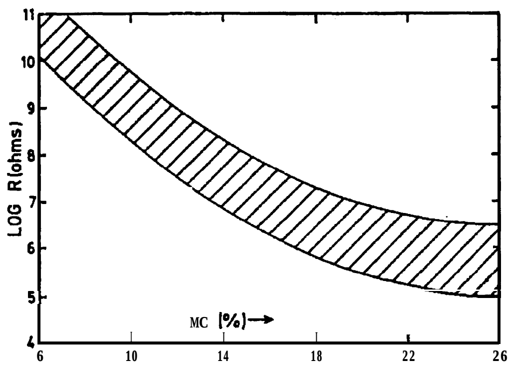

Figure 5 Electric resistance versus MC for most of commercially available wood species [8]

3.1 Comparison of three types of sensor readings

A limited calibration was carried out using timber species, Opepe and Beech, for GD1 sensor buffer. These choices of timber were dictated by the groups own particular requirements. Recalibration is necessary if other timbers are used.

Holes, 10 mm in diameter, were drilled into a number of Beech samples. The GD1s were pushed into the holes and the holes were sealed with silicon caulk to ensure that the outside atmosphere does not affect the buffer environment. Sensors were not inserted near obvious defects to ensure that the electrodes give more consistent readings. Three sensors were installed in the same conditioning chamber at 75% relative humidity (RH) and 20°C. Table 1 shows some of the MC measurements. Measurements were taken over a six month period. Although there is some variability between sensors, the fluctuation for a given sensor were less than 0.5% MC, showing long term reliability.

Table 1 Percentage MC readings from three different types of electrodes

(CT type sensor is type referred to in [3])

	Electrodes	MC
Set 1	Pin-type	14.1
	CT type sensor	11.7
	GD1 top pair	12.9
	GD1 bottom pair	12.9
Set 2	Pin-type	14.4
	CT type sensor	13.1
	GD1 top pair	12.9
	GD1 bottom pair	13.1
Set 3	Pin-type	13.7
	CT type sensor	12.8
	GD1 top pair	13.7
	GD1 bottom pair	14.1

In Table 1, the GD1 buffers of set 1 and 2 are Beech and that of set 3 is Ramin. Although the samples have not been oven-dried and we do not know the exactly final MC, it is very interesting that the readings from GD1 sensors are systematically lower compared with those from direct pin insertion. The CT type sensors consistently lower readings than the GD sensors, presumably being caused by very high contact resistance.

Pin-type electrodes and wood sensor can only reflect the MC at the depth of contacting with the samples. There is commonly moisture gradient inside the sample at any time, the average value from GD1 sensor gives more reasonable results.

The speed of moisture sorption greatly depends on the surface to volume ratio of the sensor. For the CT type wood sensors, only top end exposed to its environment, so response of wood sensor is relatively slow especially under drying conditions compared with GD1 sensor.

3.2 GD1 in specified RH

Table 2 gives a measure of MC in various RH conditions for an individually calibrated sensor. Only if an individual calibration data is available for each sensor can an “absolute” MC be resolved to the precision given in this table. However, even without an individual calibration data, the table gives the tracking sensitivity of a sensor.

Table 3 shows the MC readings based on the individual resistances of electric network in Figure 4(b). At present, the relationship between the overall MC and the resistances both along the wood grain and perpendicular to the grain are being work

Table 2 Sensor calibration, showing mean values of MC

MC % / Sensors	Percentage RH at 20°C			
	33	66	76	93
Oven-dried MC	8.48	13.50	15.12	22.5
GD1 No.1	7.78	12.34	14.60	15.84
GD1 No.2	8.00	13.52	14.94	17.42
GD1 No.3	--	11.92	14.22	15.62

out. The data in Table 3 indicate uncertainties in the MC for a given RH or calibration measurement. On average, the uncertainty between measurement from the two sensors is less than 0.3%. An investigation is on the way to estimate in the uncertainty of the "absolute" MC if individual sensor calibrations are not available. It is quite difficult to offer a universal calibration for the sensors as this will be buffer material-specific and will have fabricating uncertainty; however, other workers should have no difficulty in using the technique presented here and calibrating for their own particular needs.

Table 3 MC readings based on individual resistances defined in Figure 4(b)

Conditions	Percentage MC readings from			
	R1	Ra	Rd	R2
GD1 No.4 at RH 55%	11.7	11.7	11.1	11.4
GD1 No.5 at RH 55%	11.4	11.5	11.3	11.5
GD1 No.4 at RH 75%	15.7	15.6	15.8	13.8
GD1 No.5 at RH 75%	14.9	15.1	14.8	15.1

4 Discussion and Conclusion

The data obtained to date shows good consistency and reproducibility. However, various improvements are necessary, partly for automation of the set-up and partly to ensure high accuracy.

Early prototype sensors indicated much variability. General improvements have been made to sensors by improving machining techniques using uniform batches of materials, dimensional uncertainties and consistent sized screws. Screw electrodes are secured into precision holes for minimising contact resistance variations.

Very roughly, for every 10°C deviation of temperature from the calibration temperature of 20°C, an error of 0.5 % MC results, although the current tests have been performed at constant temperature, 20°C. Calibration over a range of suitable temperature (e.g. 0°C to 30°C) is necessary for in-situ use. Suitable thermocouple sensors will be introduced into the buffers to automate temperature compensation.

Equilibrium MC values are history dependent, i.e., the final MC depends on whether the buffer is absorbing or losing moisture. This hysteresis effect can be substantial under certain conditions, affecting the readings by typically up to 1% MC. Investigations are underway to determine procedures for compensating for this effect.

In conclusion, the sensors described provide stable readings, and the data collected indicated the reliability in the long term. By using measurements from effectively a network of resistors, results are more accurate and more reproducible.

The manufacture of electrodes is straight-forward and based on low-cost materials. Inter-sensor variation in performance is being minimised by improved machining and engineering, although there will always be slight variations between sensors caused by material variability. The sensors have the potential for detecting moisture gradients even though this facility has yet to be exploited.

Abstract
Referring to numbers of international scientific reports it arises that Sustainable Building Constructions are the only acceptable possibilities yet.
The Sustainability of a construction deals with responsible choices of materials and energies as well as similar choices of production and execution.
The so-called Porcupine Diagram shows the whole lifecycle or flow of building materials and illustrates the environmental impact dramatically.
As a conclusion from various research studies, concerning sustainable building, it became clear that the principles of "Thinking globally - acting locally", "Short as well as Long term planning", "Attunement to all Kinds of Recyclingprocesses", "Conservation of Resources" but also "Internalisation of the Problems" has to be considered honestly in order to be able to build sustainable. Human(e) Ecology, Bionics, Harmonics and new paradigmas, including ethical dimensions will help to find (re)new(ed) approaches and technologies towards sustainable building.
The author developed the necessary modells, methods and design aids, often translated into rules of thumb in order to support sustainable building in an efficient and even relatively easy way.
The choice of materials and technologies has to answer already fundamentally the demands for a healthy Indoor Environment. For the realisation of a qualified build environment the Right for the Environment is essential, which has to be supported by Legal and Procurement Practices. An environmentally-conscious Management will be needed to get the things done.
Together with such an integral view - the development and application of an environmentally-sound building technology might be one of the central tasks in order to reach results, which checked by Environmental impact and assessment methods, can be accepted. Proper Design aids and already rules of thumb lead to rather succesful results.

Eiwironmentally-Sound Building Technologies

Referring to numbers of international scientific reports it arises that Sustainable Building Constructions are the only acceptable possibilities yet.
The Sustainability of a construction deals with responsible choices of materials and energies as well as similar choices of production and execution.

The so-called Porcupine Diagram shows the whole lifecycle or flow of building materials and illustrates the environmental impact dramatically.

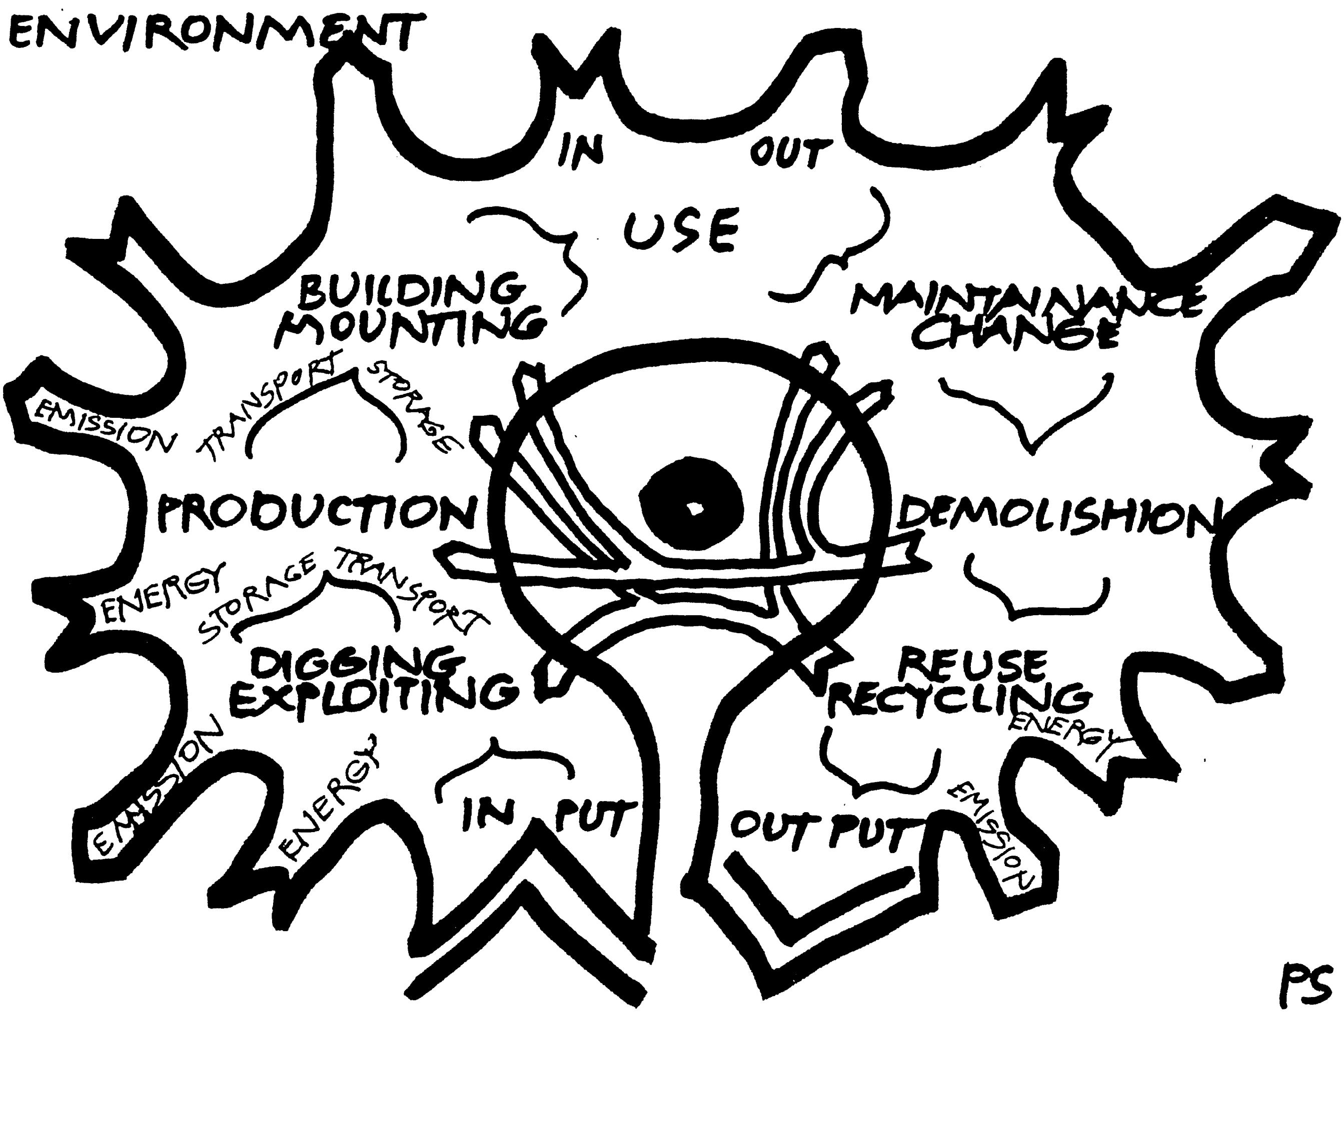

Figure 1
The Porcupine Diagram shows the whole life-cycle or flow of building materials and illustrates dramatically the environmental impact.

As a conclusion from various research studies, concerning sustainable building, it became clear that the principles of "Thinking globally - acting locally", "Short as well as Long term planning", "Attunement to all Kinds of Recycling P rocesses", "Conservation of Resources" but also "Internalisation of the Problems" has to be considered honestly in order to be able to build sustainable. Human(e) Ecology, Bionics, Harmonics and new paradigmas, including ethical dimensions will help to find (re)new(ed) approaches and technologies towards sustainable building.

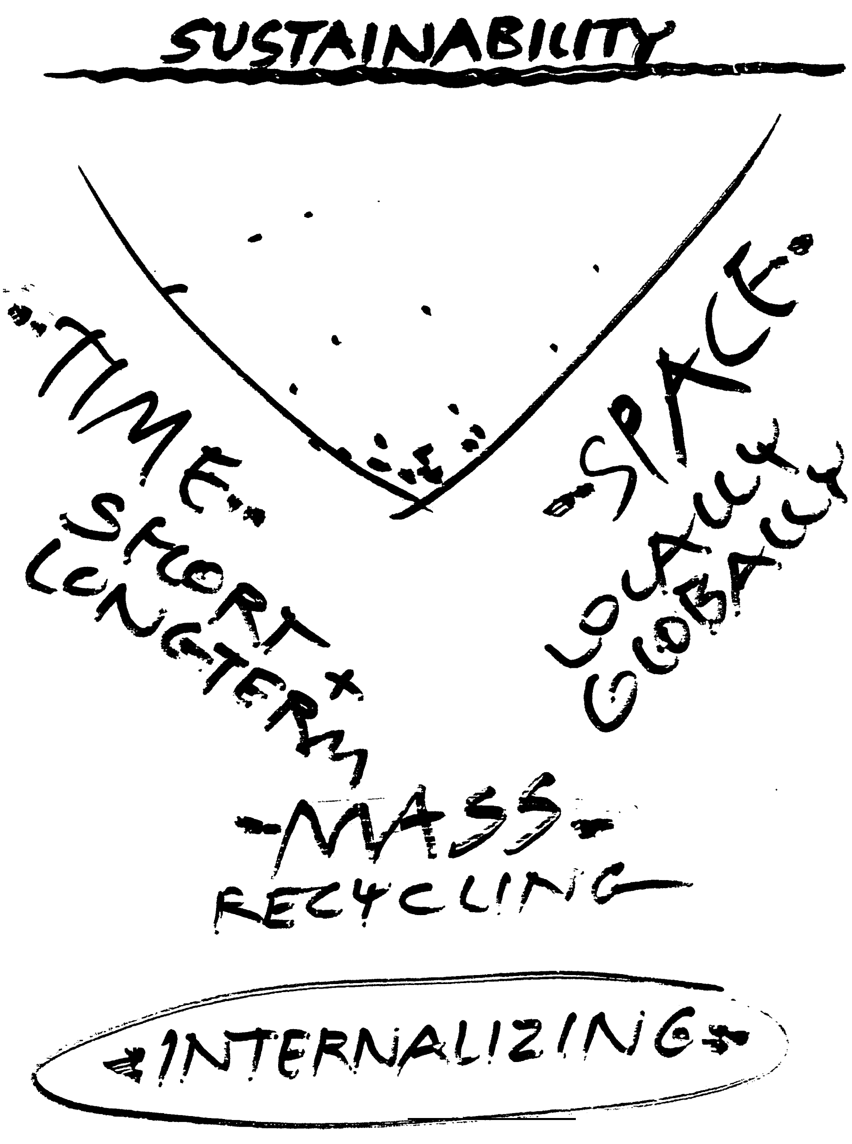

Figure 2
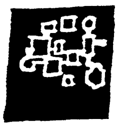
The Principles which have to be respected in space and time together with the most important namely the Internalisation of the actual problem.

The author developed the necessary modells, methods and design aids, often translated into rules of thumb in order to support sustainable building in an efficient and even relatively easy way.

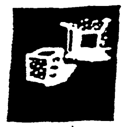
The choice of materials and technologies has to answer already fundamentally the demands for a healthy Indoor Environment. For the realisation of a qualified built environment the Right for the Environment is essential, which has to be supported by Legal and Procurement Practices. An environmentally-conscious Management will be needed to get the things done.

1. Location, Orientation, Use



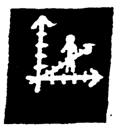
Choose a healthy site, consider the orientation, optimize the function for a practical use.

2. Space and Mass



Shape useful (closed or open) protecting space. Include identity and expression into the building mass.

3. Canon, Modular Coordination

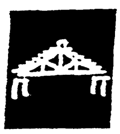


Apply harmonious and ergonomical measures, in numbers. dimensions. weights - modular coordinated - eventually in a meaningful way.

4. Indoor Climate, Installation, Furnishing

Create a cosy and comfortable indoor climate with minimal installations and a flexible equipment and furnishing in order to earn a suitable atmosphere.

5. Structure and Construction



Design (load carrying) sheltering structures simple and understandable. durable constructions. which do not demand various kinds of means (e.g. eievators) because of their gigantic character.

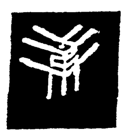
6. Energy and Material

Use mainly durable. sustainable. endless (available/growing). easy reusable or recycleable. soft. clean. "natura", energies and materials.

7. Production & Building Proces

Produce in a humanly, healthy way with a wise choice concerning handicraft or industry, selfheip or automatization and in cooperation and participation on ail possible levels.

8. The Art of Joining



Joint/connect/compose all building parts or elements in a harmonious way. rather solid. but demountable. simply efficient. Joints as nuclei determine (already) the whole.

Figure 3
Some vital rules of thumb structured along the 8 Components in order to reach a suitable built and Sustainable Environment.

Together with such an integral view - the development and application of an environmentally-sound building technology might be one of the central tasks in order to reach results, which checked by Environmental impact and assessment methods, can be accepted. Proper Design aids and already rules of thumb lead to rather succesful results.

Towards a new integrated IS0 - standard for sustainable building

G. Soronis
Swedish Building Standards Institution, Stockholm, Sweden
A. Raphael Makenya
Architectural Design and Technology, Royal Institute of Technology, Stockholm, Sweden

Abstract
The International Organization for Standardization, ISO, is currently producing standards for sustainable development within the industry, in its effort to minimize negative influence on the environment and to promote a long-term resource economy. This paper gives a state of the art review of the current work within IS0 14000 series (environmental management), IS0 9000 series (quality management) and outlines the second draft for an ISO-standard for Service Life Planning of Buildings (ISO/ TC59/ SC 14). This paper also highlights the need to integrate considerations concerning sustainability in building in the current work within ISO/ TC 59/ 14. This can be developed from a basis of scientific knowledge and empirical experience and by utilizing the principles of IS0 9000 and IS0 14000 series.
Keywords: Durability, service life, standards, sustainable building.

1 Introduction

Organizations of all kinds are increasingly concerned to achieve and demonstrate sound environmental performance by controlling the impact of their activities, products or services on the environment, taking into account their environmental policy and objectives. They do so in the context of increasingly stringent legislation, the development of economic policies and other measures to foster environmental protection, and a general growth of concern from interest parties about environmental matters including sustainable development.

International standards covering environmental management are intended to provide organizations with the elements of an effective environmental management system which can be integrated with other management systems. All these international standards are not intended to be used to create non-tariff trade barriers or to increase an organization's legal obligations.

The main ISO-standards for environmental management is the IS0 14000-series. This standard shares all management system principles with the IS0 9000-series of quality systems standards. Thus, IS0 9000-series can be used as basis for all environmental management systems.

The work within ISO/ TC59/ SC14 as described below, aims to give guidelines for sustainable building by utilizing the principles of IS0 9000 and IS0 14000 in a model for service life planning of buildings.

Unfortunately, all the ISO-standards in this area, except the standard ISO/ TC59/ SC14, are addressed to a general use and not for people concerned with building. In every day life, when problems must be solved "now", these standards are not easy to use for the common man who needs standardized knowledge in the field. For this reason, it is important to initiate a new work item for developing an ISO-standard, which includes principles from all the existing standards for sustainable building as described in the next chapters.

2 Aims

The purpose of the work presented here is to:

- To give a state of the art review on existing international standards for sustainable housing
- To outline the current work within IS0 for the development of standards for design life of buildings
- To propose guidelines for linking IS0 9000 and IS0 14000-series to the current work within ISO/ TC59/ SC14 "Design Life of Buildings".

3 State of the art review

3.1 IS0 9000-series

The IS0 9000 series contains International Standards dealing with quality systems and quality management that can be used to external quality assurance purposes. The alternative quality assurance models in those standard series, contains distinct forms of "Functional or organizational capability" suitable for two-party contractual purposes.

The five standards of the IS0 9001-series as mentioned below, give the basic guidelines for quality assurance and are now broadly used in all building processes:

- IS0 9000, Quality management and quality assurance standards - Guidelines for selection and use. This standard is to be used to clarify the distinctions and relationships among the existing quality concepts. It can be also used for the selection and use of the standards for quality systems and quality management (IS0 9001-9004).
- IS0 9002, Quality systems - Model for quality assurance in design/ development, production, installation and servicing. This standard is to be used when conformance to specified requirements is to be assured by the supplier during several stages which may include design/ development, production, installation and servicing.
- IS0 9002, Quality systems - Model for quality assurance in production and installation. This standard is to be used when conformance to specified requirements is to be assured by the supplier during production and installation
- IS0 9003, Quality systems - Model for quality assurance in final inspection and test. This standard is to be used when conformance to specified requirements is to be assured by the supplier solely at the final test.
- IS0 9004, Quality management and quality system elements - Guidelines. This standard is to be used to describe basic elements for carried out and implementing a quality system.

3.2 IS0 14000-series

The IS0 14000-series are currently in a development process. The following ISO-documents are now implemented as international standards:

- IS0 14001, Environmental management systems (EMS) - Specification with guidance for use. This standard can be used to specify requirements for an environmental management system, to enable an organization to formulate a policy and objectives taking into account legislative requirements and information about significant environmental impacts. It applies to those environmental aspects, which the organization can control and over which it can be expected to have an influence. It doesn't itself state specific environmental performance criteria.
- IS0 14004, Environmental management systems (EMS) - General guidelines on principles, systems and supporting techniques. This standard can be used to provide guidance on the development and implementation of environmental management systems and principles, and their co-ordination with other management systems. The guidelines in the standard are applicable to any organization, regardless of size, type, or level of maturity, that is interested in developing, implementing and/or improving an environmental management system.
- IS0 14 10, Guidelines for environmental auditing - General principles. This standard can be used to provide general principles of environmental auditing that are applicable to all types of environmental audits. Any activity defined as an environmental audit in accordance with this standard should satisfy the recommendations given in it.

- IS0 1411, Guidelines for environmental auditing - Audit procedures - Auditing of environmental management systems. This standard can be used to establish audit procedures that provide for the planning and conduct of an audit of an EMS to determine conformance with EMS audit criteria.
- IS0 1412, Guidelines for environmental auditing - Qualification criteria for environmental auditors. This standard can be used to provide guidance on qualification criteria for environmental auditors. It is applicable to both internal and external auditors. Criteria for the selection and composition of audit teams are not included, reference is made to IS0 14011 for information in this subjects.

The following ISO-documents are now in a development stage and will be implemented as international standards during 1997-98:

- IS0 1420-series, Environmental declarations and marking
- IS0 143 1, Environmental performance
- IS0 14040-series, Life cycle analysis (LCA)
- IS0 14050, Environmental terminology.

3.3 ISO/TC 59/SC 14 - Service life planning of buildings

This IS0 draft of an international standard for service life planning of building is currently developed within ISO/TC 59/SC 14 (former committee notation: ISO/TC 59/SC 3/ WG 9). This document [1] presents the generic principles, which can be applied in estimating the expected life of a building of any type to be built in any environment. It can also be applied in estimating the remaining life of an existing building. The Standard is in five parts as follows:

- Part I: general principles for evaluating whether the expected service life will be at least as long as the design life
- Part II: methods to be used in determining the expected life
- Part III: information on quality assurance, maintenance and performance auditing.
- Part IV: references to relevant standards, other literature and a glossary
- Part V: recommends formats for the data to be used and the reports to be generated.

The standard is planned to serve designers, owners, potential buyers/ investors, educators, etc. and the benefit they should gain from it. It will point out that while it is difficult (sometimes impossible) to make precise estimates of building life, the availability of a standard approach will put estimates on a common basis. The methodology used for prediction of service life of the building component follows the principles of the British, Japanese and Canadian national guides for service life planning of building [2].

4 Summary and conclusions

From what has been described above, the following conclusions can be made:

- Environmental optimization of every product, project, and enterprise in the building industry and real estate management becomes more and more as natural and as indispensable as an optimization from the viewpoint of business economics. In this paper, the challenge of the development of a new international standard for sustainable building has been described on the basis of existing ISO-standards and IS0 work items. The need of many interrelated standards forming a logically-consistent, coherent framework for sustainable building is pointed out.

- As described previously, international standardization for sustainable building is fragmented in a number of standards which are information intensive. At present, it is difficult, if not impossible, to glean the needed standard information from the scattered sources in the above mentioned standards. As such, a new work item has to be initiated to integrate all standardized knowledge which deals with the building and its environmental impact from a life cycle perspective with the current work within ISO/ TC 59/ SC 14 " Design Life of Buildings".
- While, sustainable building requires a large measure of knowledge the utilization of computer-based standardization will become necessary. Routines to facilitate the use of computer in all standardization are in place [3].

5 Acknowledgements

The authors wish to acknowledge that, development of these ideas concerning standardization of sustainable building owes much to discussions with others, particularly with members of the technical committees in CEN, ISO, CIB and RILEM.

The effects of mineral fines on thermal properties of wood composites

M.L. Benmalek, A. Bouguerra, A. Ledhem
Groupe Physique Environnement Bâti. Equipe gestion technique du bâti. Institut Universitaire de Technologie. Rennes. France
R.M. Dheilly, M. Queneudec
Laboratoire Matériaux Thermique, Institut Universitaire de Technologie, Amiens, France.

Abstract:
Large quantities of waste generated from aggregate quarries or from the production of stone building materials are present in many countries and constitute a environmental nuisance. New technologies have been developed to recycle these wastes into insulating materials. Several types of fines, which differ in their mineral composition, are studied herein in order to compare the resultant effects on both the physical and thermal properties of wood concretes. Thermal conductivity is measured from a full-saturated to oven-dry conditions .

The experimental results are then presented, and the ensuing analysis serves to suggest the possibility of manufacturing insulating and load-bearing materials using little energy.
Keywords: Thermal properties, waste, wood concretes.

1 Introduction

Large quantities of mineral fines, generated from operating aggregate quarries, are present in many countries. These industrial wastes are not actually being reused at the current time and could constitute a significant environmental problem. The choice has been made to recycle them by manufacturing lightweight concretes.

Previous work [1 to 3] has demonstrated this possibility through reliance on one of the following processes: the creation of cells forming a fine-cement paste (cellular concrete), or the addition of wood shavings into a fine-cement paste (wood concrete).

The materials developed can be both insulating and load-bearing, or insulating composites, depending on the specific composition. In this paper, only the weight reduction by wood aggregate will be considered.

The aim of this work is to study the comparative effects of mineral fines on wood concrete's thermal properties. When placed in a moist atmosphere, wood composites can retain water by the adsorption process. This phenomenon is highly dependent upon the matrix [4] related to its water affinity. It is well known that moisture content can particularly affect thermal performances. Thermal conductivity will be measured from fully-saturated to an oven-dry conditions.

2 Materials and experimental program

2.1 Raw materials

The selected mineral fines are presented in Table 1. They have been collected from mud after drying at 105°C for 24 hours in a drying oven, the waste is hence in a ground form. The powders are then maintained in a dry cell.

Fine	Origin	Main minerals components
GR	mud resulting from sawing operations on massive granite rock.	feldspar, mica and quartz
SA	mud resulting from the exploitation of sandstone quarry by washing aggregates obtained by crushing.	quartz
C1	mud resulting from the exploitation of alluvial aggregates by washing.	kaolinite and ~5% of quartz
C2	mud resulting from the exploitation of alluvial aggregates by washing.	kaolinite and ~75 % of quartz

Table 1: Mineral fines

The grain size distribution curves, obtained by a laser granulometry technique, are displayed in Figure 1.

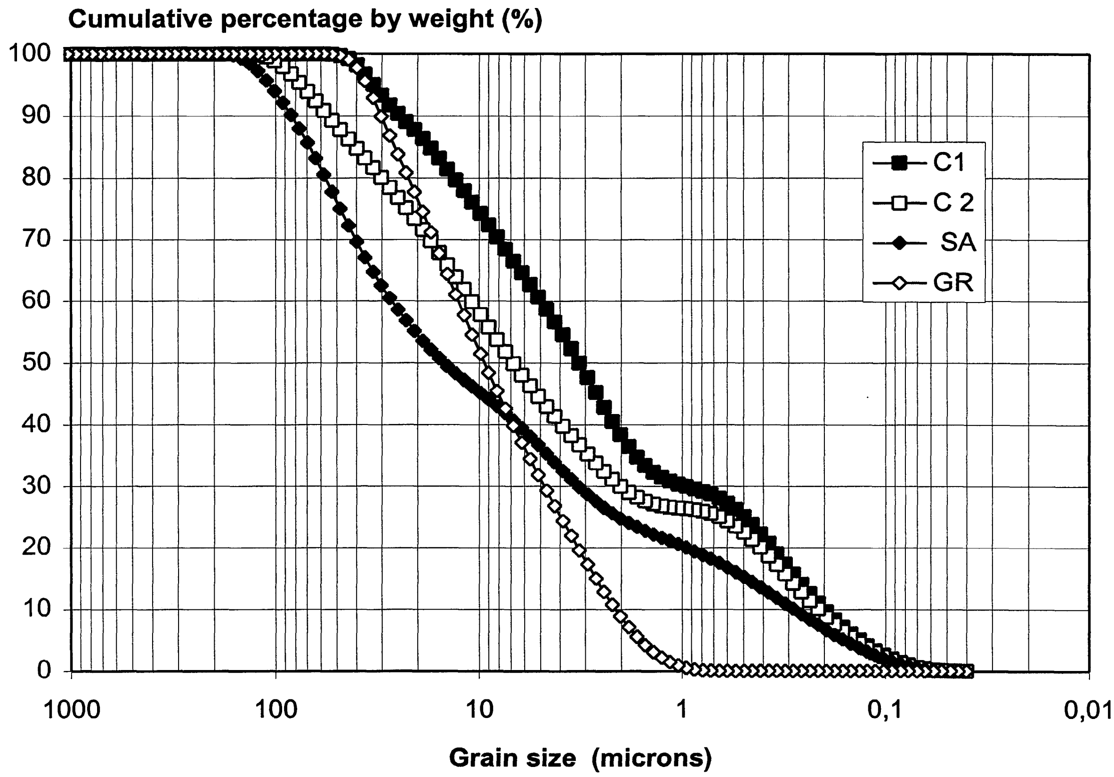

Fig 1: Grain size distribution curves of studied fine minerals

The other physical characteristics are shown in Table 2. The dry densities have been determined by pycnometry [1].

Fine	Dry density (kg/dm^3)	Thermal conductivity (W/mK)
GR	2.64	2.58
SA	2.62	4.72
C1	2.62	2.35
C2	2.65	3.62

Table 2: Some physical characteristics of studied fine minerals

The thermal conductivities of the powders have been measured by the method recently developed by A. Bouguerra [5]. It should be noted that all of the selected fines in granular form are heat conductors in comparison with ground wood (λ ~,15W/mK

[5]), in particular the sandstone fine (λ = 4.72 W/mK). The proportions of quartz seem to be a factor of importance.

The characteristics of the stabilized wood aggregates are: apparent density: 255 kg/m^3, moisture content : 9 %, water absorption, by weight : 120 %.

The cement used to ensure the chemical stabilization is the CPA CEM I 52.5, in accordance with the European Standard EN 196-1.

2.2 Formulation of the composite materials

All of the lightweight concretes studied have been produced with the same dry-weighted mix.

The proportions used, by weight, were: cement : 25 %; mineral fine: 50 %; and wood aggregate: 25 %

The workable mixing water content was calculated using the empirical relationship in [1]:

$$W = W_1C + W_2F + W_3W_A$$

Where: C = cement weight (kg); F = fine mineral weight (kg); W_A = wood aggregate weight (kg); W_1, W_2 and W_3 = experimental coefficients relative to the cement, fine mineral and wood-treated aggregates, respectively. These have been determined such that the mixture with water exhibits a normal consistency. W_1 = 0.35 in accordance with A.Moslemi [6] and K.Alrim [1].

W_2 has been determined experimentally by the authors: W_2 = 0.45 for granite and sandstone powders; W_2 = 0.70 for clay powders; and W_3 = 0.80 in accordance with A.Bouguerra [5].

Dry cement and mineral fines were mixed in a laboratory mixing machine, in accordance with the French Standard NFP 15437 before adding the wood aggregates. Water was then gradually added when the dry mixture became homogeneous. Afterwards, the concrete was moulded and placed into a controlled-temperature and moistness cell (Θ = 20°C and HR = 90%), in accordance with NFP 15401. Following removal, the samples were maintained in the cell and cured for 28 days. Then, those samples intented for density and mechanical characteristic measurements were put in a drying oven (105°C) up until a constant weight was achieved. Those samples intented for the thermohygrometric measurements were immersed for 28 days into distilled water for curing. The saturation (constant weight) was obtained before testing.

The internal dimensions of the molds used in this investigation were 100 mm x 100 mm x 100 mm.

For measuring the thermal conductivities of specimens at various water contents, the line source method [7,8] was employed. The measurements were performed at 20°C. A series of water contents, from a fully saturated to an oven-dry condition was generated by progressive drying in a microwave oven. This technique insures a homogeneous distribution of the water inside the specimens [9]. The specimens are preliminarily placed into plastic bags and sealed by welding. Then they are packed inside a climate - controlled cell until the temperature equilibrium has been reached.

3. Experimental results

3.1 Physicomechanical characteristics

Table 3 provides the characteristics of the composites developed. It can be observed that the dependence of compressive strength on dry density has not been well established when the fine minerals used are basically different. In spite of its higher density, granite displays a lower compressive strength. For equal densities, the compressive strength of the sandstone composite is more than twice that of the clayey composite. The clayey composite C_2 displays a density that's lower than the composite C_1, yet its compressive strength is higher.

These results serve to demonstrate the significance of the findings.

Fine mineral employed	Density	Compressive strength(MPa)
GR	770	3,3
SA	730	4,6
C1	740	2,0
C2	700	2,2

Table 3: Physicomechanical characteristics of the composites

3.2 Thermal conductivity

Temperature and moisture content are among the most important factors influencing the thermal conductivity of lightweight concretes. In this work, the measured results of the dependence of thermal conductivity on the moisture content of the lightweight fine concretes produced herein have been analyzed. Thermal conductivity measurements were carried out at different water contents of the samples, yet always at the same temperature: 20°C. Figure 2 shows the experimental results obtained.

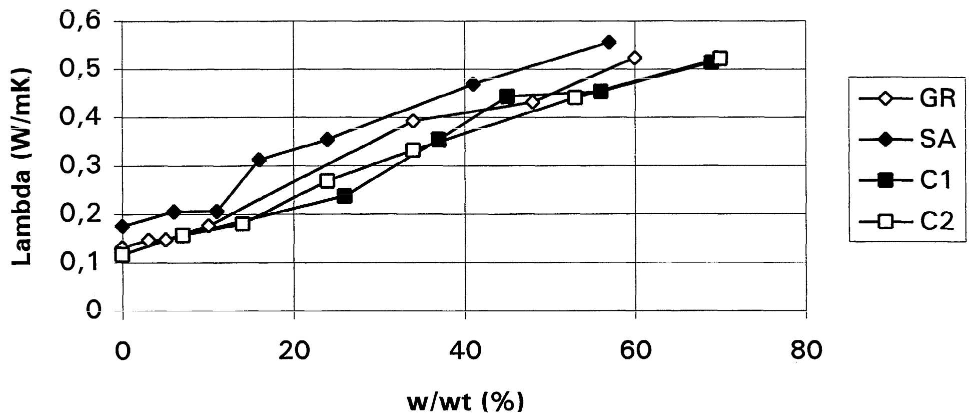

Fig 2: Effect of the water content on thermal conductivity for the various lightweight concretes.

In a dry state, the conductivity of sandstone is the highest, while that of the other composites remains very close.

This behaviour, with the increase in moistners, is also the same despite the values of λ, which are always higher in the case of sandstone. Within the limits of experimental error, no difference between the two clayey composites studied is detected.

A comparison between experimental and theoretical values reveals the recommended relationship of the American Concrete Institute [10] has been obtained:

$$\lambda = \lambda_0 \left[1 + K\left(\frac{w}{wt}\%\right)\right]$$

λ_0: coefficient of thermal conductivity at the dry condition or at w/wt = 0 (W/mK)
K = 0.06 for lightweight concretes and 0.09 for normal weight concretes
w/wt : water content.

The results are listed in Table 4.

Fine mineral employed	w/wt (%)	λ_0 (W/mK)	λ_{th} (W/mK)	λ_{ex} (W/mK)	difference/λ_{th} (%)
	60		0.602	0.523	15
GR	34	0.131	0.398	0.392	1.5
	5		0.170	0.147	15.6
	3		0.154	0.146	5.5
	41		0.605	0.469	29
SA	24	0.175	0.427	0.354	20.6
	16		0.343	0.312	9.9
	6		0.238	0.205	16.1
	56		0.510	0.454	12.3
C1	45	0.117	0.433	0.444	-2.5
	37		0.376	0.354	6.2
	7		0.166	0.157	5.7
	53		0.489	0.441	10.9
C2	34	0.117	0.356	0.332	7.2
	24		0.285	0.268	6.3
	7		0.166	0.156	6.4

Table 4: Theoritical and experimental data of thermal conductivity

The theoretical values are, in the majority of cases, greater than the experimental values. Except in the case of sandstone, this difference is even more significant as the moisture content increases. This can be explained by the results obtained by A. Bouguerra. He has shown that in the case of saturation by capillarity, the water localizes essentially in the matrix. The wood aggregates play the role of cutting off the capillarity. This is due to the double porosity of the wood concretes: macroporosity, provided by the aggregates, and the microporosity of the matrix. This phenomenon is more distinct in the case of sandstone. At the present time, we do not possess sufficient explanatory elements, nonetheless, it should be pointed out that the fine mineral actually contains the largest-sized grains.

4 Conclusion

On the basis of these test results, the following set of conclusions can be drawn.

The mineralogical composition of the studied fine exerts an influence on the physical properties of the lightweight concrete, yet this influence would require entering into too great of a level of detail .

The main purpose of this work was to evaluate the possibility of recycling mineral industrial wastes in lightweight, low environmental-impact materials, which necessitated both manufacturing by means of technologies enabling low-energy consumption and advantageous thermal characteristics. The experimental results have shown that the designed lightweight fine concretes do possess a high insulating capacity. The coefficient of thermal conductivity in the dry condition is, in any event, less than 0.2 W/mK for a density near 0,7. Its variation with respect to water content is overall in good agreement with the ACI recommendation. The mechanical performance is indeed sufficient to take into consideration the design of insulating or both insulating and load-bearing blocks.

Abstract :
The authors have developed technologies to recycle clay waste as insulating materials. The clay waste used in this work is mainly composed of kaolinite. The weight reduction is obtained by using wood aggregates.

This paper gives the influence of therrnohygrometric conditions on thermal performances of clayey concrete lightened by wood aggregates.
In order to determine the thermal conductivity and to reduce the water migration effects, a transient « Line Source Method » was used. The rate of saturation, expressed as the ratio of the volume content of water to the total porosity ranges from 0 to 1. The temperature range (0-60°C) covers the majority of thermal conditions in which the material is used. Thermal conductivity curves are given for different weight percentages of wood aggregates (0, 25, 30, 40, 50%). The influence of temperature, rate of saturation and wood aggregates content on mass transfer is analysed.

It can be observed that for temperatures below 20°C, the values obtained are very close. The deviation is greater as the rate of saturation increases and as the wood aggregates content increases. The maximum value reached for the thermal conductivity, λ decreases as the wood content increases. For temperatures above 20°C, the experimental curves have a tendency to diverge. This effect is even more-pronounced as the wood content rises. The phenomenon of evaporation-condensation is thus not encountered at temperatures lower than 20°C. For higher temperatures, the mechanism of transfer by conduction through the various phases combines with a heat transfer which is largely attributable to phase changes. It would seem that wood aggregates do participate in the phenomenon of condensation-evaporation within the range of temperatures greater than the ambient temperature and that mass transfers with the aggregates are essentially made in the vapor phase. Finally, it is shown that in normal operating conditions, temperature and moisture do not considerably influence the thermal conductivity of the designed materials.
Keywords : Lightweight concrete, thermal conductivity, thermohygrometric conditions

1 Introduction

Over the past quarter century, developing countries have been subjected to major demographic transformations, thereby necessitating a policy approach that accommodates exponential urban growth rates. In light of the deteriorating economic conditions often encountered, one recommended solution is to utilize local resources and to transform them into both technically- and economically-competitive materials which meet the requirements of a population in the throes of complete cultural evolution. Among such local materials, clay and wood are quite often present.

Furthermore, the industrialized nations are confronted with the problem of the wastes they produce. For example, in the western part of France, deposits of marine sand fossils from the end of the tertiary era have been in great demand. Sands being used currently contain a sizable clayey fraction that must be eliminated by washing. Residues from operations represent a volume which can only continue to increase.

Our objective herein has thus been two-fold: to reuse the by-products from industrial operations, and to develop techniques for using local materials.

Awareness of environmental quality issues has led to many of the insulators currently on the market being considered as pollutants, from the standpoint of either their manufacturing process or the eventual building site wastes generated. The approach our team has been pursing over the past several years is therefore to transform these clayey wastes into lightweight environmental impact-resistant insulating materials. In order to accomplish this, various techniques have been employed: the creation of a cellular structure, or weight reduction by the introduction of lightened aggregates. For the former, «cellscan» can be created by a either chemical reaction [1,2] or by entraining air [1, 3 to 6]. For the work presented herein, it is the weight reduction by wood aggregates [1, 7 to 13] which is. This technique does in fact make it possible to reuse the wastes from two types of industrial domains. Moreover, wood and clay are two widespread local resources in many developing countries.

Nevertheless, the simultaneous presence of clay and wood in the hardened materials can raise concerns of an increased sensitivity to water, which would serve to decrease the composite's thermal performance. A study of conductivity, in relation to both temperature and humidity, has thus been conducted.

2 Materials and experimental conditions

The cement product is a CPA-CEMI 52.5 (EN 196-1) type cement currently obtained from Lafarge industry, whereas, the clay waste used in this work is mainly composed of kaolinite [12, 14]. The particle analysis shows that 55% the particles are under $2\mu m$ and the longer diameters are of $70\mu m$. However the real limon part ($2\mu m<\phi<70\mu m$) is certainly overestimated since the separation of the clay particles by the operator is made by leaching with addition of a floculating agent.The absolute density is 2.65 and Atterberg limits are $W_L=48\%$, $W_P=36\%$, $I_P=12\%$. The thermal conductivity of the powder is 3.45 W/m.K [12].

Wooden aggregates are derived from pine waste and are stabilized by thermal processing and mineralization. The thermophysical properties are : bulk density = 255kg/m^3, moisture content = 9%, water absorption = 120%, thermal conductivity = 0,07W/m.K, thermal conductivity of ground wooden aggregates = 1.15W/m.K

The principle of weight reduction by using wooden aggregates has previously been described by Al-Rim [1]. The mixing machine conforms to standard EN-196-1. In the first step, dry waste and cement are introduced in the mixing machine and mixed in a dry state before wooden aggregates are added. Water is then gradually added to the dry mix. The water content is calculated using the expression : $W=0.35*C+W_f*A+1.5*B$ [1] where C, A, and B are the weight of cement, clay, and wooden aggregates respectively. W_f is the amount of water determined so that the mixture with water has a normal consistency (f=1 850Pa).

The concrete is then poured into moulds and placed in a controlled temperature and moisture cell (Temp.=20°C, RH=90%) in accordance with standard NF P 15401. After removal, the samples are maintained in a drying oven (70°C) until a constant weight is achieved before testing.

Table 1 gives the variations of dry density and total porosity versus the % of wooden aggregates, for the mix : cement = 20%, clay+wood aggregates=80%.

Apparent density and total porosity have been determined by mercury intrusion porosimetry.

Table 1: Wooden aggregates proportions, apparent density and total porosity of studied materials

% wooden aggregates	apparent density	total porosity
0	1.28	48.5
25	0.91	63.6
30	0.82	64.9
40	0.74	67.7
50	0.67	70.4

In order to determine the thermal conductivity and to reduce the water migration effects, a transient « Line Source Method » was used to obtain the required values in moist materials while conductivity thermal tests [12]. The measurements were performed on samples having dimensions 10x10x10cm^3. The following procedure was used in preparing the samples for laboratory measurements. A hole corresponding to the probe length (10cm) was drilled into each sample. The samples were saturated with water in accordance with the RILEM recommendation [15] and placed in sealed plastic bags. Thereafter, the samples were put in a climatic cell until temperature equilibrium was reached. Gradually, water contents were obtained as the drying process proceeded from the saturated to the dry state through progressive drying in a microwave oven. This technique insured a homogeneous distribution of water inside the material [16].

3 Experimental results and analysis

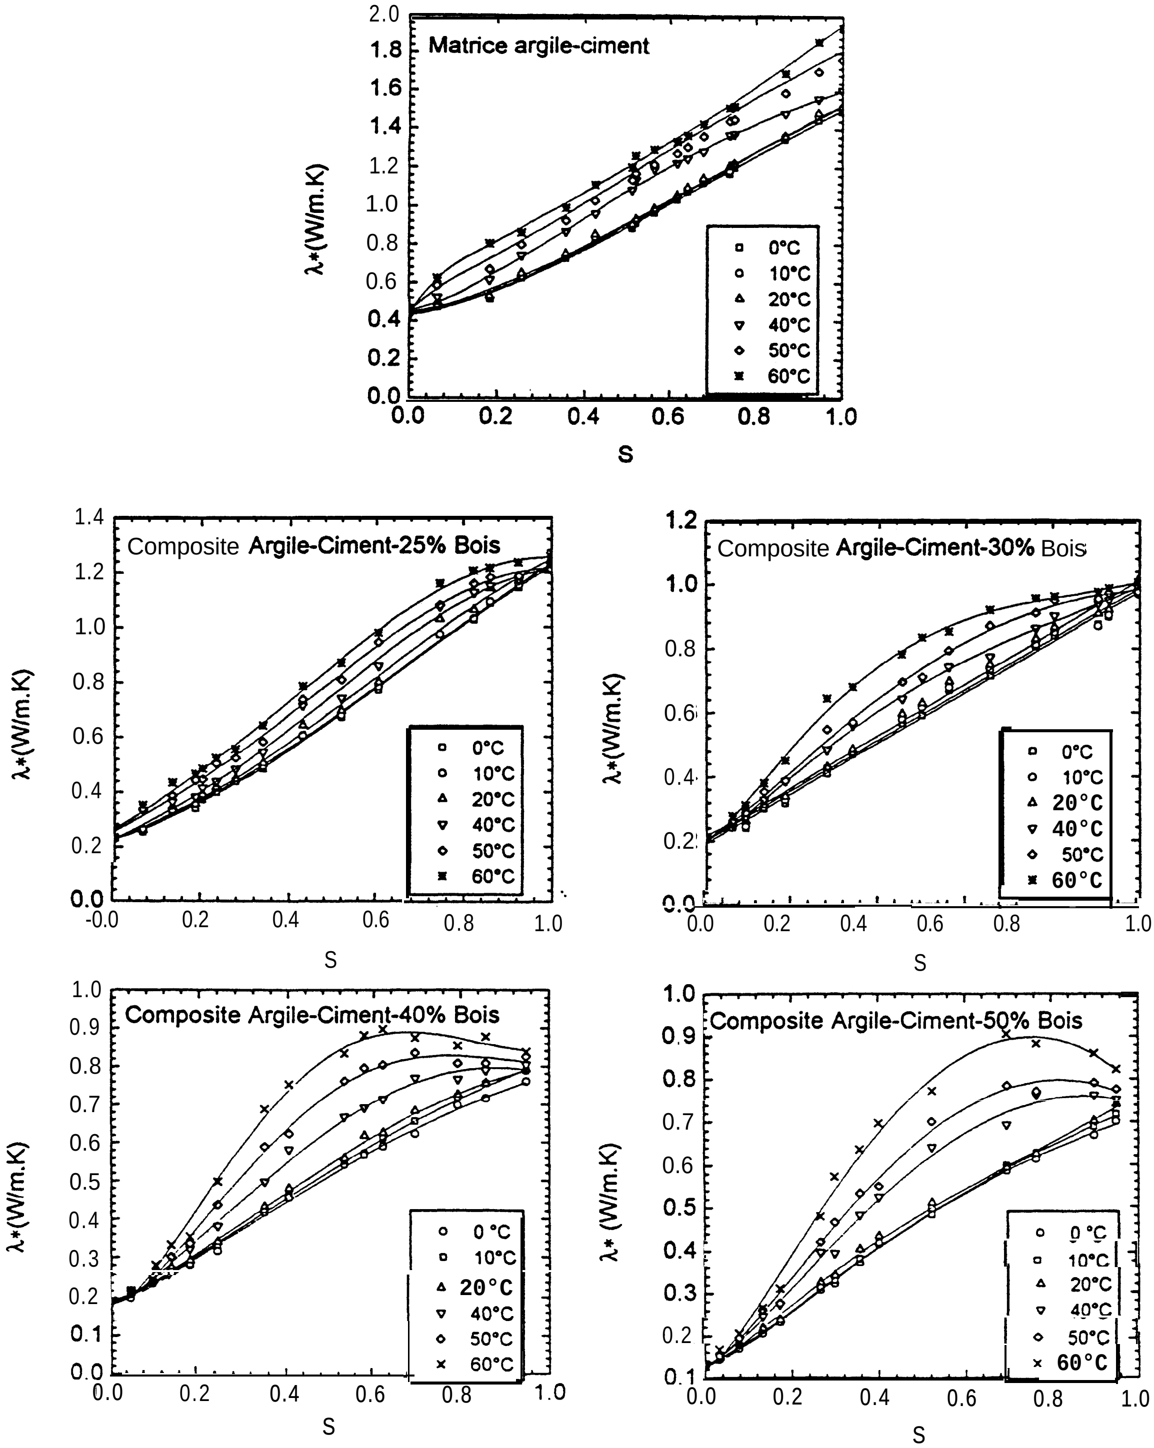
We have chosen the rate of saturation as a variable in order to determine the ratio of the volume content of water to the total porosity. The temperature range (0-60°C) covers the majority of thermal conditions in which the material is used. Thermal conductivity curves are given for different weight percentages of wood aggregate. It can be observed that for temperatures below 20°C, the values obtained are very close. The deviation is greater as the rate of saturation increases and as the wood aggregates content increases. The maximum value reached for the thermal conductivity, λ decreases as the wood content increases. For temperatures above 20°C, the experimental curves have a tendency to diverge. This effect is even more pronounced as the wood content rises. The phenomenon of evaporation-condensation is thus not encountered at temperatures lower than 20°C. For higher temperatures, the mechanism of transfer by conduction through the various phases combines with a heat transfer which is largely attributable to phase changes. Under the effect of a temperature gradient, water evaporates in warm zones of the porous middle, then distributes to cooler zones where, by condensation, it frees the latent heat of vaporization [17].

The maximum curvature observed on those curves having higher temperatures appears at a higher rate of saturation since the proportion of wood content in the composite rises (0.5 for 30% of wood, 0.7 for 50%). It therefore would seem that wood aggregates do participate in the phenomenon of condensation-evaporation within the range of temperatures greater than the ambient temperature. We have been able to observe by magnetic resonance imaging [12] that up to room temperature, in the case of saturation by capillarity, the water was essentially localized in the matrix, and that the increase in the amount of wood aggregate does not introduce any significant dispersion in the variation of the conductivity versus the rate of saturation. The vapor pressure decreases as the temperature drops ; it would thus appear that mass transfers with the aggregates are essentially made in the vapor phase. This finding is in keeping with previous work which shows that up to room temperature, in the presence of liquid water, wood aggregates act as a capillarity cut [12]. Finally, if the thermal conductivity is strongly influenced by the rate of saturation, this effect is negligible under normal working conditions (RH=65%, Temp.=20°C). Indeed, the isothermal sorption curves have shown that the mass content of water under these conditions remains in the order 3 % within the range of densities studied, i.e. for a wood aggregate content of 30 %, a rate of saturation of about 0.04.

4 Conclusion

This study has demonstrated influence of thermohydric conditions on the thermal performance of clay-based concretes lightened by wood aggregates. It has been shown

Figure1 : Effect of the temperature and water content on thermal conductivity



that under normal operating conditions, temperature and moisture do not affect the thermal conductivity of the designed materials.

This work lies within the general topic of study focused on : «High Environmental Quality Housing». It would be helpful to recall some of the other results obtained concerning this material [12]. A comparative study with other materials has shown that the thermal conductivity was very close to that of wood concrete with cementitious matrix, but that the mechanical performance was, in general, higher with an equal density despite a lower cement content (200kg / m^3 for a density of 0.8 versus 350 to 400kg / m^3). Similarly, the high value of the calorific capacity coupled with the weak thermal diffusivity make for a material that is valuable for its thermal storage characteristics despite its rather low density (1300J / kg.K and $2.3 \times 10^{-7} m^2 s^{-1}$ respectively for a density equal to 0.8). Moreover, up to room temperature, in contact with liquid water, the presence of wood aggregates tends to slow the progression of the imbibition capillary front as well as decrease the quantity of water being absorbed by the material. These results illustrate the possibility of designing technically-sound materials from clay wastes.

A lightening process of clay-cement pastes by recycled oxblood

M. Ruzicka, and A. t'Kint de Roodenbeke
GPE, Universite de Rennes1 , Institut Universitaire de Technologie, Rennes, France
R.M. Dheilly, M.Quéneudec
LBMT, Universite de Picardie Jules Verne, Institut Universitaire de Technologie, Amiens, France

Abstract:
Blood is a very powerful air-entraining agent and can be used to foam clay-cement paste. The foaming process depends on the components of concrete and can be optimized by certain additives.

This paper describes the influence of such factors on the volumic proportion of air entrained and the mechanical properties of hardened materials.
Keywords: Air entraining agent, insulating materials, lightweight concrete.

1. Introduction

Blood has been used in building materials from a long time as a means of improving the workability and impermeability. Powdered blood has first been added to concrete in the Soviet Union during the 1970's. In France, Venuat M. [1] has shown that a small quantity of powdered blood is sufficient to entrain 5 to 25% air, the air bubbles are small, well-distributed and separated from one another.

The studied material is a clay-cement mixture foamed by stabilized haemoglobin stem from the separation of animal blood. The clayey part is presently an unused by-product of the utilized clay-containing sand. Over the last few years, the authors' studies have been focused on transforming this by-product into low environmental-impact insulating materials [2 to 16].

The foaming process is very complex, it must be optimized with respect to the features of workability and mechanical performances of the hardened concrete criteria.

2 Materials and experimental conditions

The clay waste (A) used in this work is mainly composed of kaolinite [14]. The granulary analysis show that the part under 2 μm is 55 % and the higher diameter is 70 μm. However the real limon part (2 $\mu m < \phi < 70\ \mu m$) is certainly overestimated because the separation of the clay part by the operator is made by leaching with addition of flocking agent. The absolute density is 2.65 and Atterberg limits are $W_L = 48\ \%$, $W_P = 36\ \%$, $I_P = 12\ \%$.

The cement (C) is a CPA - CEM I 52.5 (EN 196-l).

The air entraining agent (H) is oxblood haemoglobin powdered and stabilized.

The mixing water (E) is drinking water taken from the public water supply network at a temperature of 20 ± 2 °C and a pH = 7.75 before adding NaOH and HCl into normal solution.

The components are first dry-mixed during 2 minutes in a mixer which is usally used for normalised mortar (EN 196-1).

Next, water is gradually added until obtaining a homogeneous mixture. The haemoglobin powder is then added and the mixing is extended at 120 t / min during 30 minutes.

The equipment used to measure the apparent viscosity is a Brookfield DV III rheometer .The volume of the enclosed air is determined with the help of an aerometer for mortar (EN 413 - 2).

3 Experimental results

3.1 The influence of the components on the rheological characteristics

3.1.1 Cement

With the quantity of clay being held constant, the influence of the cement is studied in the presence or absence of haemoglobin. Results have been plotted in Figurel. It can be observed that in the absence of haemoglobin, adding cement serves to increase the viscosity.

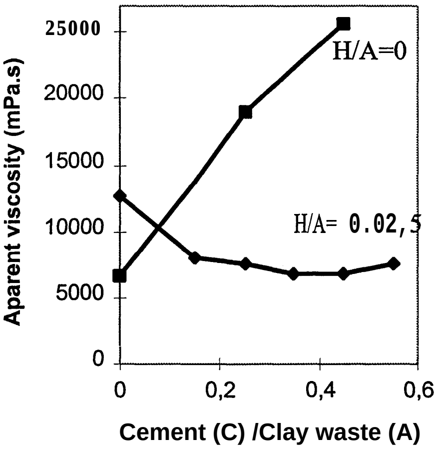

Figure 1 : Influence of the cement on the apparent viscosity (time of shearing : 0.5 min, ϖ = 50t/min, E/A = 0.75)

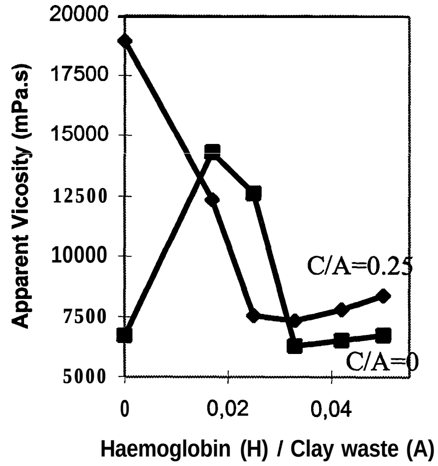

Figure 2 : Influence of the haemoglobin on the apparent viscosity (time of shearing : 0.5 min, ϖ = 50t/min, E/A = 0.75)

In the presence of haemoglobin in very weak proportions, a clearly greater viscosity, approximately double of that without cement can be noticed. The presence of haemoglobin would therefore have a rigidifying effect on its own on clay grouts. In contrast, as the quantity of cement increases, the viscosity of the foamed mix decreases; for a ratio C /A=0.35, the viscosity of a grout of clay obtained with a ratio E/A=0.75 can then be found. An analysis of the densities shows that the volume of foam tends to follow the same type of law.

The slight increase in viscosity beyond a C /A ratio = 0.45 can be explained by the consumption of a greater amount of water in connection with the hydration of the cement.

3.1.2 Haemoglobin

The influence, of the percentage of haemoglobin on the viscosity, has also been examined in the presence or absence of cement. Results are plotted in Figure 2, for C/A ratios of 0.25 and 0. In the presence of cement, the apparent viscosity, which is high for a mix without any haemoglobin, decreases as the ratio H/A increases. Beyond an H/A value of 0.033, a slight increase in viscosity can be observed, along with poorer flowability. In the absence of cement, no foam production takes place, with the mix of clay and water remaining relatively fluid while the addition of a small quantity of haemoglobin (H/A=0.017) increases suddenly the viscosity. It is difficult to conceive that increasing the fine part of 1.7% could nearly triple the viscosity of the mixture despite the very high specific surface of the added fraction. It could have therefore be assumed that a clay-haemoglobin interaction mechanism is responsible for this phenomenon, which does not appear in the presence of cement. As the quantity of haemoglobin continues to increase, a significant drop in the viscosity is to be noted, a long with a light foam production which can be attributed to the mechanical agitation of a very fluid mix.

3.1.3 Water

As the increase in the quantity of mixing water rises, the decrease in viscosity becomes more pronounced and the volume of foam rises. Nevertheless, the display is not necessarily improved.

3.2 Study of the air-entraining process

Several factors are able to modify the amount of entrained air: the proportion and nature of basic constituents, various chemical processes, temperature, characteristics of the mixing process, etc.

3.2.1 Influence of the pH of the mixing water

A comparative study was carried out on a pure clay paste (A + E), supplemented with either treated haemoglobin (A + E + H) or cement plus haemoglobin (A + E + C + H)

Figure 3 displays the evolution of the amount of enclosed air by adding H^+ and **OH'** ions

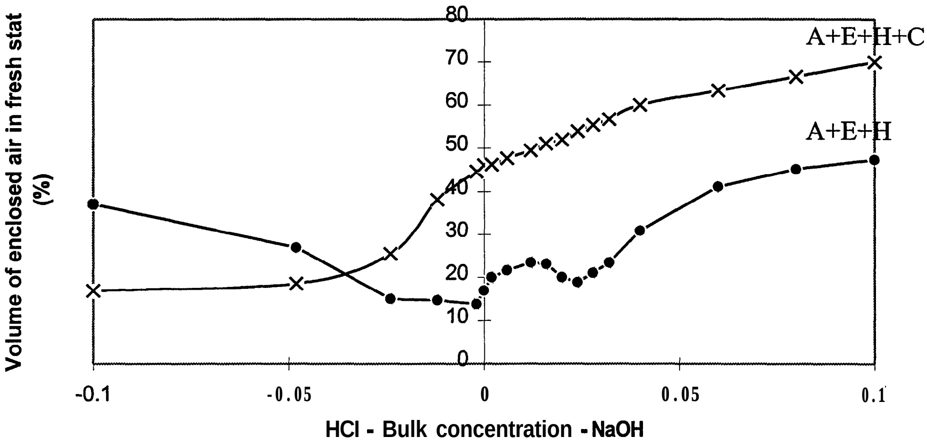

Figure 3 : Influence of the concentration of the mixing water, on the volume of the enclosed air

The entrained quantity of air is greater in the presence of cement for a water with no addition of either H^+ or OH- ions. In the presence of cement, the amount of enclosed air steadily increases from 45 to 70 % in the case of bulk concentrations of sodium hydroxide varying from 0 to 9 %. In contrast, this amount first decreases in a steady fashion when the acid concentration increases and then stabilises at 20 % as the acid concentration approaches 4 %. In the absence of cement, the inverse would apply during the addition of air, with the volume of entrained air increasing from 10 to 40 %. During the addition of sodium hydroxide, air entraining is also facilitated except when the concentration turns out to equal approximately 2 %. Measurements of the fresh mixture density [17]serve to corroborate these remarks, however, such measurements have not yet been interpreted.

Previous works [17] has shown that, in the absence of cement, the lightening and the moulding can be indiscriminately promoted by either H^+ or OH- ions. In contrast, in the presence of cement, if air entraining could be enhanced by introducing OH- ions, no improvement in fluidity would actually be experienced. The addition of H^+ ions is therefore entirely unfavourable.

3.2.2 Influence of the binder nature

The entraining of air seems to be closely linked to the presence of cement in the material. The question thereby raised whether or not the phenomenon is due to the composition of the cement wherein the medium's pH level is increased by the cement. Measures of the amount of entrained air in the absence of clay, have thus been performed for four binders: cement CPA, aluminous cement, hydraulic lime, and aerial lime. In all four cases, the pH is high. The amount of entrained air for these different binders are plotted in Figure 4.

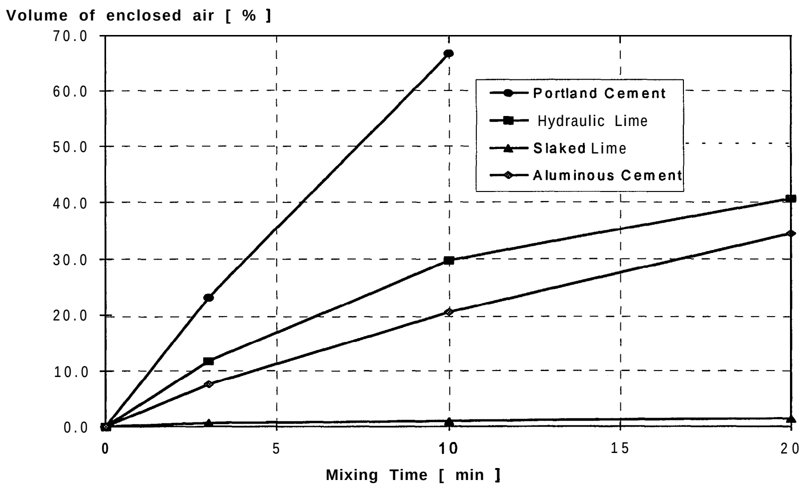

Figure 4 : Volume of enclosed air as a function of the binder and mixing time

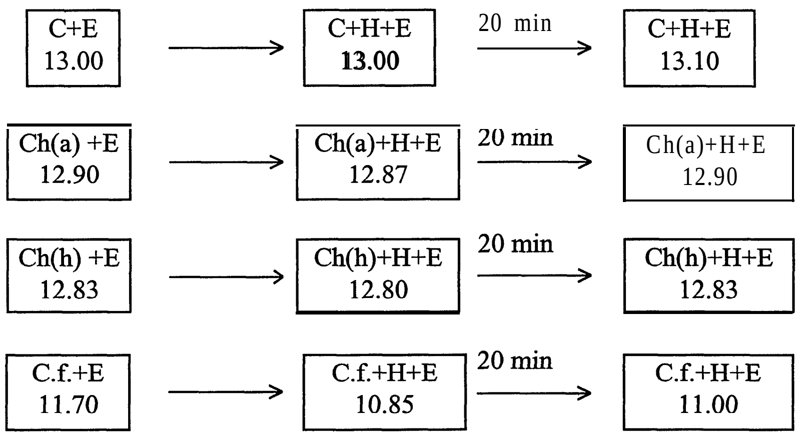
It can be observed that the pH level does not suffice in explaining the foam's production. Indeed, the grout derived from a base of aerial lime possesses a pH closer to that of cement grout (before and after mixing) (Figures); however, no air entraining effect is present. The nature of the binder would therefore seem therefore to play an important role. Nevertheless, this phenomenon as of this day has still not been completely clarified.

3.3 Influence of the mixing process

It has previously been shown that the presence of soda always favours the entraining of air. We will therefore use a treated water in order to study the mixing. Figure 6 displays the evolution in the apparent viscosity with respect to mixing time. This relationship is indeed not regular. Moreover, observation to the naked eye allows us to observe that at 0 min of mixing, the mix exhibits the form of a plastic paste. At between 5 and 10 min, a rather thick foam begins to appear, which is relatively mobile, while at between 20 and 30mn, the foam becomes very voluminous and immobile.

We have thus attempted to improve the workability. After mixing for a given period, the foamed material is left to rest for 15min. Mixing is then repeated for another 20 seconds. Observation to the naked eye reveals that the fluidity has been clearly improved, yet this is not visible on the viscosity curve (Figure 7).

The study of workability shows that as opposed to the foam obtained after the standard mixing, the « remixed foam » flows more easily. This improvement is probably due to a change in the foam's structure.



Ch(a) : Slaked lime, Ch(h) : hydraulic lime

Figure 5 : Influence of the nature of the binder on the pH, E=7.75 et H+E=7.83

3.4 Mechanical strength

Figure 8 shows the evolution of the compressive strength with respect to density. The lightening due to the presence of the soda served to improve the mechanical strength characteristics beyond those of the non lightened material.

4 Conclusion

The general purpose of this study was to recycle clayey fillers stemming from aggregate quarrying activities by producing low environmental-impact insulating materials. The lightening step was performed by a proteinic air-entraining agent, which was a reused industrial waste. From a study of the components' influence, it can be proven that the presence of cement is a major factor in the foaming process. The amount of entrained air can be modified by addition of H^+ or OH- ions. This would depend on the binder composition. A mixing process has been developed in order to improve workability and facilitate moulding. The mechanical performance obtained is satisfactory.

A RC filler slab with non-autoclaved cellular concrete blocks for sustainable Construction

M. P. Jaisingh, L. Jaisingh and B. Singh
Central Building Research Institute, Roorkee, India

Abstract
Flyash is a major industrial waste which pollutes the atmosphere. The thermal plants in India will generate about 100 million tonnes of flyash per year by the turn of the century. Acres of usable land are wasted for dumping of ash. Transportation poses handling problems; besides, the proposition is uneconomical. In this context, utilisation of this waste material in building construction will go a long way in solving its disposal problem. Towards this end, a technology has been developed at the Central Building Research Institute (CBRI), Roorkee, India, to construct reinforced floor/roof slab with non-autoclaved cellular concrete filler blocks cast with flyash, lime, cement and a foaming agent. Autoclaved cellular concrete blocks are being used in the building industry to some extent in India. But as they require autoclaving for the production, they are costly. Hence non-autoclaved units have been developed with a suitable proportion of the constituents. The blocks are of size 260 x 560 mm, tapering down to 250 x 550 mm and are 110 mm thick. The floor/roof slab is cast with cement concrete of grade Ml 5 with these blocks as fillers. Reinforcement bars are provided in two perpendicular directions in the space between the blocks. Room size filler slabs were tested for their structural and functional performance at CBRI. Deflection recovery tests, failure load tests and impact load tests were conducted. Functional properties like thermal performance index, sound absorption coefficient, leak proofness etc. were also studied. The paper describes the experimental studies and results.

Housing shortage is a common problem in most of the developing countries and there is a need for appropriate construction techniques which are economical and affordable. The requirement of housing in India by the turn of the centuary is expected to be 39 million units and even if 10 percent of the construction is done with this technique, it will result in utilisation of 10 million tonnes of flyash. Compared to conventional insitu RC slab, this technique is economical and will result in saving of cement and steel and is an ideal step towards generation of affordable housing, for developing countries.
Keywords: Construction, filler slab, flyash, non-autoclaved cellular concrete blocks.

1 Introduction

Flyash is a major industrial waste and large scale use of this material in building construction will go a long way in solving the disposal problem of this pollutant material. Hence filler slab technology for flooring/roofing has been developed at CBRI. In this technique, the slab is cast with non-autoclaved cellular concrete filler blocks, produced from flyash, lime, cement and a foaming agent. Utilisation of flyash in large quantities for the production of the blocks is an advantage and also the technique results in saving of cement and steel and cost of construction, compared to conventional reinforced concrete slab for floor and roof.

2 Construction technique

The floor/roof consists of a cast insitu RC filler slab with non-autoclaved cellular concrete filler blocks as shown in Fig. 1. The filler blocks are 110 mm thick and 260 x 560 mm at top tapering down to 250 x 550 mm at bottom. The slab is cast with cement concrete of grade M15. Spanning in two perpendicular directions, the slab can be designed as a grid with compression taken by the deck concrete at top and tension taken by the reinforcement at the bottom in the rib portion. The cellular concrete blocks act as non-structural fillers. The technique can be adopted for floor/roof in single and multistoreyed residential and other types of buildings. Conventional roof/floor finish could be laid above the filler slab. Ceiling plaster could be avoided in low cost constructions and also where better acoustic performance is called for. In other situations the ceiling may be plastered.

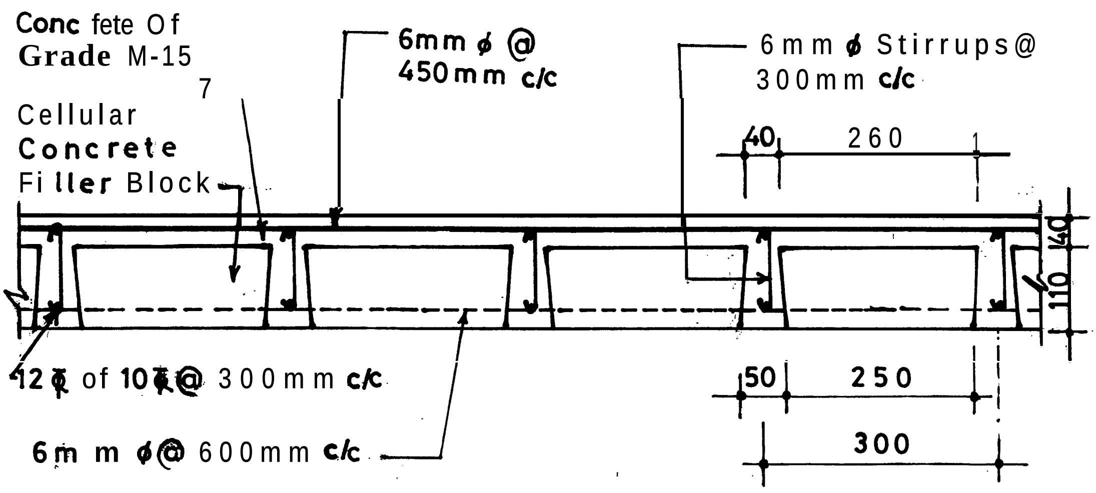

Fig. 1 RC filler slab (section)

3 Cellular concrete blocks

Autoclaved cellular concrete blocks are being used in the building industry in India to some extent. But as they require autoclaving for their production, they are costly. To make it economical, non-autoclaved cellular concrete blocks have been developed using flyash, cement, lime and a foaming agent. Several mix proportions were tried before arriving at a suitable mix from considerations of density and strength to withstand the stresses to which the blocks are subjected to, during construction. Quantities of materials required per cu.m of concrete for the selected mix are given below :

Cement	: 140 kg
Lime	: 35 kg
Flyash	: 528 kg
Foaming agent (Aluminium powder)	: 0.32 kg

Since flyash is available in fine particle state, it requires no further grinding. Cement [1, 2] lime [3] and flyash [4], as per the proportion mentioned above, are wet mixed in a high speed mixer to a homogeneous slurry. Aluminium powder is then added and mixed thoroughly. Hydrogen gas liberated by the aluminium powder, due to its reaction with lime,aerates the slurry. The slurry is then poured into steel moulds of size 560 x 260 mm tapering to 550 x 250 mm in plan and having a height of 110 mm. The slurry is filled only to three fourth the depth of the mould. Due to aeration, it rises upto the top or slightly above the top of the mould. Setting takes place in 10 to 12 hours in tropical climate. After setting, the part of the concrete above the mould is trimmed off and demoulding is done 24 hours after casting. The blocks are kept at casting platform for 2 days and after they have attained strength to withstand handling stresses, they are shifted to curing yard and cured under wet gunny bags for 14 days. The blocks are then allowed to air dry, for another 14 days.

4 Construction of floor/roof slab

The reinforcing bars for the bottom of the slab in two perpendicular directions are tied together and placed over the shuttering with concrete cover blocks tied to them. Cellular concrete blocks are then assembled over the shuttering in the space between reinforcement bars, leaving a gap of 40 mm between adjacent blocks in the two perpendicular directions. The blocks are then aligned properly and reinforcement cage for the flange portion is tied and placed over the cellular concrete blocks (Fig.2). Concrete cover blocks shall be tied to the reinforcement in the flange also to ensure required cover. The blocks are sprinkled with water repeatedly so that the surface is at a near saturation point. This is necessary to ensure that the blocks do not absorb excessive quantity of water from the fresh concrete. Concrete of grade M 15, made of coarse aggregate of maximum size 12 mm, is then laid in the space between the blocks and compacted using a needle vibrator. Immediately, the flange concrete above the filler blocks is laid and compacted using plate vibrator. The top surface is then finished properly. A camber of 1 in 250 may be provided to the shuttering in case of floor slab so that the ceiling of floor is level after removal of shuttering. In case of roof, a slope of 1 in 60 may be provided to the shuttering so that the top of the roof will have a slope of about 1 in 80 after the shuttering is removed. The concrete shall be cured for 14 days byponding water over it. The shuttering shall be removed after that. The ceiling may be plastered one month after removal of shuttering.

Fig. 2 RC filler slab under construction

5 Structural design

The filler slab may be analyzed as a two way spanning grid slab. The midspan section is designed as a T-beam with cast-in-situ concrete of flange taking compression and reinforcement at the bottom of the slab in the web portion taking tension. In case of continuous slab, the support section is designed as doubly reinforced rectangular beam with the width ofbeam equal to the thickness ofweb. To control deflection, the span/depth ratios have been considered as per the relevant Indian Standard Code of Practice. A 150 mm thick slab can span upto 3.6 m in case of simply supported and upto 4.5 m in case of continuous spans. In case of larger spans, a higher slab thickness is called for the control of deflection. In this case, filler blocks of thickness more than 110 mm may be used.

6 Structural/ Functional performance

6.1 Deflection recovery test

Deflection recovery test was carried out on the RC filler slab of clear span 3.6 m (Fig.3) considering residential floor load as per IS:456-1978[5]. The slab was subjected to full dead load and 1.25 times imposed load for a period of24 hours and the deflectionmeasured. The measured deflection was only 1 in 750 of the span. The imposed load was then removed and after 24 hours, the deflection recovery was more than 90 percent indicating that the slab passes the test.

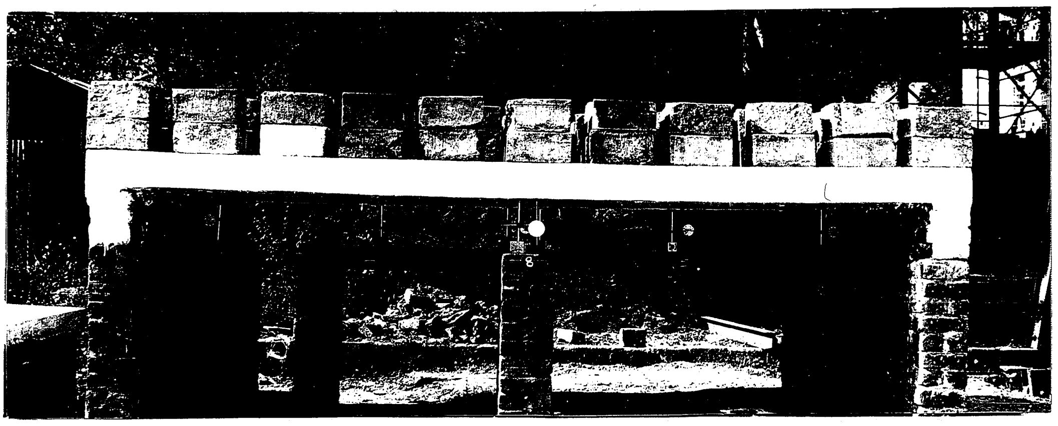

Fig. 3 Deflection recovery test

6.2 Failure load test

The slab was further subjected to failure load test. Deflections were measured and development of cracks noted at each stage of loading. The first crack was noticed at a total load of 6.7 kN/m2. The loading was stopped at a total load of 13.4 kN/m2 which is almost 1.5 times the design limit state load of 9 kN/m2. Further loading could not be done due to problems in stacking concrete blocks/sand bags over the layers already stacked. Pattern of cracks in the slab at penultimate stage of loading is shown in Fig.4.

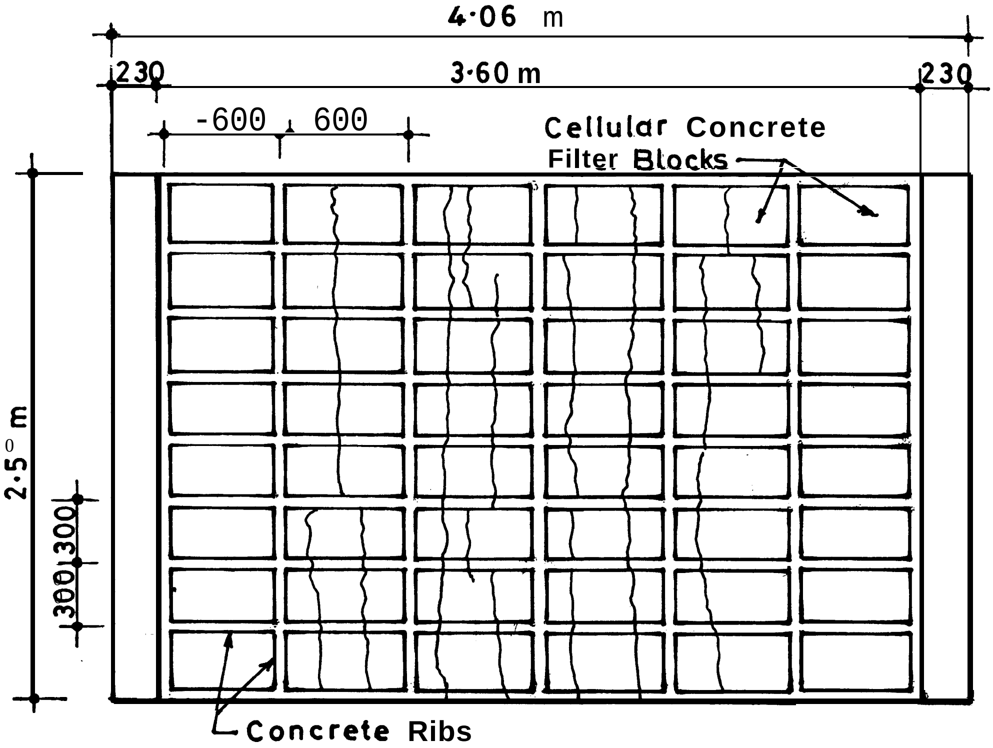

Fig. 4 Crack pattern in slab (ceiling)

As the test slab was constructed as a one way spanning member, cracks had occurred perpendicular to the span. **Major cracks had** occurred at the junction of filler blocks and cast in-situ ribs, specially in case of three ribs in the middle. Other cracks had occurred within the filler blocks and the cracks had passed through the ribs parallel to the span. The cracks were wider at bottom and tapering down towards top. No cracks were noticed in the flange portion

6.3 Impact load test

Though codes of practice **do not suggest any** procedure for testing slab against impact, some tests were carried out to check the impact resistance of the slab. A gunny bag filled with 40 kg of sand was dropped from a height of 1.5 m. No damage was observed. A 5 kg weight was dropped from a height of 1.2 m over an area of 700 mm2. Though indentation of about 2 mm was noticed at the top of the slab, where the weight struck it, no other damage was observed. The slab was also subjected to another type of impact test by pounding turmeric, one of the hardest materials used in Indian kitchens, in a "Hamam Dasta" (a heavy steel vessel), kept over the unfinished slab. No cracks or signs ofweakness had developed during or after the tests. Hence filler slab is safe against impact expected in residential and office buildings.

6.4 Thermal performance

The thermal performance [6] for the RC cellular concrete filler slab roof and the conventional RC slab roof with same roof treatment above are given below.

Specification of roof slab	**TPI**
1. 150 mm thick cellular concrete filler slab with 90 mm thick lime concrete	85
2. 100 mm thick RC slab with 90 mm thick lime concrete	134
3. 150 mm thick filler slab with 75 mm thick mud-phuska & 50 mm thick tiles	75
4. 100 mm thick RC slab with 75 mm thick mud-phuska & 50 mm thick brick tiles	110

It can be seen that with the same roof treatment, the filler slab is thermally superior to conventional RC slabs.

6.5 Sound absorption

The sound absorption properties of cellular concrete and dense concrete are 0.27 percent and 0.1 percent respectively. Thus, it can be concluded that, if the ceiling of the filler slab is kept unplastered, it is superior to conventional RC slab in sound absorption and it is suitable for class rooms, lecture halls, conference halls, auditorium etc.

6.6 Leak proofness

The slab without any treatment over it was tested for leakage by ponding water over it continuously for one week. No dampness was seen below. This indicates that if the construction is done properly, there is no chance of leakage in filler slab. However, as an ample measure of caution, it is advisable to have a waterprooftreatment above the roof slab.

7 Economy

A comparison of the consumption of materials and cost of construction of the filler slab with conventional RC slab is given in Table 1. In case A, the comparison has been made for a 3.6 m x 3.6 m two way spanning continuous slab and in case B for a one way spanning simply supported slab of span 3.6 m.

Slab	Item	Cement (kg/n?)	Steel (kg/m^2)	cost ($Rs./m^2$)
A. Two way spanning continuous slab	a) Conventional slab 120 mm thick	38.4	7.1	415
	b) Filler slab 150 mm thick	32.0	4.0	346
	c) Savings (percentage)	16	44	17
B. One way spanning simply supported slab	a) Conventional slab 120 mm thick	48.0	6.5	450
	b) Filler slab 150 mm thick	32.0	3.5	338
	c) Savings (percentage)	33	46	25

Table 1. Comparison of cost and consumption of materials

It can be seen that adoption of filler slab in place of conventional RC slab will result in a saving of about 17 percent in cost. In addition, there is a saving of 16 to 33 percent in cement and about 45 percent in steel.

8 Conclusion

This technique of construction can be easily adopted for the construction of all types of buildings, once the cellular concrete blocks are available in the market. This is possible if entrepreneurs set up production units near Thermal Power Plants, where they are given flyash free of cost and space and facilities like power and water supplied at no-profit, no-loss basis. The large scale production of the blocks will help in the problem of disposal of flyash to a great extent. In addition, it will result in saving of cement and steel and will lead to affordable housing

Politecnico di Milano - Milano (ITALY)

Abstract
A one-dimensional numerical model has been developed in order to represent rain absorption by porous building surfaces. The analysis has been performed on clay brick in two different boundary conditions: the former with a water-proof boundary condition in correspondence of the inner side of the wall, the latter with an indoor U.R. equal to 50%. A constant flux boundary condition has been applied to the external surface. The flow system is non-hysteretic and isothermal, and osmotic effects associated with soluble salts are absent.
The use of this method has permitted the evaluation of the time at which saturation occurs in correspondence at the outer surface of the wall, vs. rainfall rate.
The adopted mathematical model is based on unsaturated flow theory in porous media and on the concept of the representative elementary volume (REV). The governing equations are the mass balance equation in a porous medium and the Darcy's law. The unknown variable is the moisture content in the porous medium that is described by the difisivity parameter.
The solution is obtained by means of a finite element spatial discretization (Galerkin formulation) and the time derivative is reproduced by finite differences; the non-linearities of the problem are worked out with a modified Picard scheme. Cholesky's method is utilised for the solution of the set of system equations. The numerical code is in Fortran language. The reliability of the code has been tested comparing the numerical results with Philip's analytical solution where the difisivity is constant.
Keywords: moisture migration, numerical modelling, saturation time, diffisivity parameter, brick, rainfall

1 Introduction

The investigation of moisture migration in building materials is extremely important for the characterisation of behaviour in relation with durability, waterproofing and degradation of appearance.

At the moment, moisture is one of the primary causes for the damage observed on the envelope of buildings, increasing the importance of the development of research with the aim of defining regulations concerning the design of building walls in respect of moisture.

The scientific explanation for the many ways it may occurs has frequently been difficult due to the complexity of the problem. The use of a flexible and robust numerical model, able to simulate particular cases of interest, is fundamental to analyse and to predict the performance of building materials under any kind of external input. Finite element method is particularly suited to handling complicated geometry and boundary conditions.

2 Analysis of moisture migration

The fundamental law that describes the flow of water through an unsaturated porous material is Darcy's law which in horizontal direction may be written

$$\mathbf{q} = -K_x \frac{\partial h}{\partial x} \tag{1}$$

where: h is the hydraulic tension head [L], $\mathbf{q}$ is the volumetric Darcy velocity [L] [T^{-1}], k_x is the hydraulic conductivity of porous medium in horizontal direction, dependent on moisture content [L] [T^{-1}].

A building wall made of solid clay common brick is considered. The infiltration process is supposed isothermal and non-hysteretic; the osmotic effects due to soluble salts are negligible.

Introducing the moisture content θ as main variable, Darcy's law becomes:

$$\mathbf{q} = -K_x(h)\frac{\partial h}{\partial x} = -K_x(h)\frac{dh}{d\theta}\frac{\partial \theta}{\partial x} = -D_x(\theta)\frac{\partial \theta}{\partial x} \tag{2}$$

where

$$D_x(\theta) = K_x(h)\frac{dh}{d\theta} \tag{3}$$

is the diffusivity of the porous medium.

Assembling the Darcy's law and the mass balance expression, the governing equation of moisture migration in a porous medium takes this form:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x}\left(D_x(\theta)\frac{\partial \theta}{\partial x}\right) \tag{4}$$

The knowledge of the hydraulic diffusivity D as a function of moisture content θ defines completely the flow.

3 Numerical modelling

The finite element method has been applied to describe the water movement in a finite solution domain Ω of length L.
Linear functions are used to determine the value of moisture content in elements. As weighting functions the same linear functions are introduced (Galerkin formulation).
The hydraulic diffusivity is supposed constant in each element and equal to the arithmetic mean between the values at the corresponding nodes.
Assembling the terms related to each element (e), the following system of non-linear partial differential equations is derived:

$$[\mathbf{C}]\left\{\frac{\partial \theta}{\partial t}\right\}+[\mathbf{D}(\theta)]\{\theta\}=\{\mathbf{F}\} \tag{5}$$

where

$$C_{ij}=\int_{\Omega^{(e)}}\left(N_i N_j\right)d\Omega^{(e)} \tag{6}$$

$$D_{ij}=\int_{\Omega^{(e)}} D(\theta)\left(\frac{\partial N_i}{\partial x}\frac{\partial N_j}{\partial x}\right)d\Omega^{(e)} \tag{7}$$

and F_i is a source or sink term for nodes located at the boundary of the domain.
The system of equations (5) is then solved applying the finite difference method:

$$\left([\mathbf{C}]+\alpha\Delta t[\mathbf{D}(\theta)]\big|_{t+\Delta t}\right)\{\theta\}_{t+\Delta t}=\left([\mathbf{C}]-(1-\alpha)\Delta t[\mathbf{D}(\theta)]\big|_t\right)\{\theta\}_t+$$
$$+\Delta t\left(1-\alpha\right)\{\mathbf{F}\}_t+\alpha\,\{\mathbf{F}\}_{t+\Delta t} \tag{8}$$

where α can vary between 0 and 1. In the present study the implicit method is adopted ($\alpha = 1$) to guarantee stability in the solution and absence of numerical oscillations.
To linearized the system of equations (8) the modified Picard iterative scheme is performed. The solution is the obtained using the direct Cholesky method.
The reliability of the code developed has been tested comparing the analytical solution drawn by J. R. Philips [1] in a semi-infinite domain with $D=D^*$ = constant, independent from the moisture content. With these simplifications the equation (4) becomes:

$$\frac{\partial \theta}{\partial t}=D^*\frac{\partial^2 \theta}{\partial x^2} \tag{9}$$

subject to
$\theta(x, t=0)=0$,
$\theta(x=0,t)=\theta_1$,
$\theta(x\to\infty,t)=\theta_0$,
where θ_1 is the moisture content at saturation and θ_0 is the residual moisture content.
The analytical solution is:

$$\theta = erfc\,\frac{x}{2}\left(D^{*}t\right)^{-1/2} \qquad (10)$$

In Fig. 1 the moisture content is represented at t = 1, 2, 3 minutes from the beginning of the simulation. It's evident a complete correspondence between numerical and analytical values.

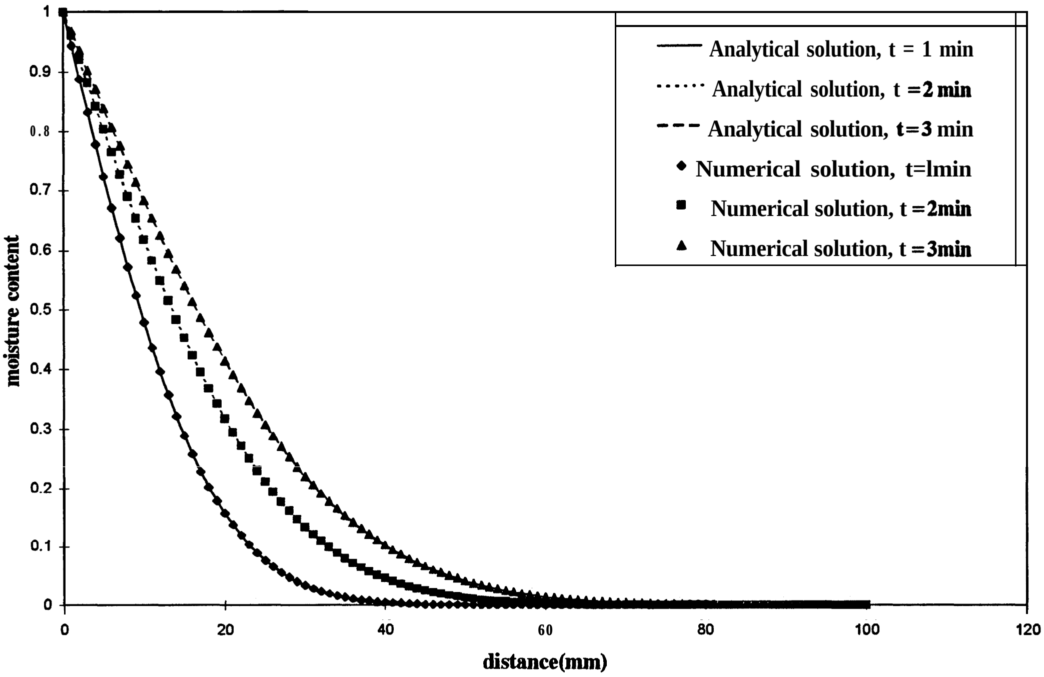

Fig. 1 Comparison between the analytical relation as proposed by Philip [1] and the numerical solution obtained for t = 1, 2, 3 minutes.

4 Analysis of absorption

The migration of water into the building fabric from a surface exposed to rainfall is simulated in two different situations: the former with a water-proof boundary condition in correspondence of the inner side of the wall, the latter with a water content at the inner side equal to the irreducible value, that reproduces a constant indoor U.R. equal to 50%, in well aerated surroundings [2].

q_0 is the rate at which rain is received per unit area of surface: it is calculated adopting the Lacy's formula [3]:

$$q_0 = 0.222\, W R^{0.88} \qquad (11)$$

where W is the wind speed and R is the rainfall rate.

A scheme of the situation analysed is presented in Fig.2.

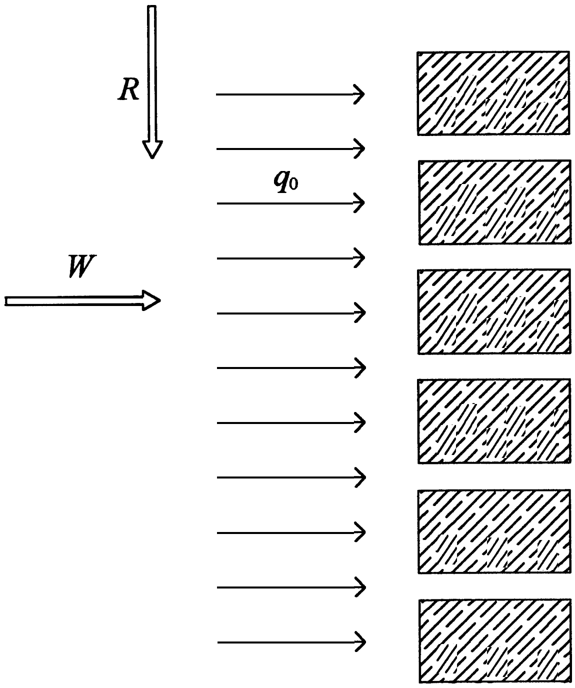

Fig. 2 Absorption mechanism of rain at the outside wall.

The hydraulic diffisivity is calculated from the expression:

$$D(\theta) = \frac{S^2}{\theta_1 - \theta_0} 0.00224 \exp(7.5\theta_r) \quad (12)$$

which has been tested experimentally for a number of building materials [4].
S is the hydraulic sorptivity of the porous medium [L] [$T^{-1/2}$] and $\theta_r = (\theta - \theta_0)/(\theta_1 - \theta_0)$ is the normalised water content

4.1 Case 1 − water-proof inner surface

Moisture migration is analysed in a clay common brick having these characteristics:
$\theta_0 = 0.002$ cm^3/cm^3,
$\theta_1 = 0.262$ cm^3/cm^3,
$S = 1$ mm/min$^{1/2}$,
$L = 12$ cm.
The initial and boundary conditions are:

$\theta(x, t = 0) = \theta_0$ for $0 \le x \le L$;

$D(\theta)\frac{\partial \theta}{\partial x}(x=0, t) = -q_0$ for $t \ge 0$;

$\left.\frac{\mathrm{d}e}{\partial x}\right|_{x=L,t} = 0$ for $t \ge 0$.

The water content profiles have been obtained for increasing values of rain received per unit area of surface: q_0 = 25, 50, 75 mm/hr. The results are represented in Fig. 3, 4 and 5.

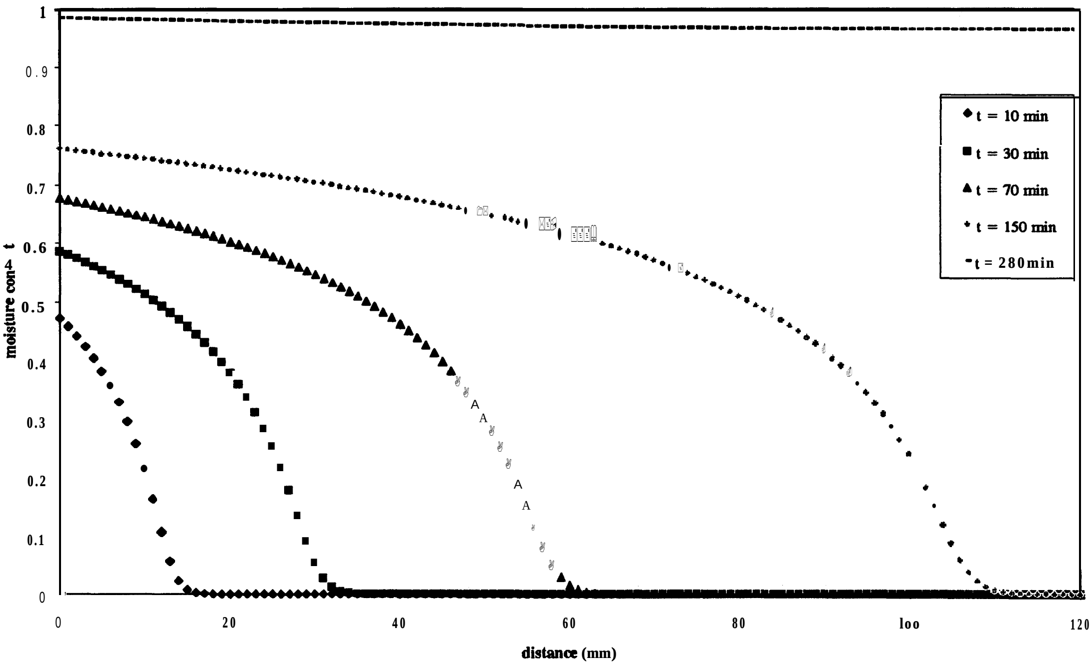

Fig. 3 Moisture content profiles (q_0 = 25 mm/hr)

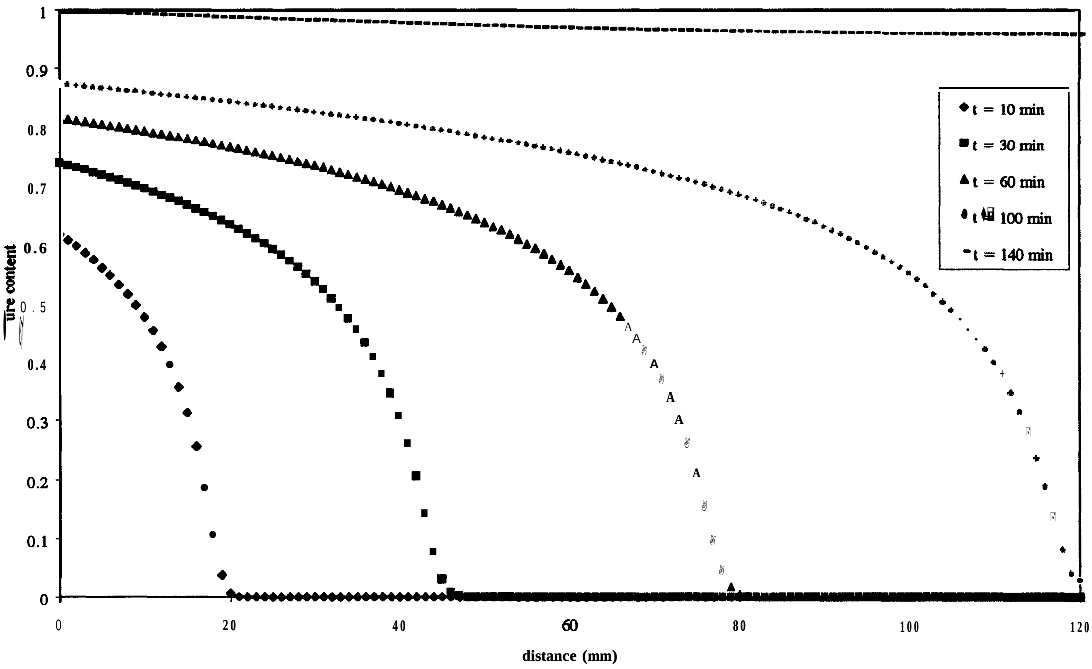

Fig. 4 Moisture content profiles (q_0 = 50 mm/hr)

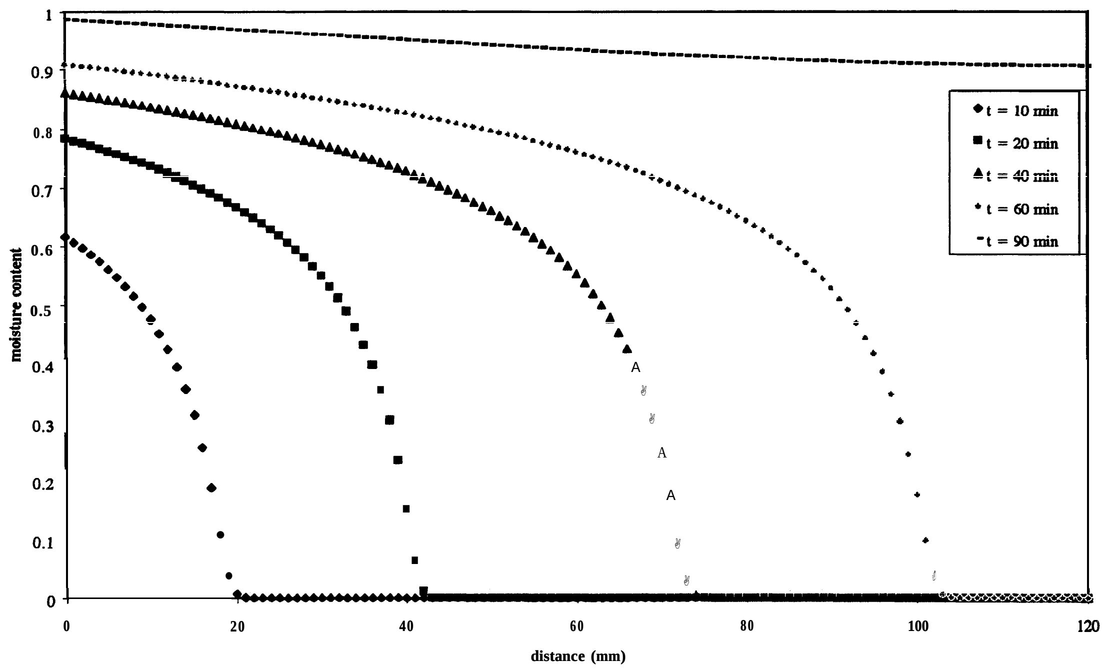

Fig. 5 Moisture content profiles (q_0 = 75 mm/hr)

4.2 Case 2 - irreducible moisture content at the inner surface

This scheme reproduces a continuous circulation of air in contact with the inner surface of the wall, so as to maintain a U.R. equal to 50%. This constant percentage of relative humidity guarantees an irreducible moisture content at the surface of the wall [2]. The characteristics of the building material are the same as in case 1.

The initial and boundary conditions are:

$\theta(x, t=0) = \theta_0$ for $0 \le x \le L$;

$D(\theta)\dfrac{\partial\theta}{\partial x}(x=0, t) = -q_0$ for $t \ge 0$;

$\theta(x = L, t) = \theta_0$ for $t \ge 0$.

The moisture migration is represented in Fig. 6, 7, 8 for q_0 = 25, 50, 75 mm/hr respectively.

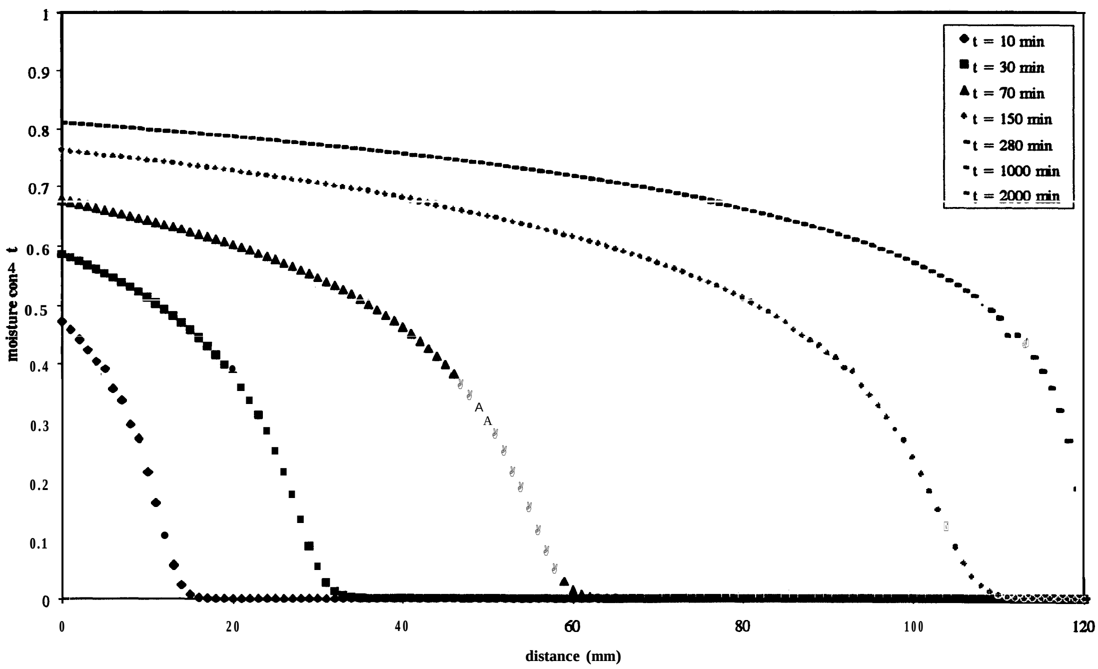

Fig. 6 Moisture content profiles (q_0 = 25 mm/hr)

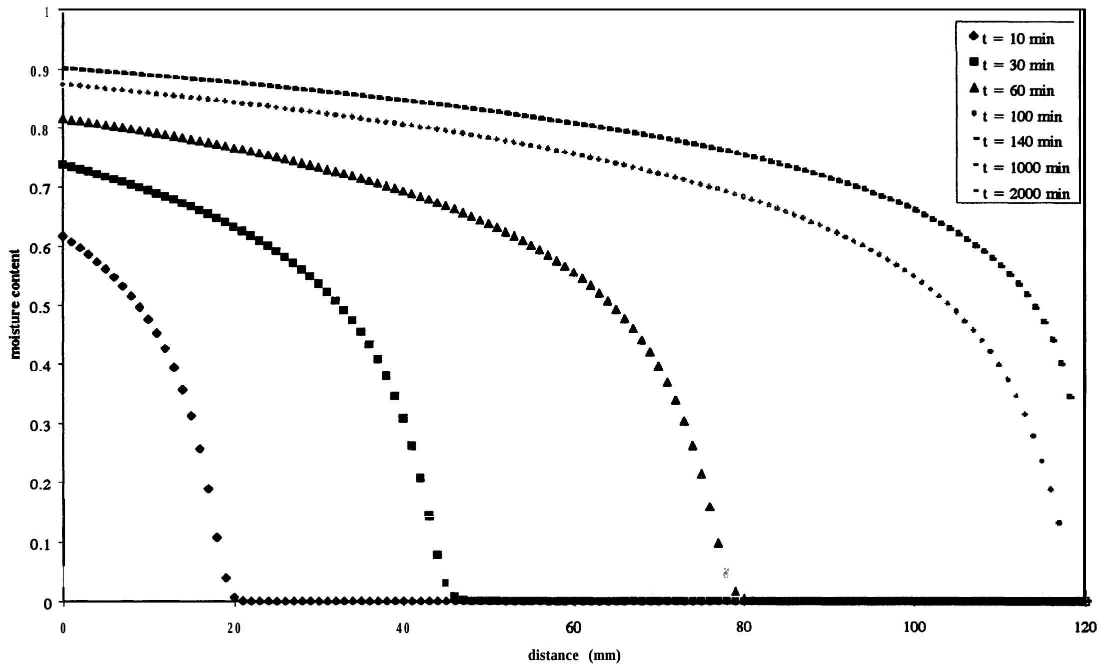

Fig. 7 Moisture content profiles (q_0 = 50 mm/hr)

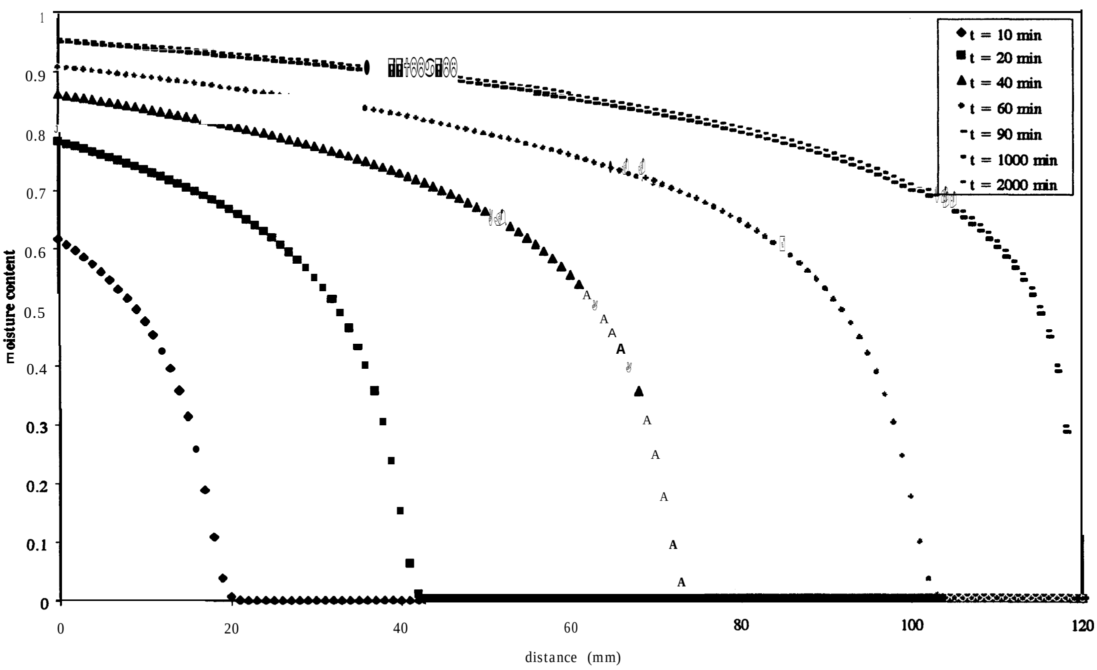

Fig. 8 Moisture content profiles (q_0 = 75 mm/hr)

5 Conclusions

The analysis of moisture migration inside a common clay brick for two different boundary conditions at the inner side of a wall has shown the different behaviour of this material for what concern saturation time of outer surface.

In case of a water-proof surface a linear relationship between incoming moisture flux and time of saturation has been observed (Fig. 9).

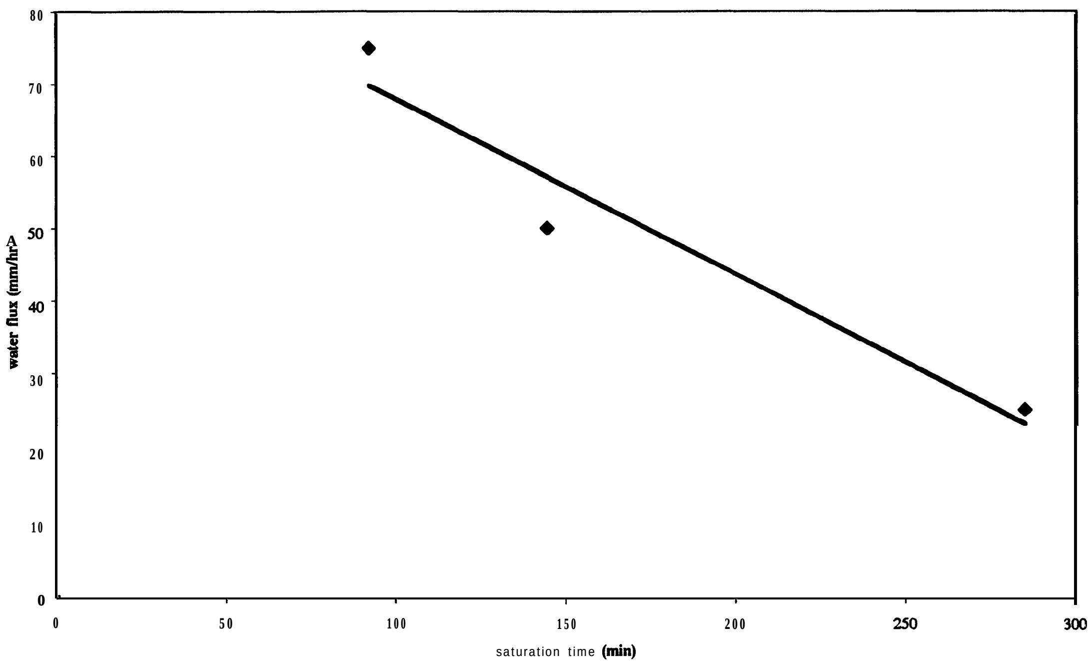

Fig.9 Saturation time of outer surface as linear function of moisture flux received in case 1 (water-proof inner surface)

For a constant indoor U.R. that ensures a constant irreducible moisture content at the inner surface the saturation of the outer side is never been achieved.
At this point it's reasonable to come to the conclusion that not only the choice of an appropriate building material could effect the durability and degradation of appearance: the conditions of surroundings inside and outside the construction should be analysed in their completeness to test the different behaviour of building fabrics. This aim, as shown, can be achieved in an appropriate way performing some numerical simulations under different solicitations.

Data Collection and Handling for Environmental Assessment of Building Materials by Architects and Specifiers

S Edwards and S Hobbs
Centre for Sustainable Construction, BRE, Garston, Watford, UK

Abstract
BRE has spent two years working on a UK Department of Environment, Transport and Regions funded project to develop a methodology for collecting data on building materials and components which involves twenty-five industry partners. The project is due to be completed in early 1999.

This paper describes how BRE has dealt so far with the challenges presented by collecting data from this diverse industry, including the issues arising from non-specific and over-specific information sets. The issue of industry sponsored LCA data generated using specifically devised methodology is also raised and it is suggested that such data should be scrutinised carefully to ascertain its suitability for wider applications.

Some of the rules and guidelines which will be applied in the process of handling the data to present it to architects and specifiers are described, with particular reference to the allocation for recycled material and embodied energy.

The convention chosen by BRE is that all scrap - both new and old - is considered to be “free” of resource use, energy or pollution costs, except for that which is incurred in transport to its point of use and in its transformation in the second production process. As data are collected and analysed, the robustness of this convention will be tested.

The preferred definition of embodied energy currently held by BRE is that it should be expressed in terms of the primary energy content of all the materials which are used in the process as fuels, together with the energy content of those feedstocks which are fossil hydrocarbons and are currently extracted as economic fuels.

Key **words:** Environmental Assessment; LCA, materials; specifiers

1 Introduction

In January **1996,** BRE began a three year collaborative project, Environmental Profiles of Construction Materials, Components and Buildings, funded by the UK Department of Environment, Transport and Regions. The project aim is to devise a UK methodology for the collection and presentation of data about building materials and components, to ensure that architects, specifiers and their clients can have access to reliable, up-to-date and comprehensive information. This project will result in a UK National Database of Building Materials and Components. When dealing with building materials however, it is important to realise the limitations of Life Cycle Assessment as developed by the International Standards Organisation [la] which is normally applied to single products. There is a need for an adapted life cycle assessment process suitable for comparing many different materials with varied lives and applications, coming from a variety of sources and processes.

BRE's partners in this project are twenty-five trade associations who are involved in providing the data from their member companies. A standard questionnaire has been produced by BRE and a brisk timetable for collection drawn up. The response to the call for data by different organisations has been very varied and has raised a number of issues. In addition to the problems during data collection, there is the challenge of deciding the most equitable way to treat the data once it has been obtained. This paper discusses the ways in which BRE and its project partners have tackled the data collection process and some of the developments in our methodology.

Any data collection activity must recognise the commercial realities of industry and the considerable investment of time and commitment involved. Industries are understandably cautious about providing life cycle inventory data for a number of reasons. Their main concern is the unknown impact of the analysis on their commercial position resulting from:

- Uncertainty about their relative performance
- Fear of poor performance because they use inputs from less efficient industries.

This is something which must be addressed by increasing industry involvement, for example through personal letters, news sheets and by meeting with those who are to be involved directly, in order to allay their fears. However, it should be recognised that many materials producers still consider publicising environmental performance to be a new and uncomfortable idea, so the dialogue achieved through data collection is a valuable contribution to the promotion of environmental improvements in the UK construction materials industry.

2 The LCI data collection process

The different histories, structures and concerns of the trade associations working with BRE have led to them providing data to the Profiles project in a number of different ways. Some of these are outlined below. These differences require us to make judgements and decisions about the best way forward to meet the aims of the project and our experience so far is summarised and discussed in this section.

2.1 Provision of generic data

Over the course of the project, the trade association for a particular product has been willing to provide data but the industry was concerned about its potential use. Their response to this has been to convene a special working party to consider how the range of products they create for construction should be represented in the project.

The working party decided to provide data about their industry's "typical product", using unattributable data and products. They came to this decision for two reasons. Firstly, because the industry infrastructure is very varied and consists of modern plants, as well as plants which are far less efficient but produce much sought-after products. Secondly, because the process is geographically diverse, due to the nature of the raw materials they use, they felt that the variation between products across the country could provide misleading results.

Their working party has begun by making an independent choice of the typical process and typical product for which they will provide data. BRE has requested that they make the process they are undertaking as transparent as possible and is seeking to ensure that the project receives data that can be accepted with confidence but which the industry does not feel is an infringement of their confidentiality.

Where data collection processes are not transparent, it is not possible for researchers to verify data received for a project. In such circumstances, the only recourse is to take this "typical" data and then apply knowledge from existing data to assign relative values to their different products. This is not satisfactory, but does provide a route for updating existing data and thus improving upon the *status quo.*

2.2 Provision of 'representative' industry data

An example from the opposite end of the spectrum has been the response of another industry which has provided data on the manufacture of products from just two plants, belonging to the same company. Two plants represents quite an achievement for the trade association, who at first doubted the possibility of collecting new data at all. They have chosen two highly representative factories and now believe that their data would not be improved by collecting more widely. This data is of a good quality due to its highly transparent nature, the ease with which it may be checked and the age of the data. The extent to which it is representative for the UK will be checked against published sources as well as by peer review by other industry sectors.

Some data on overseas production of materials is also highly selective, owing to the scarcity of data on the subject, and there is a danger that the efficiency in the country of origin is significantly more or less than average. The most reasonable solution is to ask industry experts how much they consider these figures to differ from the norm.

This is similar to the situation for most metal ore extraction which also takes place overseas. Studies available are ***ad-hoc*** and incomplete but are all that researchers have to rely upon. The primary and secondary processing industries in developed countries usually exercise no control over the processes and hence data from distant mines, and so their studies of their materials typically focus on processes within their own factories. Like other LCA researchers, BRE will use available figures with appropriate indications of quality.

2.3 Inclusion of industry sponsored LCA results

The members of the construction materials industry differ greatly, in terms of resources and history, in their ability to provide environmental information. Some industry sectors are much further advanced in their appreciation of LCA than others and are aware of potential advantages that LCA can bring to their sector. This is good news for the acceptance and development of the methods behind LCA. Some partners in the BRE project are representatives of industries engaged in large international LCA studies and the results of these will be their contribution to the project. The results are end figures and could potentially provide a welcome short cut for smaller national studies.

These international studies each have their own methodology, which is a potential problem for the present project, designed to create a common methodology for the construction materials industry. It is highly desirable that we use data for comparative studies which have been derived using the same allocation rules, boundary settings and conversion factors for at least the most significant aspects of the life cycle, i.e. those that make the biggest contribution to the impact of a product. Ideally the project team will have access to the raw data from these international studies in order to apply their own rules and thus convert them to comparable values.

Where industry specific rules have been applied, the value of the resulting data are difficult to interpret when those rules do not conform to those of a project. However, if there is no alternative then such data can be used, but the source of the data and its differences must also be made clear in the associated literature.

2.4 Excluding poor performers

Some industries are very small and there are very few manufacturers of a product. This provides a special challenge to LCA studies, where the confidentiality of the contributors cannot be protected by generating average figures in the usual manner. An example has arisen where two-thirds of a small industry belong to the trade association. These manufacturers are happy to contribute data which will be provided to us as one figure that they have agreed on - they prefer to make a common stand rather than compete with each other. The other third of the industry, however, uses a far less efficient process than the others and its inclusion would adversely affect the data from the other two-thirds. Consequently, the trade association have not sent the questionnaire further than their members. This does not help the purchaser of this product, however, whose goods “off the shelf’ could come from any manufacturer.

Researchers have a difficult task to provide meaningful data for architects without penalising good performers. This problem clearly highlights the need to have the next stage of environmental profiling available for manufacturers to exploit; i.e. individual product declaration, something which BRE is working on.

2.5 Data collection in context

From the experience of other data collection exercises, it has clearly been a considerable achievement to get so many industry representatives meeting together and providing data for a common purpose. The data, in all its varied forms, will make an extremely valuable contribution to existing information sets. However, no-one should underestimate the difficulties of using these data as inputs to LCA. This project, and others like it, are still having to discover new ways to cope with the uncertainty and variability present in data provided within the limits of commercial realities. As our knowledge increases, many of these obstacles should disappear as we become able to focus with increasing precision upon those areas which will allow designers and clients to make a difference to the environmental impact of the construction and refurbishments of buildings

3 Rules and guidelines

To analyse and present the inventory data obtained through data collection it is necessary to establish rules and guidelines. The following paragraphs explain how BRE has developed aspects of these procedures to accommodate the needs of material producers whilst maintaining an equitable system for all products.

3.1 Allocation to co-products

The IS0 DIS 1997 [la] recommends that inputs or outputs of a system should be partitioned between its different products in a way which reflects the underlying physical relationships between them. However, if this is not possible, allocation between co-products can be in proportion to their economic value. It is unlikely that a single allocation procedure can be used for all co-products in an LCA. Most require a mix, each one clearly justified, possibly with the inclusion of sensitivity analysis to aid choice between options. For this project, the preferred option is to use physical relationships but, where the level of detailed data collection is inadequate to do this, allocation will be in proportion to the three year average selling price at the factory gate of each co-product.

3.2 Recycling

Recycling is an important issue for building materials. It must be clear when materials move within a process as scrap and when they move from one to another as by-products or waste. There are three categories of recycled material which must be considered:

1. Produced and recycled within an industrial process
   So-called "home scrap" is a material flow which is internalised within the inputs and outputs of the process boundary and so is ignored in the inventory. However, it results in an improved conversion efficiency and reduced waste output.
2. Material from one industry which becomes the raw material for another
   This is sometimes called "new scrap" because it generally arises soon after the initial material was produced. An example is the material produced after the pressing of car bodies from sheet steel.
3. Post-consumer waste that is recycled and becomes a raw material. This "old scrap" is that which arises at the end of a product life.

The convention chosen by BRE is that all scrap - both new and old - is considered to be "free" of resource use, energy or pollution costs, except for that which is incurred in transport to its point of use and in its transformation in the second production process. However, even scrap materials which are traded and have a value will have zero burdens and this is an exception to the convention described above, that by-products could be allocated interventions in relation to their price. As data are collected and analysed, the robustness of this convention will be tested and reference will be made to the detailed examples given the IS0 DIS [lb].

When a material has been processed from both virgin and recycled sources, its environmental interventions will be calculated using the current average proportions of the two for the use of that material in construction and the interventions will be only those of the virgin material.

3.3 Imports

The inputs and outputs attributed to imports of raw materials, feedstocks and products will, wherever possible, be based upon analyses appropriate to the country of origin and will include the energy of transportation. Where data for the country of origin are not available, the input and output data will be based upon the closest domestically produced product with an addition made for the transportation from the country of origin. The exception to this is for imported refined fuels and electricity; these are attributed the same environmental interventions as those generated from primary sources for use within the UK.

4 Classification of inputs and outputs

The preparation of the inventory in LCA produces a long list of values for a wide variety of substances - raw materials, fuels used, emissions to air, water and land. The next stage in LCA is categorisation in preparation for impact assessment. It is not intended to carry out impact assessment in this project; the aim is to produce an environmental profile of the results of the inventory. However, it is possible that some of the data will be grouped into categories to enable single values to be assigned to particular effects. Embodied energy can be considered to be an input category of the life cycle of a material, while embodied carbon dioxide is an output category.

4.1 Embodied energy and embodied carbon dioxide

There is no definition for embodied energy in the IS0 Standard or DIS. The generally accepted definition is that produced by International Federation of Institutes of Advanced Studies (IFIAS) at a summer school on energy analysis in 1974: "the total primary energy that has to be sequestered from a stock within the earth in order to produce a product or service" [2].

The energy used in the extraction and processing of a material or product used in construction is sometimes defined *as* its *initial* embodied energy. This distinguishes it from the energy used at other stages in the material life cycle, for example in repair and maintenance.

Although values for initial embodied energy may be calculated on a mass basis as part of the unit process data, they must only be used to make comparisons between viable alternative functional units i.e. components, elements or whole buildings with the same function. Once an element or building has been defined (either a “real” design or an archetype) then the whole life of the materials and products can be included in the embodied energy value - the energy used to extract, transport and process raw materials, to convert them into manufactured products and components, to transport them to the construction site and incorporate them into a building. Just as with any other environmental effect over the life of a building, the values should also include the embodied energy of the materials used in the repair, maintenance and refurbishment of the element or building, as well as the energy to dismantle them and dispose of the materials from which they are composed [3].

The definition used for this project for the embodied energy of a material over the life of a building is:

The total primary energy that has to be sequestered from a stock within the earth in order to produce, transport, maintain and dispose of the materials within a specified product, component, element or building.

Embodied carbon dioxide will be estimated as a separate value because, although a major proportion is the result of the use of fuels of all kinds, some processes in building materials production release CO_2, for example when carbonaceous materials are heated and when carbon anodes are oxidised in aluminium reduction.

4.2 Calculation of values

The definition of “stock within the earth” requires interpretation in order to determine which input data should be aggregated to calculate a single value for embodied energy.

The interpretation adopted by IFIAS when concerns were first raised about the use of fossil fuels, required that only non-renewable hydrocarbons (and then confined to those which are extracted as economic fuels) are included in the estimate. Fuel and energy use is converted from delivered to primary terms and then only the energy obtained from fossil fuels, and not that produced from renewable sources, is included in the aggregated estimate.

This approach is used by others working in the area, particularly those with a background in energy analysis. A study from New Zealand defines energy as that “from fossil fuel sources (coal, gas, oil or other petroleum products), electricity or geothermal steam” [4]. However, there are other studies [5] in which embodied energy data are the sum of all the delivered (process) energy consumption during the manufacturing process.

There is the opinion amongst the industry representatives who are partners with BRE in this project, that all energy is valuable and contributions from all sources ought to be included in the embodied energy value. By adopting this view, embodied energy is effectively “energy consumption”; an aggregation of all fuels and energy including that from wind and hydro-electricity and timber residues. The two values for embodied energy and embodied CO_2 together provide a way of distinguishing between processes which rely on fossil fuels and electricity, which will have comparatively high embodied CO_2 values, and those which use renewable energy sources, such as timber-based residues for which embodied CO_2 will be lower.

For embodied energy calculations, primary energy will be evaluated as the sum of:

a) the gross calorific value of the fossil fuels extracted from reservoirs within the UK or imported in crude form into the UK
b) the thermal equivalent energy generated in nuclear power stations calculated as the electricity generated divided by the average thermal efficiency of nuclear stations
c) refined fuels and electricity imported into the UK, counted as having the same embodied energy per unit of fuel as those generated from primary stocks for use within the UK.

The term "embodied energy" is effectively an accounting analysis and in no way refers to the physical or chemical composition of the materials, and is not meant to imply that there is an inherent energy content that can be recovered by combustion. Consequently, the only energy of feedstocks included in this calculation is that obtained from fossil hydrocarbons which are extracted as economic fuels e.g. oils. This view is shared by the authors of the guidelines for the Athena project [6a, b]. The impacts of the use of other organic materials as feedstock and renewable energy sources are addressed within the inventory and further phases of LCA.

The preferred definition of embodied energy currently held by BRE is that it should be expressed in terms of the primary energy content of all the materials which are used in the process as fuels, together with the energy content of those feedstocks which are fossil hydrocarbons and are currently extracted as economic fuels.

Experiences from life-cycle assessments on steel and concrete composite bridges

J. Widman
The Swedish Institute of Steel Construction (SBI), Stockholm, Sweden
and Luleå University of Technology, Dept of Steel Structures, Lulea, Sweden

Abstract
The Swedish Institute of Steel Construction has made LCA's on steel and concrete composite road bridges in order to detect important environmental impact parameters and to find areas where improvements are necessary. The experiences may be a foundation for future environmental studies on bridges. In this project two of the most common Swedish steel bridge types were studied, one box girder bridge in 8 spans and one I-girder bridge in a single span. Both bridges are spanning over water. All main materials in the sub and super structures were included in the analysis. Details as bearings, joints and drainage system were excluded.

Combustion engines in vehicles contribute to a big share of the airborne emissions, such as CO and NOx. Though, the cement and steel manufacturing processes emit most of the CO2. The concrete in steel bridges contributes to between 40 and 50% out of the environmental impact, and the fact that steel bridges need less material than concrete bridges shows that steel bridges are good environmental choices. Three different impact assessment methods have been used to get multi-comparable and objective assessment results, the EPS Method, the Environmental Theme Method and the Ecoscarcity Method. There are very big differences in the results from the methods. In spite of the small amounts, alloys as Molybdenum contributes to most of the environmental burden from the materials according to the EPS method. This put steel in a less favourable position when comparing LCA results with other materials. This fact also affect the total EPS results, showing that the bridge is polluting more than the traffic (5000 vehicles a day) over 50 years. One joint result from the two others is that the use of the bridge (traffic) is the most polluting part during the life cycle, depending of NOx, emissions and big use of energy. The complete study with results and experiences is presented in [8].
Keywords: bridge, concrete, construction, environment, EPS, LCA, steel, zinc

1 Background

Life Cycle Assessment according to an established method is one way to reach satisfactory and comparable results regarding environmental impact from emissions, raw material use and energy consumption, independent of material or construction. The results can be used for environmental product declarations, process and product improvement analysis, as a tool in the IS0 14000 work and other environmental work where the industry has to be competitive and fulfil external demands.

The construction and material manufacturing industries are recognised as polluting industries, and are therefore put under special observation, not only in Sweden. The nature and ourselves need low-pollutant building component manufacturing and usage, in order to maintain health and welfare. Therefore, it is very important to collect objective environmental information and environmental impact life-cycle data about steel, and distribute it to those who can influence the choice of constructions and materials, and by that the environmental situation of tomorrow.

2 Analysis

2.1 Objects

This example includes a study made for a steel box girder bridge with concrete decking in 8 spans, and a steel I-girder bridge with concrete decking in a single span. Data from Sweden, Norway and Finland were used.

Bridge 1 is 492 metres long (longest span 65 metres) and 13.0 meters wide. The height of the superstructure varies between 2.0 and 3.3 metres. The single girder is painted with zinc epoxy and polyurethane, and the railings are specially designed tubular profiles with zinc coating. The bridge is situated in the Höga Kusten area about 600 kilometres north from Stockholm, spanning over a lake. Schematic sections are shown in figure 1.

Bridge 2 is 60 metres long (span 49 metres), 7.5 metres wide and superstructure height of 2.5 metres. The two I-girders (h=1.9 m) are painted as bridge 1, but with standard hot-zinced U-profiled railing beams. The bridge is spanning over a river, situated about 550 kilometres north from Stockholm.

For the comparing calculations, the data for the connecting road have been used with normal conditions. No extra ground improvement or piling is included. The traffic intensity used in the calculations is 5000 passing vehicles a day for bridge 1, and 500 vehicles for bridge 2. This corresponds to the site conditions. The length of the compared road and the driven distance for the vehicles is the same as the length of the bridge.

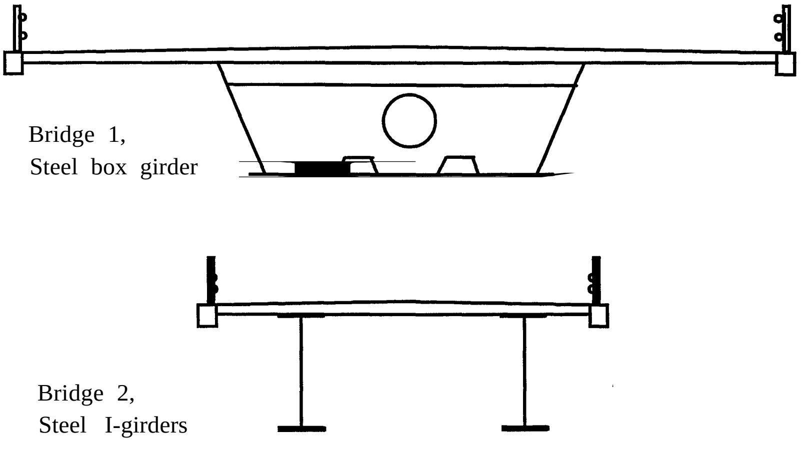

Figure 1: Schematic sections for the two studied bridges.

2.2 System boundaries

All processes from cradle to grave are included, i.e. raw material extraction of primary materials and additives, refinement processes, product manufacturing, construction and transports, and also an assumption of the utilisation, maintenance and demolition phases. Production of mills, machines and vehicles, refining of oil products and production of electricity is not included in this analysis. The normal electricity in Sweden is produced from water and nuclear power plants. The wintertime top use of fossil fuels is not included.

Studied bridge components are the substructure including piling and the superstructure including railings and deck surface. Small details, joints and bearings are excluded. Studied materials and products are constructional steel and steel piles, reinforcement steel, hot zinced steel railings, concrete for substructure, concrete for superstructure, deck insulation, asphalt surface, zinc and steel protective coating (zinc-epoxy and polyurethane paint). The data is used and adapted to Swedish conditions. The bridge utilisation used in the calculations is 50 years.

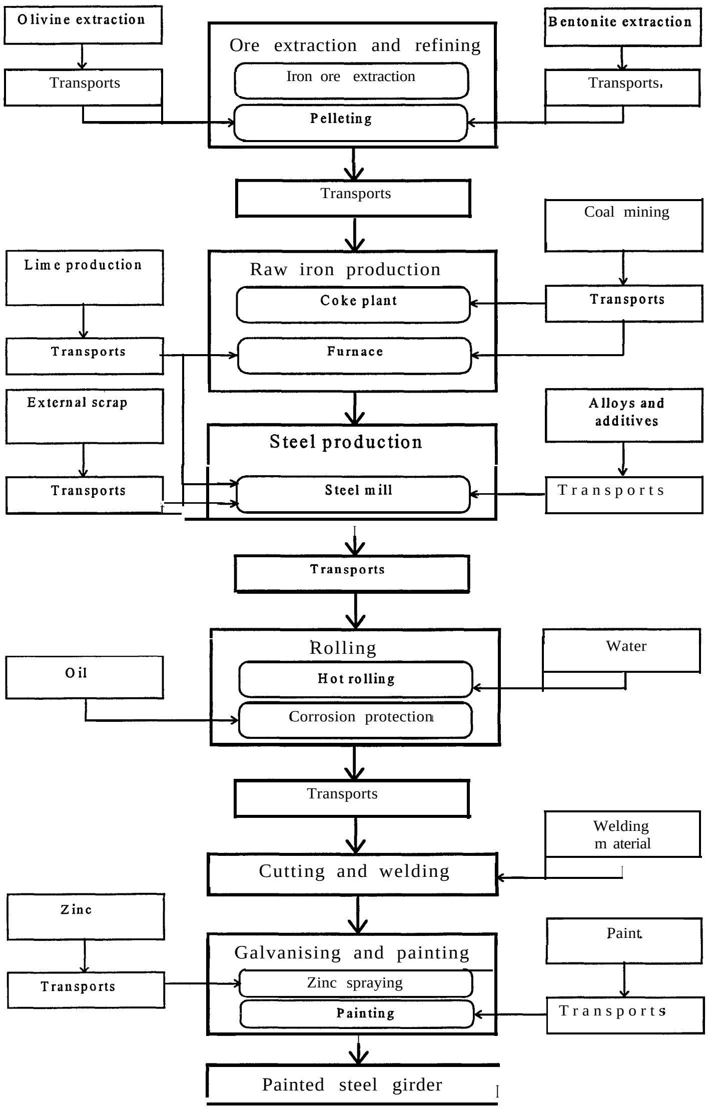

Figure 2: Example on material input for a steel girder

2.3 Inventory

The inventory includes all state-of-the-art data available on the products and processes within the system boundaries. Data is collected from manufacturers in Sweden, Norway and Finland. The studied unit is environmental impact (as kg air emission) per square meter lane. The product inventory follows a specified scheme that is individual for each product. Material input for the steel girders is shown in Figure 2. An LCA study include energy input and also material and energy output for all processes. The material output is described as primary product, by-products, waste and emissions to air and water.

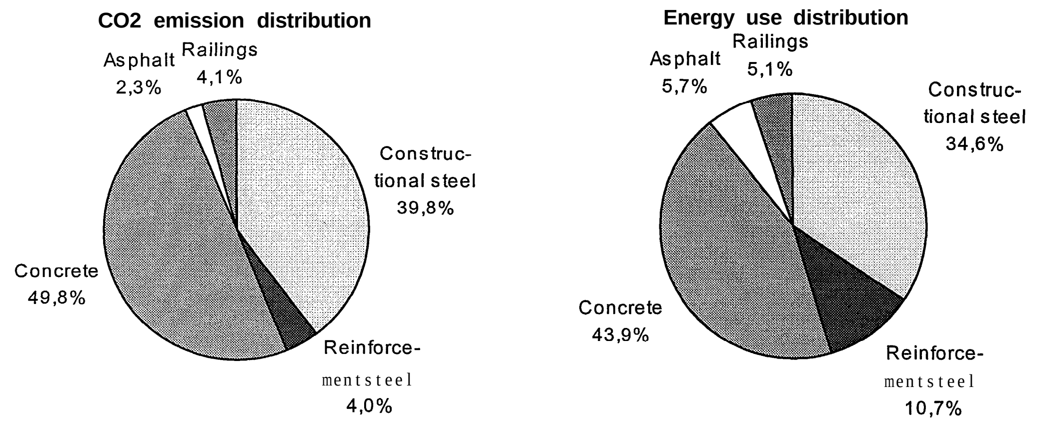

Figure 3: Two examples on inventory result distribution for the box girder bridge

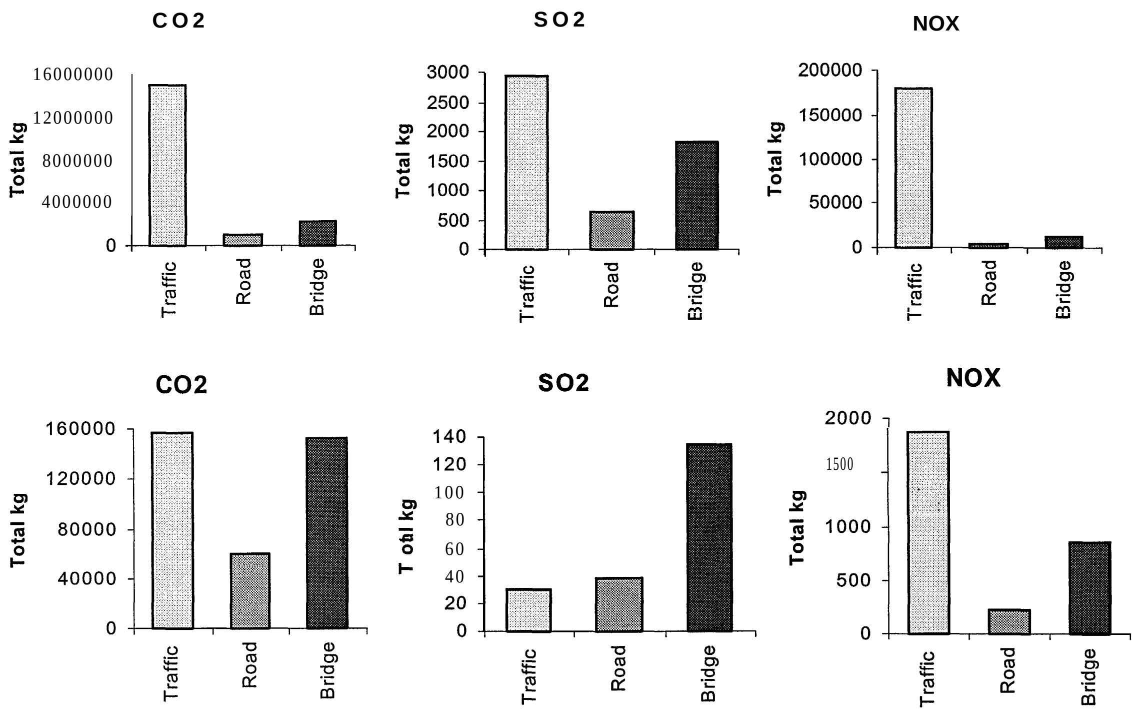

Figure 4: Inventory result comparison examples for bridge 1 (top) and bridge 2

The allocation principles used for the multi-recyclable materials steel and aluminium are according to [1]. The other product allocations have been executed with the cut-off method according to [5].

The inventory results can be analysed in many ways. Figure 3 shows the distribution for the global warming emission CO2 and the total energy requirement for the different studied parts in the bridge. These data are valid for the box girder bridge. One result is that the shares from coating are below 0,2%, and are therefore not presented in these figures. The coating manufacturing data are not complete according to secrecy.

Vehicles carrying the materials and products contribute to an important part of the CO and NOx emissions. The main sources of the CO2 emissions are manufacturing of cement and steel. The comparisons of important emissions and energy between bridge, road and traffic are shown in Figure 4. The original road LCI data come from [7].

3 Assessments

3.1 Environmental impact

The environmental impact assessments have been made with three different European methods: EPS (Environmental Priority Strategies in Product Design), the Environmental Theme Method and the Ecoscarcity Method.

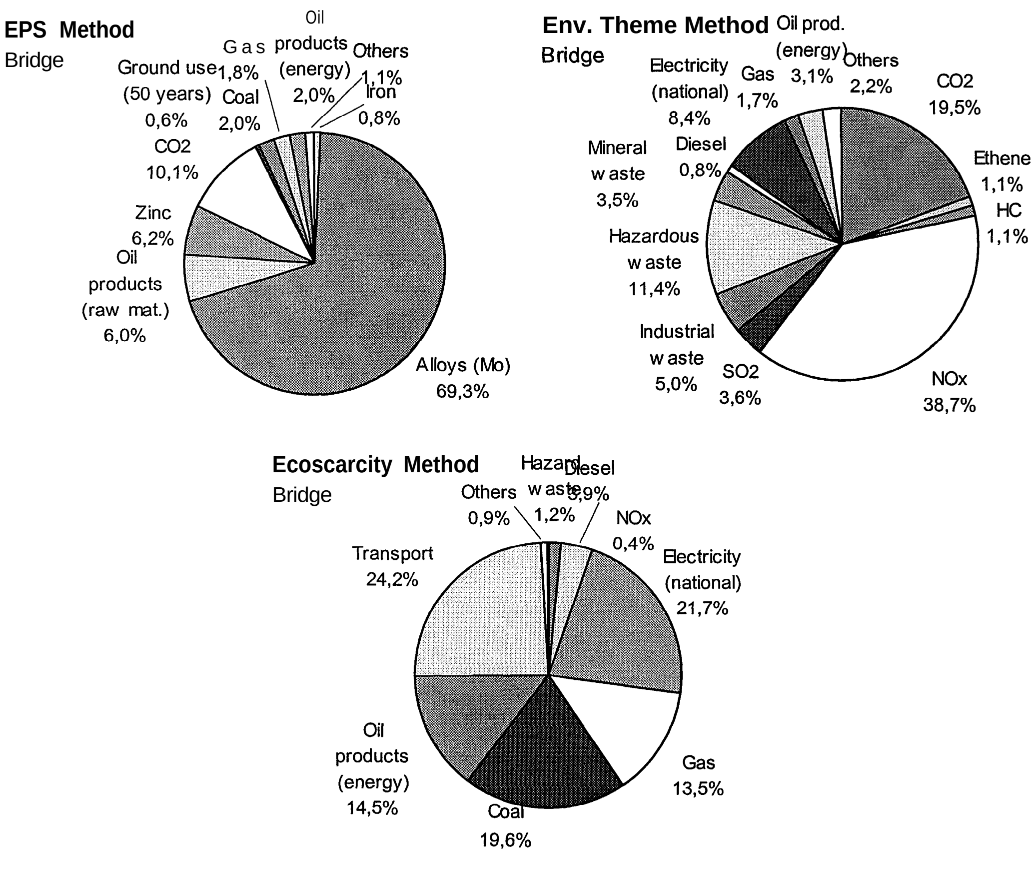

Figure 5: Assessment results from three methods for the box girder bridge

The original thought with the EPS method was also to assess the total environmental burden cost from emissions, energy use and raw material extraction, based on willingness to pay to avoid the different burdens. These assessment methods are adapted to Swedish conditions concerning political goals, material availability or ecological hazardousness.

The EPS Method is based on the willingness in the OECD countries to pay in order to avoid specific environmental impacts. The Environmental Theme Method is based on categorising of environmental burdens in effect categories, compared to the total environmental burden. The Ecoscarcity Method is based on the relationship between the current impact and the maximum acceptable (critical) impact within a specific geographical area.

The impact results from these methods for bridge 1 are shown in Figure 5. The combustion of fossil fuels affects the results obviously. This include mainly heating and transports. As shown, the CO_2 and NO_x impacts are the dominating emissions. The presence of alloys in the figures, more than 90 percent is Molybdenum, is a result of the rare raw material (ore). Zinc is also regarded as an environmental burden because of the same reason. The Ecoscarcity Method is punishing all use of energy very hard. The results from the two bridges are rather similar, except for the traffic. The percentage of concrete is higher in bridge 2, therefore giving more CO_2 emissions and less impact from alloys and other metals.

In Figure 6 comparisons have been made between bridge, road and traffic for the two studied bridges. This has been made to put the bridge in its intended function. The differences are highly depending on the traffic amount passing the bridge. The difference between the traffic on the two bridges is obvious (5000 and 500 vehicles per day).

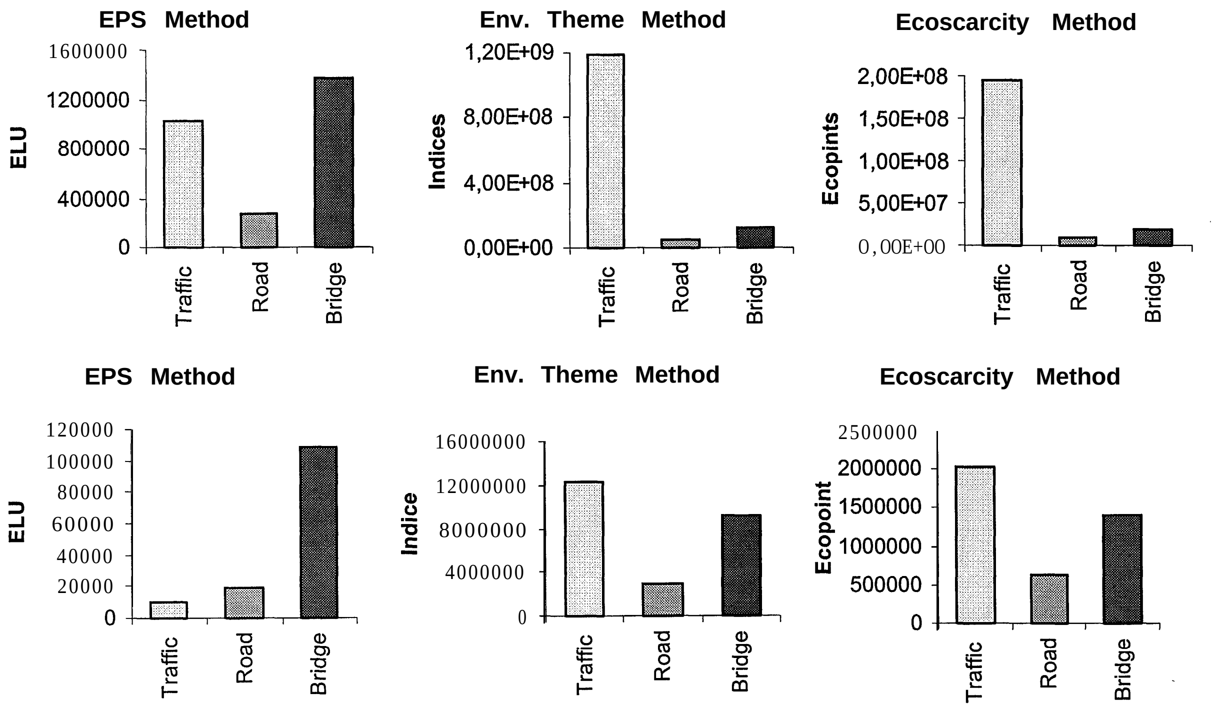

Figure 6: Assessment result comparison examples for bridge 1 (top) and 2

3.2 Environmental cost

The approximate method for evaluating the environmental burden cost give too approximate results to be used practically. These results show that the environmental cost for bridge 1 exceed the construction cost five times. This is the cost that the people in the OECD countries are willing to pay to avoid certain environmental effects. A method for evaluating the real total cost for building a bridge could be useful for this purpose. Some methods are under development in Sweden. The current cost assessment methods are too approximate to give reliable results. These will therefore not be shown in this presentation.

4 Improvement analysis

The emissions CO2, NOx, SO2 and CO correspond to more than 95 percent in weight out of the total airborne emissions. A reduction of these emissions will therefore improve the total environment impact from building and using the bridge. These can e.g. be reduced by changing the transport systems from road to railway traffic, use of bio-fuels for the vehicles, process development or changes of the cement production, and also by using coal and coke more efficient when producing steel.

Further optimisation of the material amounts used for construction of the bridge also reduces the total environmental burden. As environmental effects from the maintenance part is very small, there is not important to increase the longevity by using a lot of corrosion protective substances or extra amounts of material to prevent material deterioration. Examples of such reducible protecting materials are concrete, paint and zinc.

In spite of the small amounts, alloys as Molybdenum get high environmental impact values compared to other materials, all because of the rare raw material. It is not possible to avoid micro alloys in the steel material, but this shows the environmental advantages of choosing micro alloyed steel before steel with higher percentage of alloys. The use of high strength steels (more than 420 MPa) would reduce the total material amounts, but they usually include higher percentage of alloys as Molybdenum. Though, steel can be regarded as a good environmental choice for bridges.

Quantitative evaluation of the effect of pollutants on the atmospheric corrosion of structural metals

D.Knotkova and K.Kreislova
SVÚOM Praha a.s., Prague, Czech republic
P.Boschek
Charles University, Prague, Czech republic

Abstract
Evaluation of the effect of atmospheric environment including acidifying pollutants on weathering steel, zinc and aluminium is based on 8 years results of testing in open air and in rain-sheltered position within the ICP UN ECE on effects on materials. An extensive statistic analysis of results (environment, corrosion losses) was performed.

A five-factor model was proposed as derived from principal component analysis. This model covers 84% of explained variance. An additive logarithmic model was chosen as the most advantageous. The calculated deterioration functions were proposed to be the priority aim of the IC Program - control of SO_2 effect. Other variants of the regression function may be optimal for other technical and scientific applications.
Keywords: Atmospheric corrosion, structural metals, effects of pollution, regression function, logarithmic model.

1 Introduction

International cooperative program UN ECE for evaluation of atmospheric pollution impact on materials including monuments was carried out on 39 sites of the participating countries between 1987 and 1995. Program provided a lot of data for derivation of relations to quantification of effects on materials.

SVÚOM Praha a.s., as fulfils function of a sub-centre for structural metals and so it focused on derivation of deterioration equations for these materials in the way that aims of the Convention of Long-Range Transboundary Air Pollution bodies are followed preferably.

2 Set of data

The input quantities are average values of corrosion losses and of environmental quantities for corresponding period. Corrosion effects were evaluated for 3 structural metals exposed in open air and sheltered conditions:

- weathering steel (Czechoslovak steel Atmofix 52 A, chemical composition according to Czech Standard: C < 0,12%, Mn 0,30 - 0,80% , Si 0,25 - 0,70%, P 0,07 - 0,15%, S < 0,04%, Cr 0,50 - 1,20%, Ni 0,30 - 0,60%, Cu 0,30-0,55%, Al < 0,01%),
- zinc (> 99,5%),
- aluminium (> 99,5%).

Basic climatic parameters (temperature, relative humidity, time of wetness and sunshine hours), concentration of gaseous pollution (SO_2, NO, O_3) and precipitation (amount, pH, conductivity, amount of SO_4^{2-}, NO_3^-, Cl^-) were measured on each test site. All data were reported to, and completed by the Norwegian Institute for Air Research -- NILU. Summarized environmetal data for period 1987-95 are in the report by NILU [1]. Parameters included for regression analysis are presented in Figure 1.

3 Derivation of the regression functions

3.1 Selection of the regression function type

We focused on an additive logarithmic model:

$$Ln(1 + CORR) = a + b.Ln(1 + SO_2) + c.Ln(1 + TOW) + \ldots$$

which can successfully substitute advantages of additional and multiplicant models and which is a result of the following analysis:

A. The linear model is probably the most useful simplification in a situation when the relations cannot be univocally substantiated.

B. Analysis of distribution of observed quantities (both corrosion and environmental) with the use of Shapiro-Wilk's test of normality [2] proved relatively strong deviations from the normal distribution in a high number of quantities.

That is why we transformed the quantities using Ln (1 + x) logarithmic function. Shapiro-Wilk's test of normality shows considerably better goodness of fit of the transformed quantities with a normal distribution.

C. If we use a logarithmic transformation of components in the linear regression model, we cover also the advantages of a multiplicative model due to the properties of a logarithmic function (Ln (XY) = Ln (X) + Ln (Y)).

3.2 Selection of regressors

If quantities showing a considerable degree of statistical interdependence (multicolinearity) are included into the model, it is obvious that:

- the risk of the regression function unstableness appears,
- weight of the influenceable SO_2 factor will be superimposed by other colinear factors.

Therefore we carried out an analysis of the structure of dependence between potential regressors (environmental factors), using the principal components analysis (PCA) with orthogonal varimax rotation [2]. The analysis was repeated

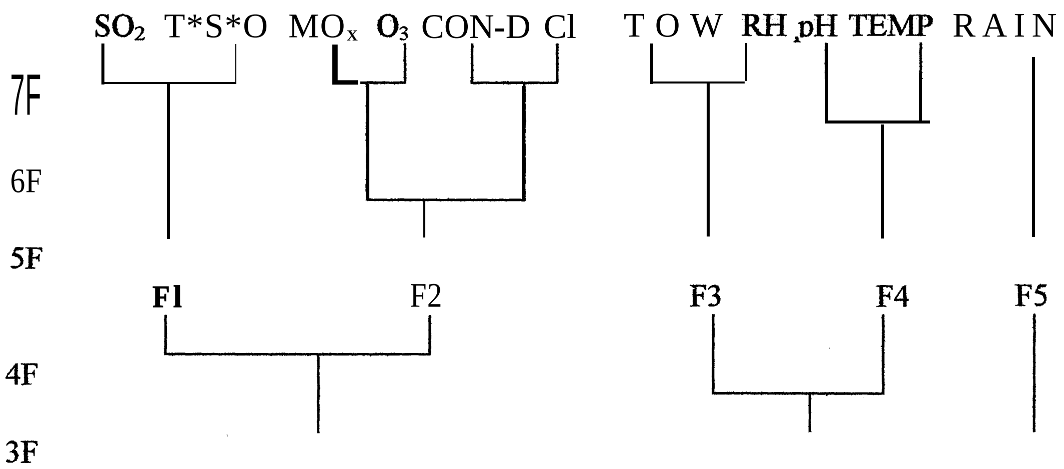
- separately for individual exposure periods (1, 2, 4 and 8 years),
- simultaneously for all four exposure periods, which a priori pointed out the variance of presupposed factors.

The input quantities are logarithms of the average values of environmental quantities for corresponding periods in Ln (1 + x) form.

To determine the primary number of extracted components - factors we have chosen the Kaiser-Guttman criterion [2]- the number of eigenvalues bigger than one. We gradually reduced the number of extracted independent factors (components) until the value of three. This way we obtained a tree-graph that describes the correlation taxonomy of individual environmental factors.

It is evident that the more independent the system of predictors is, the more stable the regression equation of deterioration will be. A five-factor model (including rain), which is pointed out in Figure 1, seems to be the most suitable one for our purposes. This model covers 84 % of explained variance in data space.

Figure 1 - Diagram for reduction of factors NOX COND



The general knowledge of atmospheric corrosion together with the results of the statistical analysis (pair correlation coefficients, partial correlation coefficients, stepwise regression analysis) prove that SO_2 and TOW are the decisive factors of corrosion. The question is what other quantities shall be included into the regression model to increase the predictability. But the aim is also not to decrease the reliability and stability of the model at the same time.

Issuing from the PCA results, the F1 factor is best represented by SO_2 regressor, also because we prefer the additive logarithmic model.

Potential representation of factors F3, F4, F5 is evident - TOW, pH, RAIN (although we do not suppose a significant effect of the fifth factor representative - the rain-fall amount). The problem of the second factor (F2) remains open.

We analyzed the question of involving ozone into, the regression equation of deterioration into detail. We calculated partial correlations - dependence of the corrosion rate on the ozone concentration (with fixed levels of other environmental effects) for these purposes. We calculated these partial correlations both for really observed values of ozone concentration (O_3), and for complete set with estimated values (O_3_n) based on NO, concentration. None of the correlation coefficients is significant, and they are even of negative values in about half of the cases. This fact proves a negligible influence of the ground-ozone in the process of atmospheric corrosion of the exposed samples. Therefore ozone was not included.

Another solution was focused on evaluation of suitability of involving the following regressors: conductivity, chlorides content, pH of precipitation. The basis were results of the stepwise regression analysis compared with generalized knowledge of atmospheric corrosion.

Modelling of the regression function during the stepwise regression analysis proves that involving another variable means a higher value of the determination coefficient in many cases, but at the same time, it also decreases the portion of the SO_2 effect (lower standardized regression coefficients and relatively higher standard fault of the regression coefficient) in the regression model in almost all cases.

The proposed solution does not follow the highest values of the determination coefficient, but the preservation of a sufficient importance of the SO_2 effect together with a relatively favorable determination coefficient value (Table 1).

Figure 2 and 3 present residuals and standard error of prediction of observed values from theoretical values resulting from the regresion model used. Sites with outlying values are evident too. It is obvious that addition of other regressors into the model does not represent a significant increase of its fitting which would make a more complicated model unambigously preferable to the basic one. The basic model brings significant advantages in practical use.

In case of equation designed for steel, it is always necessary to remember that exposed was a weathering steel that behaves in a different way than an ordinary carbon steel during longer exposures (about four years and more).

Detailed results are presented in report [3].

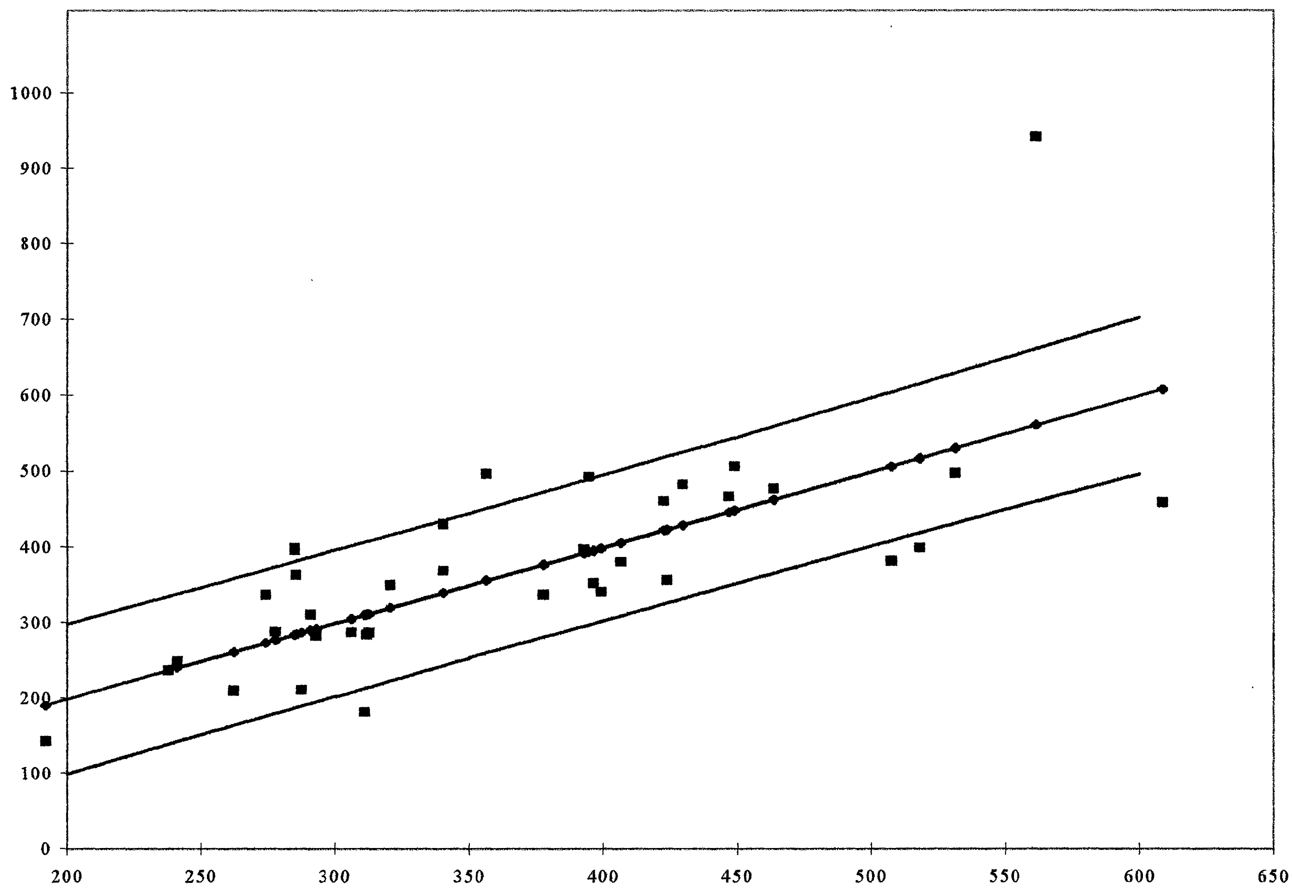

Figure 3 Analysis of residuals and standard error of prediction for weathering steel exposed 8 years under shelter

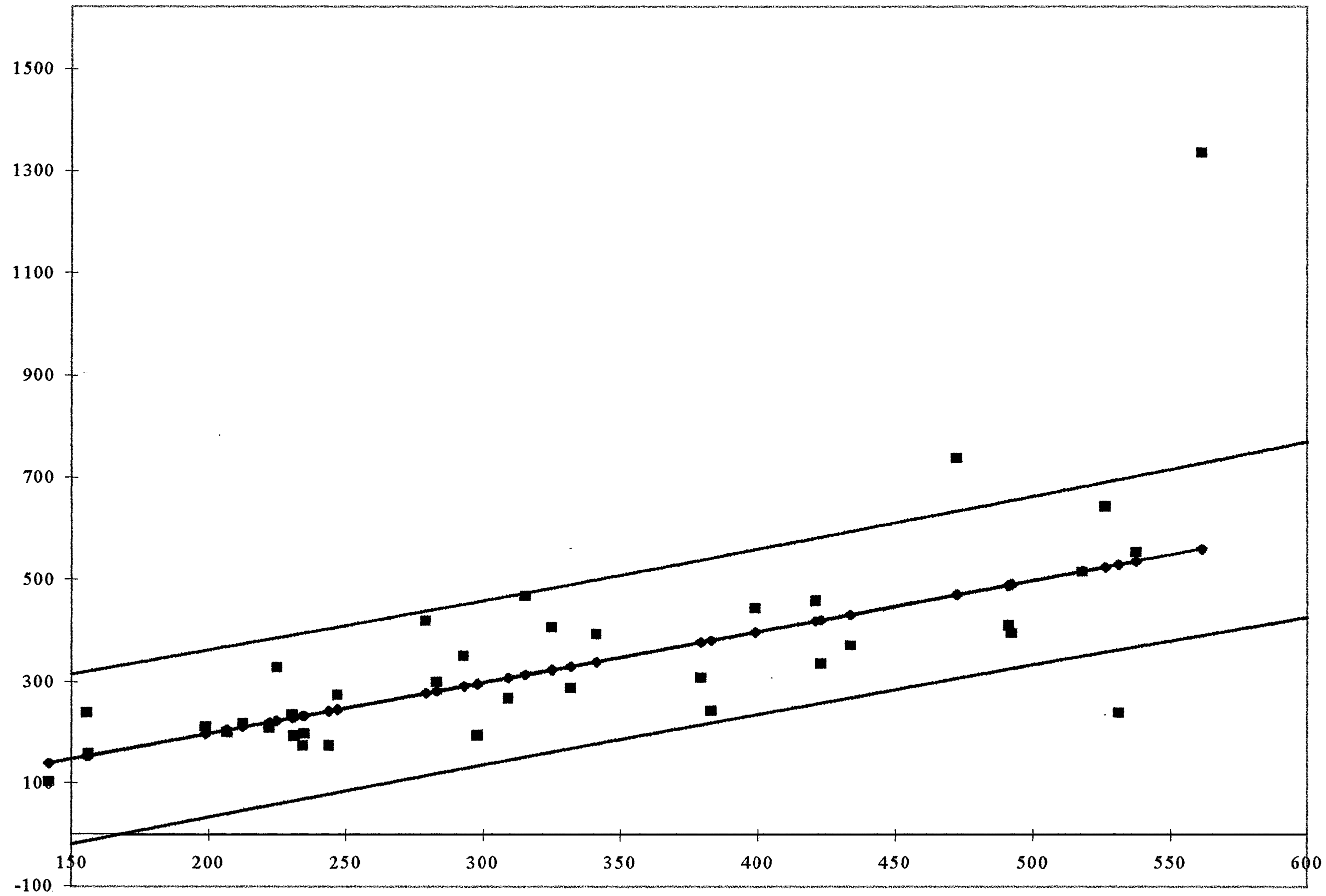
Model: $\ln(1 + CORR) = A + B_1*\ln(1 + SO_2) + B_2*\ln(1 + TOW) + B_3*\ln(1 + COND)$



4 Conclusions

Statistic analysis of corrosion and environmetal data led to following conclusions:

- an additive logarithmic model was choosen as the most advantageous
  - useful simplification in a situation of complicated relations
  - logarithmic tranformation of observed quantities shows better fit with a normal distribution
  - logarithmic transformation of components in a linear regression model covers the advantages of a multiplicative model.
- a five-factor model (Figure 1) was proposed as derived from principal component analysis (PCA). This model covers 84 % of explained variance in data space.
- regressors included in the calculated regression functions were derived with help of the stepwise regression analysis with the aim to reach relatively favourable determination coefficients but. to preserve a sufficient importance of SO_2.

In conclusion, it is necessary to repeat that the main way of using the proposed deterioration function is the control of SO_2 effect in the current stage. Addition of other variables increasing the multicolinearity of the model may lead to bigger inaccuracies in the model predictability. Other variant of the regression function may seem optimum for other purposes of use not only because of statistic analysis results, but also because of factors expressed in numbers.

Abstract
Shelter is one of the basic needs of man. The 1948 United Nations Universal Declaration of Human Rights, the 1976 Vancouver Declaration on Human Settlements and the 1991 Global Strategy for Shelter to the year 2000; are among the few testimonials to this gracious price. However, even with the above mentioned declarations, still housing situation in many parts of the globe is not satisfying. The eastern Africa region is not exceptional, and housing can be generalized as non-sustainable. A practical solution is needed as the people are in acute need of decent, sustainable and affordable housing. By interpreting and applying modem building technology and expanding the old construction methods, basing on local conditions to suit the present need, a contribution towards sustainable housing can be made. Advanced and inherited building methods and technology, normally imported from industrialized countries, can systematically be studied, modified and integrated with the indigenous ones to provide sustainable housing. This can only be achieved by considering other co-related factors in the process including, affordability level, social factors and environmental issues. In this process, it is necessary to encourage and promote local construction industries. Importantly, governments' housing policy need to be constantly reviewed to cope with peoples' requirement and choice, and global changes. It is also worthy to study building technology and experience from other successful and applicable construction methods from elsewhere. Building materials should carefully be analyzed and applied properly.
Keywords: Building technology, building methods, construction industry, eastern Africa, government policy, materials technology, sustainable housing.

1 Introduction

Shelter is considered as one of the basic needs of man. This complies with the 1948 United Nations Universal Declaration of Human Rights, the 1976 Vancouver Declaration on Human Settlements and the 1991 Global Strategy for Shelter to the year 2000. In the UNCHS Habitat Report (1986), it is emphasized that: “human settlements are not simply housing or, for that matter, merely the physical structure of a city, town or village but an integrated combination of all human activity processes including residence, work, education, health, culture, leisure etc.; and the physical, structure that supports them” [1].

The whole world face housing problems, although in different levels and circumstances. However, in developing countries including east African countries, the situation is more uncertain than in the developed countries. Population growth is one of the contributing factors. By the year 2000, as mentioned in the Habitat report [1], eight out of ten people will be living in developing countries. Mitchell and Bevan [2], also summarize that, the real problem of housing provision in the developing countries in the last quarter of the 20th century is population increase.

It is true to mention that, the provision of shelter, and the steps taken by human being and society to satisfy the housing need has changed throughout our history. As such, there is a problem on the changes in methods of housing provision, because of an increase in the sheer scale of housing need.

When analyzing other factors associated to the housing problem including urbanization, planning controls and changing expectations, there is a need to consider the fact that, housing provision and the meeting of housing needs should not only be limited to increasing the number of housing units, but all the related issues which will result in providing sustainable and affordable housing [2].

2 The housing and construction sustainability concept

The working commission CIB W82 for the CIB “International Council for Building Research Studies and Documentation” launched a project on “Sustainable Development and the future of Construction” in 1995. In their report connected with the project, Bourdeau and Huovila [3], a definition (by Kibert and alii) for sustainable construction was introduced during the First International Conference on Sustainable Construction held in Tampa in 1994, as defined below:

2.1 The definition of Sustainable Construction

The creation and responsible maintenance of a healthy built environment based on resource efficient and ecological principles.

However, this definition is broad, and can be regarded as a base for individual countries or regions when formulating their own definition according to the local priorities.

3 Housing situation in the eastern African region

The main problem as is the case in most developing countries including eastern Africa, is the shortage of affordable housing. And the informal sector is largely responsible for housing issues, especially in low-income settlements. Figures presented by UNCHS [1] for Kenya as an example, indicate that, “the construction of traditional dwellings in 1976 contributed almost 60% of gross fixed capital formation, while the informal construction sector contributed around 30% to the gross domestic product (GDP) generated by construction between 1969 and 1978.

Despite its contribution to general development and the specific provision of affordable and sustainable housing for the majority i.e. the low-income majority, the informal sector enjoys few of the benefits of the formal sector [1].

3.1 Problems and the role of the government

The problems related to sustainable and affordable housing are in principle, similar in most developing countries (including east African region). They are discussed in brief as follows:

The housing problem is partly caused by the rural to urban migration. Population growth is also associated with this problem. As the migration take place parallel to population growth, the political, economic and social systems have been unable to keep pace. In addition, financing methods are not adequate and need to be established to serve the local private construction industries and the population for their housing needs. The question of cultural and social issues, and the participation of the local people which in most cases has been neglected need to be reconsidered.

The consideration of innovations in the materials and systems used in residential construction is not fully prioritized in most developing countries [4],[5]. It is difficult to use simple techniques, to improve tradition building methods. At the same time, local professionals and decision makers often oppose tradition materials and methods. As a result, the local users become reluctant, and aspire to development and high status, usually represented by modem building materials [6].

Government policy and programs concerning housing issues in many developing countries are still not sustainable. As discussed by Nguluma [7], in Tanzania during “the 1970s and 1980s, government efforts were not sustainable because of over reliance on capital intensive methods and no-involvement of the stake holders in the infrastructure improvements”. Further, “government efforts to upgrade infrastructure and services in unplanned housing areas were expensive and not sustainable because of, on the one hand over reliance on the inadequate public sector resources and on the other, gross disregard of private and popular sector resources and initiatives to improve their environments”.

3.2 Sustainable housing: Related issues

As discussed in (3.1), sustainable housing issues are mainly related to:

- The local population - people
- Financing
- Government policy and
- The (local) construction industry.

4. Priorities towards the 21st century

In order to meet the requirement of sustainable and affordable housing as we enter the 21st century, there is a need to prioritize our goals in a global perspective. As such, similar international approaches can be applied in different countries for finding local solutions and applications.

Such an approach is given by the CIB W82 project on "Sustainable Development and the Future of Construction" [3]. Basing on their formulated following questions on future sustainable construction i.e.,

- What kind of buildings will be built in 2010, and how we adapt existing buildings ?
- How shall we design and construct them ?
- What kind of materials, services and components will be used there ?
- What kind of skills and standards will be required ?
- What kind of cities and settlements will we have then ?

It is obvious that, this approach can be adapted in formulating the priorities of the east African region. However, there will be a need to define and modify the methodology of formulating these questions in order to match with the local need, as mentioned in this paper. Examples of such questions for the local region are:

- What improvements people want ?
- What is their order of priorities/ choices, and what resources can they contribute ?
- How can the optimization of residents participation be included ?
- Feasibility study on social, economic and technical questions need to be carried out. How can this be done ?

In an effort to formulate programs for global shelter (including east African region) strategy to the year 2000 and above, it is necessary to consider that, housing demand can be met in each individual country by applying a common set of global principles and approaches. There is also a need to reorganize the shelter sector. As emphasized in the Habitat report [8], "the key to effective national shelter strategies is macro-economic policies that link the shelter sector to the economy as a whole".

5 Summary and conclusions

From what has been discussed in this paper, the following conclusions can be made, for the achievement of sustainable and affordable housing in the region:

- It is clear that there is a great need of decent, sustainable and affordable housing in this region of the eastern part of Africa
- In order to make further progress concerning sustainable building in the region in the 21"' century, existing theories must be put to an action plan by parties involved in the process, governments and its agents playing the leading and supervising role

- If sustainable housing programs in the next 21st century need to be meaningful and make an impact in practice, local building industries must be totally involved in action programs
- Governments should secure that development programs assisting the needs of the people, including sustainable and affordable housing
- The governments should also pursue a course which enables people to cater for themselves, rather than attempting to solve the problems for them without including their own wishes/ choices
- A regular and systematically analysis need to be done by monitoring the trends in building materials and building technology development, in order to constantly cope with the local need and global changes
- And from what experience has shown, the only ones who have the capacity to alleviate the housing deficit are basically the people themselves; since it is for their own use and benefit that positive solutions must be found.

6 Acknowledgments

The authors wish to thank for the useful discussions, whether oral or through publications, and remarks from professionals/ institutions who are interested and involved in housing and sustainability issues. Their contribution have been very useful in this paper work. Also, the institutions where the authors are affiliated deserve to be acknowledged for any kind of support provided.

Earth as a wall material and its impact on pollution

B. Isık
Istanbul Technical University , Architectural Faculty, Istanbul, Turkey

Abstract

Studies promoting earth as a construction material have been on going since 1978 at the Istanbul Technical University. The objective of these studies is to develop healthy and functional habitats for the growing population in this region and around the world.

The UN conference in Rio "Eco'92" encouraged to advancing earth construction advancing technology with the ecological diagnosis. It is well-known that earth construction creates a healthy indoor environment, as well as it preserves the world energy resources.

Housing is responsible for a significant proportion of energy consumption. Although there are few emission at the construction site, there may have been considerable emissions during the production of the building material as well as emissions brought about by operating and maintaining the building. The intensity of energy consumption impacts the use of the global resources. And the pollution, throughout the life cycle of the building.

Due to the high demand for housing after the World-War II. housing sector first aimed mass-production by the rationalisation and prefabrication. Next the effort was to improve the physical properties of building envelop and indoor climate, created by the materials and technologies those are industrialized products. Today the target is to sustain the biological life of humans by respecting the environment.

As one third of the world population is living in earth construction, research has been carried out to improve some of the mechanical and physical properties of traditional earth construction. These studies have shown, that stabilizing earth with 10 % gypsum and 2% lime brings advanlages to the material such as : unit weights of 1.4 t/m^3, compressive strenghts of 2-4 N/mm^2, low water absorption and shrinkage of about 1%, and values of heat conductivity of 0.4 w/m^2K.

World resources should be handled with care. Gypsum stabilized earthen building materials are suitable for mass produced housing. The physical properties of the material provides the construction industry with the following benefits: contribution to healthy housing, contributing to energy reductions, contribution to reduced pollution.

Key words : adobe construction, construction technology, earth construction technology, energy consideration, mechanization, pollution reduction, stabilization, wall material

1 Introduction

The whole environment, including the flora, atmosphere and sources of water should be protected for the survival of humans. This necessity has been signed by 154 countries during RIO I and RIO II Environment Conferences. The European Organization of Standards has published the standard (EN 832) relating to "Heat Capacity of Buildings, Calculation of Residential Energy Consumption" in CEN 1995.

Not only is the service life of housing threatening the ecological system and subsequently the human life trough environment pollution, but also entire life cycle, including: 1 .law material supply, 2. Material production, 3. Elements production, 4. Construction, 5. Service life, 6. Maintenance-repair, 7. Waste recycling stages. The research aims to contribute to preserve the natural resources by improving earth improving construction materials for the mass-housing. The reason that it very sound creates thermal comfort and is environment friendly during the construction stage, throughout the service life, as well as in recycling stage.

2 Objectives of the Housing Sector

After the end of World War II. the demand for housing increased due to the disaster, and also immigration and rapid population growth. This due to the problem was in past solved using industrialized construction technologies and prefabrication.

The next objective was to predict the physical conditions of new constructions, created by other then well known traditional materials. There after, mechanical air conditioning system were invented that required automatic control equipment and finally the age of "Intelligent Buildings" was reached.

The man-made conditioning systems are now considered to threaten the eco-system in dense settlements in addition to the industrial establishments. From these situations today's objective for "Healthy Housing" integration of [1] 1. The User's Health 2. Ecology 3. Affordability. as indicated in Table 1, today's housing objectives are focused on human and environmental criteria.

Table. 1 Objectives of the housing sector after the world wars.

1st Period (1945-) Rationalization	2nd Period (1980-) Intelligent Buildings	3rd Period (1990-) Healthy Building
Rationalization Industrialization Prefabrication	Automation of the mechanical supply for conditioning	1. User's Health 2. Ecology 3. Effordability

3 TUBITAK INTAG 622 T Research

The fact that the building industry consumes a large amount of energy and the wall material constitutes is the largest volume, reveals the importance of the wall, when focusing on issues of a healthy environment. The wall material effects the energy consumption by : 1. material production, 2. material transportation, 3. heating / cooling of the building.

Alker wall material, a short name of gypsum stabilized earth (gypsum=alçý, adobe=kerpiç), has been developed to consider the reduction of the energy. Alker

Alker wall material, a short name of gypsum stabilized earth (gypsum=alçý, adobe=kerpiç), has been developed to consider the reduction of the energy. Alker embodies less energy than other wall materials, it is locally excavated and needs a little transportation energy. A house constructed out of Alker has a low k-value, as indicated in Table 4 and Figure 1, thin enables a low consumption of energy for heating and cooling.

There are two main researches projects that have been supported by TUBITAK (The Turkish National Research Council) to promote the earth construction technology. The first project faund in report MAG 505 (1980) [2] is the basic research and provides information concerning to material properties, as shown in Table 2 and 3. The research TUBITAK INTAG 622 T (1995) [3] has been conducted for TOKI (Turkish Prime Ministry Housing Development Administration) to improve the workability and curing conditions of these materials. Result of same of this work that is focused on using the Alker technology for the mass production of housing, is provided in Table 3 and 5 below.

18-29 %	rammed earth
20-22 %	adobe blocks
24 % and more	segregation

Considering the workability and the short curing conditions, an "Alker" building has been constructed in the University Campus, wiht the aim to determine the thermal properties of the new construction technology.

4 Thermal properties of Alker for healthy and eco- housing

If the difference between surface temperature and indoor air temperature is high, air circulation can effect the user's health. Difference between surface temperature and indoor air temperature should be ± 2 ^{0}C. As the heat insulation capacity of Alker material is high, difference will remain below the limiting value. In such cases, comfort conditions, necessary for human health are provided and savings in terms of heating load are achieved. Table 6 indicates temperatures of interior surfaces for various exterior wall materials for an outdoor temperature of -5 ^{0}C and indoor temperature of + 20 ^{0}C.

Table 6 Comparison of the indoor surface temperatures, by different wall material (Outdoor: - 5 ^{0}C, indoor: + 20 ^{0}C)

	Concert Wall	Full brick	Hole brick	Light weight concrete	Alker wall
Indoor Surface Temperature (^{0}C)	+ 9.68	+ 12.44	+ 13.70	+ 14.84	+16.80

A solid exterior wall made of Alker material can provide heat insulation at the desired level one layer (uninsulated). The cost of uninsulated exterior wall made of solid concrete remains below the cost of Alker material. However, its thermal conductivity is nearly 5 times greater than the Alker material. Depending on the material used, the heat conductivity of an exterior wall with no heat insulation increases the heating energy demand that also increases turn gas proportions and environmental pollution. The low capacity of heat conductivity of Alker keeps the air clean. To reach the same k-value of walls constructed by a material other then Alker an insulation layer is necessar, thins, necessarily increases the cost of the exterior wall. The above mentioned relationship between heat conductivity and environmental pollution, heat insulation and cost for various wall materials is given in Figure 1. The need for heating energy changes depending on the type of exterior wall. As indicated in Figure 4, a building with a 19 cm. solid brick wall will requires 10.000 kWh heating energy per year, whereas a building with an Alker wall of 45 cm. thickness, requires heating energy of 632,5 kWh per year. This indicates that using Alker material would provide a 40% savings in terms of heating energy. As heating energy consumption is one of the major

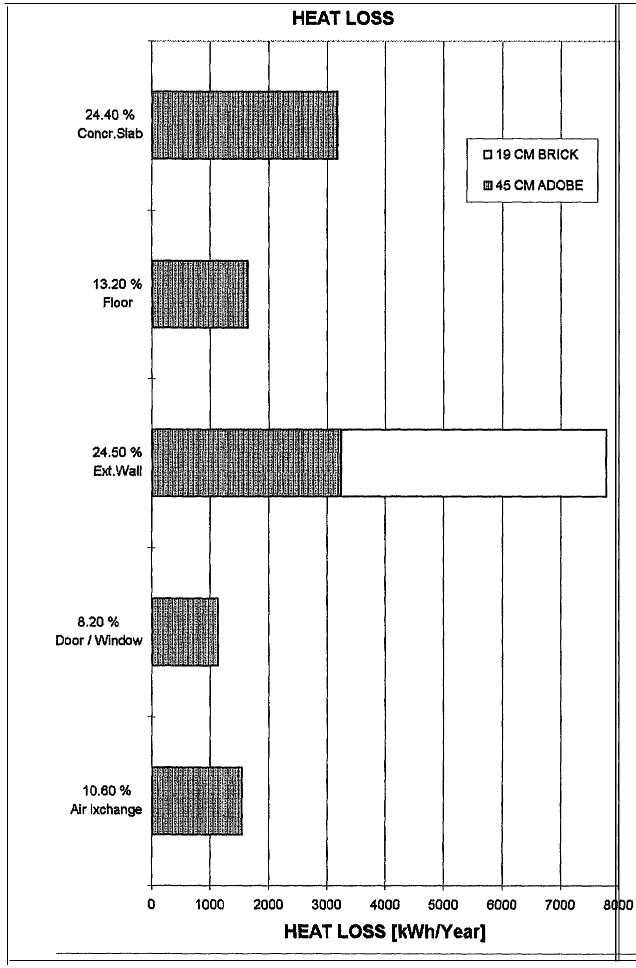

Figure 2 Heat loss

TOTAL WALL COST $ / m², 1995	11	14	12.9		4.4

factors for air pollution thermal conductivity value of exterior walls has to be reduced. The effect of 19 cm. exterior brick wall has been compared with the 45 cm Alker wall in terms of heat loss as shown in the Figure 2, using of Alker as wall material reduces the rate of pollution in the air by 30%, as shown in Figure 3.

5 Impact of the Alker construction on environmental pollution

The life-cycle of Alker material as in any other construction process consists of 1. Raw-material supply, 2. Material production, 3. Element production, 4. Construction, 5. Service life, 6. Maintenance-repair, 7. Recycling. A summary of the impact of Alker construction and the life-cycle of the Alker building on environmental pollution is given below:

1. *Raw Material Supply /Environment:* Construction of a building requires processing of raw material into construction material. During this conversion process, a different amount of energy is consumed for each particular material which leads to pollution of earth, atmosphere and sources of water. Procurement of raw materials for Alker only consists of excavating the proper soil and transportation of the same to that site, which causes no environmental pollution.
2. *Material Production / Environment:* Procurement, transportation preparation and molding of the raw material stabilized with gypsum do not require significant amount of energy. Kiln energy of the plaster and lime additives is lower, compared with cement, which provides both saving in terms of the national energy budget and reduced wastes.
3. *Elements Production / Environment:* Mechanical compacting of Alker in the formwork, takes a very short time. Preparation of mixer requires 2 minutes. Electrical power consumption is low. Construction materials manufactured with state-of-the-art technologies cannot adequately fulfill heat insulation, heat storage and humidity stabilization functions properly when used alone for construction of walls. Such functions require a separate material layer and additional labor for installation. However, Alker wall material meets such comfort requirements when used alone as a wall material.
4. *Construction Process /Environment:* The Alker construction technology is furnished with, the equipment such as mixer, band conveyor, mechanical compactor, etc. to save labor. Energy consumption is considerably low due to shortened process times brought about by the use of gypsum.
5. *Service Life / Environment:* Figure 2 and Figure 4 illustrates the reduced energy consumption (4(achieved during the service life of Alker buildings. Therefore, emission of pollutant solids and gases by Alker buildings is reduced by 30% shown in Figure 3. Savings in terms of national energy budget are achieved due to reduced energy requirements.
6. *Maintenance-Repair* / Environment: Maintenance and/or repair works are not as necessary which causes lower environmental loads.
7. *Recycling / Environment:* After demolishing of Alker wall, the waste material is biologically degradable to a full extent, or can be re-used as a construction material, if required.

6 **Conclusion**

"ALKER" walls constructed by gypsum stabilized earth material meet the requirements of healthy housing, without needing other layers thanks to its bearing, heat insulation, heat storage and vapor diffusion properties that provide considerable advantages in terms of environmental protection compared to the industrial construction materials.

Performance requirements of building products derived from construction and demolition waste

K. Sagoe-Crentsil and T. Brown
Division of Building, Construction and Engineering, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Melbourne, Australia

Abstract

This paper examines emerging trends in recycling of construction and demolition waste and its potential impact on the construction sector in Australia. Whereas concrete recycling for new construction and road pavement applications are rapidly gaining industry acceptance, progress with high level recycling of brick and general rubble remains comparatively slow. However, current initiatives toward performance-based specifications provide a basis for greater consideration of secondary materials. Data generated at CSIRO to evaluate the performance and application of plant recycled concrete is presented and discussed. The project findings highlight technical requirements necessary for the satisfactory performance of demolition waste within the framework of ecologically sustainable construction practices.
Keywords: Recycling; C&D waste; concrete; specifications; concrete aggregate; contaminants.

1 Introduction

Whilst a significant proportion of conventional demolition debris is currently recycled for use in low level fill applications, the need for higher value addition to materials such as concrete and brick is considered critical to improved recycling efficiency and better management of the construction and demolition (C&D) waste stock in Australia. Commercially, recycled concrete is rapidly emerging as a viable product with diversified construction applications [1–4]. This trend is largely driven by legislative instruments and rapidly emerging recycling industries. The current Australian government policy is to reduce waste destined for landfill by 50% by the year 2000 benchmarked to 1990 per capita levels.

This policy was published in 1992 as the National Waste Minimisation and Recycling Strategy, through the Australian and New Zealand Environment and Conservation Council (ANZECC) [5]. To achieve the objectives of the Strategy and the reduction targets set by the different states and territories would require rigorous adherence to waste minimisation principles.

Responsibility for waste management and for legal regulation of waste management lies with state, territory and local governments. In reality, the only legislative role played by the Commonwealth is to regulate the import and export of hazardous wastes under the Base1 convention.

Regional standardised methods and procedures to evaluate the potential environmental impact of recycled materials, including the quality of both input and output materials from C&D recycling facilities have begun to emerge. This includes draft specifications and local government policies for the use of recycled materials for low grade applications such as fill for road base, as well as draft guidelines to aid the specification of recycled concrete as aggregates in concrete construction [3]. These initiatives are reviewed based on laboratory assessment of the technical performance of commercially available recycled concrete aggregate (RCA) for both new concrete production and road base applications.

2 Background

About 14 million tonnes of solid waste per annum is presently generated nationally. Waste generated from refurbishment and C&D operations forms a significant proportion of this solid waste stream. Whilst a considerable proportion of demolition concrete is recycled, with the current national average in excess of 70%, other building materials such as bricks, windows and fittings are reused but on a much smaller scale. The rapid growth in concrete recycling over the last decade is demonstrated by the trends shown in Figure 1 for the State of Victoria, with similar volumes recycled in New South Wales. It is well recognised that to sustain this rapid growth rate depends largely on the creation of new markets and the promotion of recycled products.

Primary markets for crushed concrete such as foundations, bulk fill and retaining walls are rapidly being expanded to include high level applications such as graded aggregate for new concrete and landscaping.

Correspondingly, products and markets for recycled bricks currently appear to be restricted. Whilst the seconds market remains steady, consideration is now being given to the use of recycled bricks as a sub-base material for pavement applications.

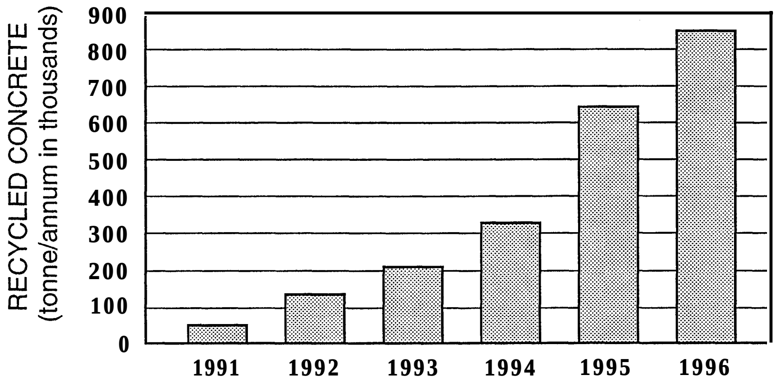

Figure 1. Tonnage of recycled concrete in the State of Victoria

Acceptability of recycled materials would eventually depend on meeting technical suitability and environmental impact requirements. In the case of RCA for concrete production, achieving satisfactory concrete performance largely depends on aggregate quality. Data generated from a pilot study of aggregates in the State of Victoria are presented.

3 Characterisation of recycled concrete aggregate

Currently, high level, high volume recycled material from demolition waste generally includes graded concrete aggregate, crushed masonry aggregates, crushed asphalt, sieve and crusher sand, a mixture of crushed concrete and masonry aggregates, crushed brick and recovered brick.

The results of a survey on properties of some commercially available RCA in are shown in Table 1. Aggregate sampling was carried out on unwashed RCA from production stockpiles in accordance with Australian Standard AS 1141.3.1. Weekly batches thus obtained were graded prior to determining their properties and impurity levels. Equivalent properties of basalt, which is widely used as natural coarse aggregate in concrete manufacture, are also included in Table 1.

Batch code	Impurity level (%)	Bulk density (AS 1141.6) (kg/m^3)	Water absorption (AS 1141. 6) (%)	Aggregate crushing value (AS 1141.21) (%)
C220797 (RCA)	0.4	2395	5.6	23.1
C290797B (RCA)	1.1	2392	5.7	22.3
C3 10797 (RCA)	0.7	2424	5.2	25.3
C040897B (RCA)	1.1	2456	4.8	23.7
C240797B (basalt)	0	2890	1.0	15.7

Table 1. Contaminant level and physical properties of coarse RCA and natural (basalt) aggregates

The results in Table 1 show total contaminant levels expressed as per cent by weight of sample. Contaminant levels typically less than 1.2% of total material weight are obtained. The relatively low levels of contaminants are matched by the comparative uniformity of measured physical properties of the aggregates. Whilst the need for extended sampling cannot be overemphasised, the results nevertheless disclose a high level of consistency and quality of the material examined. This trend can be partly attributed to the very high quality of feedstock and the screening standards of operators.

Average batch compositions were assessed on 10 kg sub-sample lots, by visual examination of the +4.75 mm fraction sieved in accordance to AS 1152. Table 2 shows sieve analysis of RCA and basalt aggregate. The test portions were oven dried to a constant mass and accurately weighed before sorting. Hand sorting of all foreign material was first carried out on the dried material, followed by wetting, to ensure complete identification and classification of all types of contaminants.

Coarse aggregates	Percentage of weight passing through sieve						
Maximum size (mm)	19	13.5	9.5	6.7	4.75	2.36	150 μm
RCA	100	91.4	28.7	7.6	5.4	4.2	0.5
Basalt	100	84	43.7	5.6	2.1	1.0	0.2

Table 2. Sieve analysis of coarse RCA

Figure 2 shows the distribution of the constituents of RCA batches investigated. The classified lightweight material consist of components with dry density less than 1950 kg/m^3.

As observed in Figure 2, the brick content of the contaminant fraction typically exceeds 50%. Most bricks are normally fired at high temperatures with relatively good dimensional stability and, as such, are potentially suitable for use as concrete aggregates.

The plaster mortar and gypsum-based components of the contaminants, however, warrant some attention despite their overall low levels, averaging 0.04% by weight of total RCA material.

A threshold sulfate content as SO_3, derived either from high sulfate content bricks or from adhering plaster mortar, necessary to induce sulfate attack in cement matrices is required. The use of alternative binders, typically sulfate-resistant cements or blended cements, is being investigated. The effect of all other components such as glass, metal, stone and plastics is considered relatively minor, given their extremely low proportions.

4 Guidelines: coarse RCA utilisation in new concrete

4.1 Material properties

Currently, draft proposals for specifications generally involve commercially produced coarse RCA material of uniform quality with particle density in excess of 2100 kg/m? Typically, contaminant levels, including brick and stony materials, are limited to no more than 1%, whilst general impurity content, comprising friable materials and materials

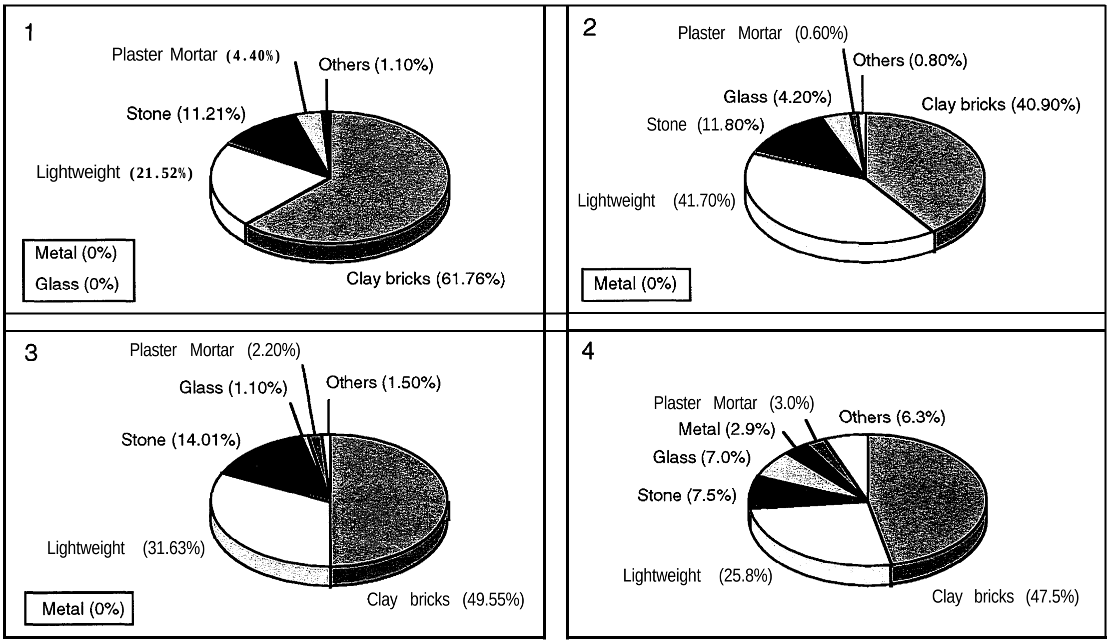

Figure 2. Detailed distribution of constituents of RCA batches

with density less than 1950 kg/m^3, is of the order of 10 kg/m? This class of aggregate may be deemed suitable for production of plain and reinforced concrete up to and including N32, i.e. 32 MPa grade concrete, with possible limits on RCA substitution levels. However, current trials at CSIRO generally disclose similar performance in both fresh and hardened states for fully substituted coarse RCA concrete and natural aggregate concretes with nominal 32 MPa compressive strength.

Whilst long-term tests are still in progress, similar durability characteristics are obtained in medium-term trials up to one year, except for variations in drying shrinkage performance. With the move towards performance based specifications (typified by AS 3600), i.e. fitness for purpose rather that conventional prescriptive specifications, it is anticipated that the RCA content in new concrete will only be restricted to cautionary recommendations for situations where limited technical data exists to support field performance.

Classifications for mixed crushed concrete aggregate and building rubble aggregate for concrete production are also being considered by road authorities, research organisations and local governments. Contaminant levels of these two categories are both limited to ≤5%, in addition to restrictions on maximum water absorption and grading requirements as per AS 1141. It may be expected that guidelines on aggregate quality will include technical detail on mix proportioning and concrete design parameters.

4.2 Guidelines: concrete performance

With regard to fresh concrete properties and concrete rheology, results from trial mixes involving commercial recycled aggregates indicate that premixing/prewetting of RCA in the concrete mixer improves workability of the fresh concrete without impairing the properties of the hardened concrete. The total water content of the aggregates therefore consists of the water contained in the pores of the particles and the free water. As with any concrete, it is the latter that strongly influences the workability, drying shrinkage characteristics and strength of concrete.

It is observed that for RCA concrete, the workability is sensitive to small changes in free water and the sand/aggregate ratio. Hence, achieving equivalent workability to natural aggregates requires a knowledge of the properties of the aggregate.

5 Guidelines: RCA utilisation in road pavement applications

Crushed, graded demolition waste is now widely considered suitable for use in lower layers of road pavement construction, subject to specified requirements. Since the key design criteria in road pavement construction is the performance of the base material under either bituminous or concrete pavements, aggregates for sub-bases and sub-grades must nominally provide uniform strong support and erosion resistance for the pavements. The grading requirements further allow for efficient use of materials with lower grade material at the bottom progressing to the highest quality material close to the surface.

The use of recycled concrete for sub-base preparation in both road and airfield pavement construction has evolved from satisfactory compliance with basic material specifications as summarised in Table 3.

Property	Specification	Test method
Bulk density	1200 kg/m^3	AS 1141.4
Particle density	**2000** kg/m3	AS 1141.6
Water absorption	≤6%	AS 1141.6
Material finer than 2.36 mm	≤3%	AS 1141.11

Table 3. Basic requirements of aggregate for road pavement applications

The requirements of Table 3 are generally supplemented with additional limits on aggregate crushing value, wet/dry strength, durability requirements, ease of compaction and material stability. Other key material properties of RCA generally specified in addition to those discussed previously may include maximum aggregate content, foreign materials content, grading and CBR.

Owing to additional plasticity requirements of different road authorities across the country, blending of RCA with natural aggregate is often required to meet tighter specifications; the proportion of RCA in such blends is generally limited to about 30%.

When cement and fly ash binders are used, both base and sub-base materials attract minimum cement content loading, with a proportion of the total cementitious material specified for fly ash typically no more than 20% for base applications. Restrictions on contaminant levels are marginally equivalent to those given in Table 3 but with limits on chloride and asphalt levels. The SO_3 content is restricted to 0.5 and 0.1% for base and sub-base materials respectively.

Since the presence of sulfates may affect long-term performance and durability of cement-bound systems, sulfate content of non-cohesive materials is nominally required to be less than 1% sulfate as SO_3 for engineered fill applications. As deleterious water-soluble sulfates require the presence of moisture to be harmful, this may be diminished by appropriate drainage or other barrier systems primarily for fill applications.

6 Conclusions

It is concluded that the key constraints to efficient recycling of C&D waste, as identified in this paper, are the control of material uniformity and the development of suitable performance specifications in line with AS 3600 in the case of concrete durability. To achieve this requires the development of quality criteria for recycled products and a review of existing specification.

The research further discloses that contaminant levels of commercially produced RCA is relatively low. This high quality is partly responsible for current initiatives to use RCA in premix concrete production to supplement applications in road pavement construction.

Whilst the potential for favourable high level applications of C&D waste remain, certain constraints restrict rapid entry of recycled products into existing markets in the construction sector. As discussed in this paper, progress towards performance-based specifications for RCA, tailored to specific applications, holds the key to increased product acceptance and new market development.

Properties of concrete incorporating fly ash and recycled demolition waste

K. Sagoe-Crentsil, A. Taylor and T. Brown
Division of Building, Construction and Engineering, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Melbourne, Australia

Abstract
High level replacement of natural virgin resources with secondary materials at all levels of construction provides a unique platform for the efficient management of the solid waste burden. This step, however, requires the development of binders that are tolerant to chemical and physical contaminants characteristic of the solid wastes. The properties of blended cements indicate that given appropriate mix designs, such binders can significantly enhance the properties of concrete and concrete products derived from demolition waste. Blended cements may comprise of Portland cement and industrial wastes, typically blast furnace slag, silica fume or fly ash from coal-fired power stations.

Performance tests have therefore been carried out on the properties of fresh recycled aggregate concrete incorporating fly ash. The results indicate significant improvement in both concrete slump retention and setting characteristics. Also, concrete durability, including permeability and compressive strength, are marginally affected. These findings suggest that higher levels of fine and coarse recycled aggregate replacement in new concrete are achievable with the use of secondary cementitious materials for non-structural applications.
Keywords: Concrete; aggregate; recycling; fly ash; durability; compressive strength; fines.

1 Introduction

The effective use of recycled materials and products remains central to current efforts aimed at optimising available natural resources in building and construction. Globally, the prospects of replacing natural quarry products with recycled concrete aggregates (RCA) in premix concrete production, for specified applications, is rapidly gaining acceptance [1]. This strategy offers clear economic and environmental benefits. In recent years, several studies have been conducted to demonstrate the viability of RCA as a source of quality construction material for use in concrete production [2, 3]. Furthermore, with the fines fraction accounting for up to 40% of the total weight of crushed rubble, there is an obvious need to use as much of this material as possible. However, the implications of RCA properties on mix design and concrete performance appear to be much less established.

This paper evaluates both rheology and the performance of RCA concrete containing significant loadings of RCA fines and fly ash. The ultimate goal, firstly, is to ensure satisfactory use of RCA and, secondly, that concrete structures are designed and constructed in such a way as to serve as a vital source of valuable recyclable material.

2 Experimental

Two separate batches of RCA fines and a single source of commercial-grade coarse RCA were used in the concrete mixes. The mix proportions were designed to provide concrete mixes with a nominal Portland cement content of 325 kg/m^3. The fly ash component was batched as a supplementary addition to the fine sand content rather than as a binder supplement. Fly ash was added to mixes to assess possible improvements in fresh concrete cohesion and workability.

The water/binder ratio of all mixes were adjusted to achieve comparable consistency and, hence, equal nominal slump of 80-t-10 mm. Reduction in the water requirement of mixes was attained by using a water-reducing admixture at the manufacturer's recommended dosage level.

Specimens were cast for compressive strength and shrinkage and cured as required under standard conditions. Table 1 shows the mix details of concrete specimens prepared, with the reference mix designated C2108A. Two sets of specimens were investigated – the first to evaluate the effect of natural fine sand replacement with recycled fines, and the second to evaluate the role of fly ash addition on concrete properties.

2.1 RCA properties

The properties and requirements of crushed concrete for use as concrete aggregate are similar to those of natural aggregates. This includes quality and grading requirements, as well as cleanliness and limits on deleterious matter that could affect the setting and durability of the concrete. Compliance of RCA to strength requirements, flakiness and permissible fines content was closely monitored to ensure satisfactory aggregate performance. Tolerance limits of chloride and sulfate are, however, yet to be established, as well as the potential for alkali-silica reaction. Table 2 shows results of sieve analyses of RCA fines used in the study.

Mix designation	Cement loading (kg/m^3)	W/B	Natural coarse (%)	Natural fines (%)	RCA coarse (%)	RCA fines 1 (%)	RCA fines 2 (%)	Fly ash (%)

Table 2. Sieve analysis of RCA fines

3 Results and Discussion

Significant variations in the fresh and hardened properties of concrete were observed with changes in the proportion and type of RCA fines introduced to the mix. The extent of bleeding of fresh RCA concrete mixes was significantly lower compared to control mixes of equivalent workability, although setting characteristics remained comparable.

Fresh RCA concrete properties and concrete consistency, as determined by the slump test and setting characteristics, have been investigated and found to be generally comparable to control mixes. For instance, laboratory test results on the setting behaviour of RCA based on the penetration resistance tests (Proctor needle) give values of initial and final set as 3 12 and 427 minutes respectively, corresponding to 3 18 and 406 minutes for control specimens made with natural aggregates.

Whilst changes in fresh concrete properties were relatively less pronounced, corresponding modifications to the hardened concrete were more readily measurable. Results obtained from concrete compressive strength and shrinkage characteristics have therefore been used to index the impact of RCA proportioning on concrete performance.

3.1 Compressive strength

Compared to the control mix made from natural materials, a reduction in the compressive strength of RCA concretes was observed at all ages. The compressive strength of concrete mixes up to 91 days are shown in Figure 1. Generally, the rate of strength gain is similar for all concrete mixes regardless of the source and type of aggregate used. The absolute strengths of the different mixes are, however, dependent on both type and

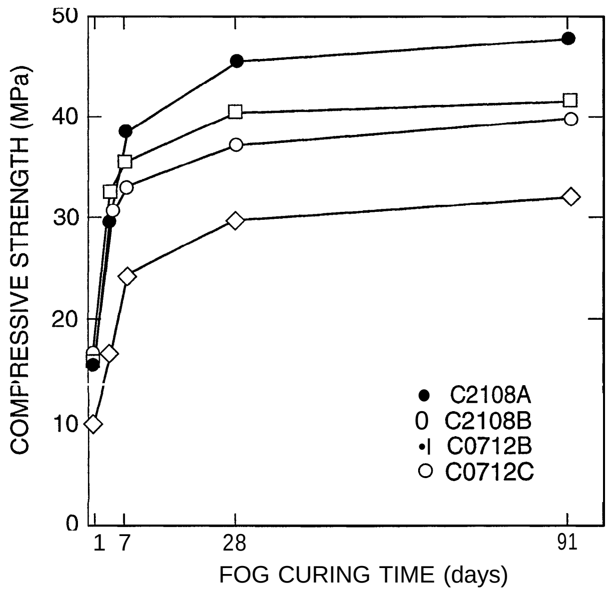

Figure 1. Compressive strength of control and RCA concrete

quantity of aggregate incorporated in each mix. This trend in strength development is further dependent on the proportion of RCA fines.

As shown in Figure 1, a 12% strength reduction is observed at 91 days when natural fines are replaced with RCA fines 1, i.e. mixes C2 108A and C2 108B. Only marginal differences in strength were observed between concretes made with RCA fines 2 and RCA fines 1.

The compressive strength of concretes made with 100% coarse RCA, but containing 50% natural fines, 50% RCA fines, and 100% natural fines respectively were relatively similar. Previous tests, however, have shown that this difference can be as high as 40% [3]. This latter result suggests that the hardened properties of concrete may be significantly influenced by both quality and grading of RCA fines.

The overall strength reduction of the RCA concretes range from about 13% for concretes containing coarse RCA and natural fines, to 32% for mixes containing only RCA materials. Such characteristic strength reductions are in line with published results [1, 4]. This trend is to be expected given that the water demand of RCA concrete often exceeds the requirements of normal aggregate concrete, particularly for mixes including RCA fines, as shown in Table 2.

3.2 Correlation between RCA properties and concrete strength

The strength of RCA concrete primarily depends on the strength of the cement paste and on the bond between the paste and aggregate. The strength of the aggregate also exerts some influence on the strength of the concrete [2], but this is nominal for most normal weight aggregates.

The bond between RCA and the surrounding matrix is influenced by the mineral composition, cleanliness, surface texture, and particle size and shape of the aggregate. Given that cement paste normally bonds better to a rough surface than a smooth or friable surface, residual coatings of clay or carbonated cement dust which adhere to RCA after mixing will alter bond properties.

Surface coatings on RCA generally tends to increase the quantity of fines in the mix and hence water requirements. Furthermore, adhering coatings impair the bond between aggregate and the cement matrix, and consequently the load transfer characteristics, resulting in overall strength reduction.

The quantity of residual fines in the mix, generated either from abrasion of the RCA during the mix or due to improper grading, has the potential to increase water demand. Therefore, within limits, mix proportions should be adjusted to compensate for potential changes in the grading of RCA fines during the mixing process.

3.3 Partial replacement of RCA fines with fly ash

Figure 2 shows plots of the compressive strength development of concrete containing different proportions of RCA fines and additional loadings of fly ash. At 10% additional fly ash loading to the fines content, only a nominal 7% drop in the **9** l-day compressive strength is obtained compared to the control made from totally natural materials. At 20% fly ash loading, the corresponding strength reduction is of the order of 25%.

The pozzolanic properties of fly ash significantly contribute to the later-age strength properties of the concrete, as indicated by the relatively rapid rise in concrete strength between 28 and 9 1 days (Figure 2). Additionally, other durability properties of RCA concrete are likely to be enhanced with the introduction of fly ash. In particular, reduced permeability may be expected [4].

The role of RCA fines in concrete strength development requires further examination with partial replacement of RCA fines with fly ash. In general, significant improvements can be achieved with the inclusion of fly ash as part replacement of the binder. Thus, when fly ash is included as part of the total binder, the optimum loading characteristics would be expected to increase significantly beyond 10%.

4 Shrinkage

The dimensional stability of RCA concrete is critical to satisfactory design in most areas of concrete construction. Figure 3 shows the dependence of concrete drying shrinkage

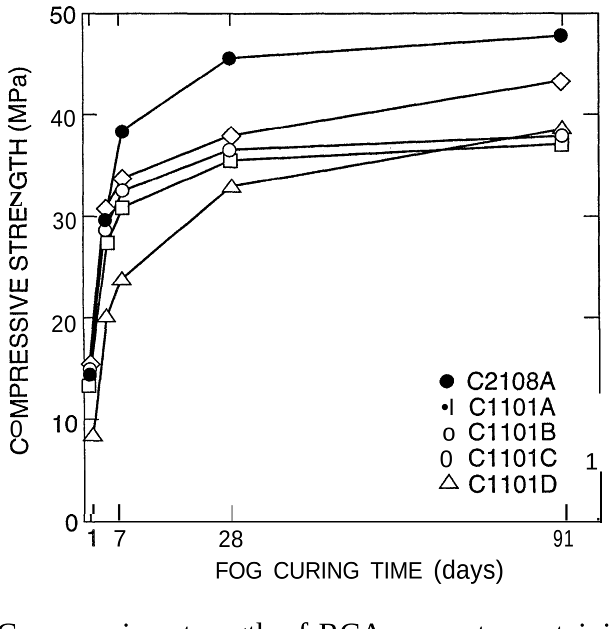

Figure 2. Compressive strength of RCA concrete containing fly ash

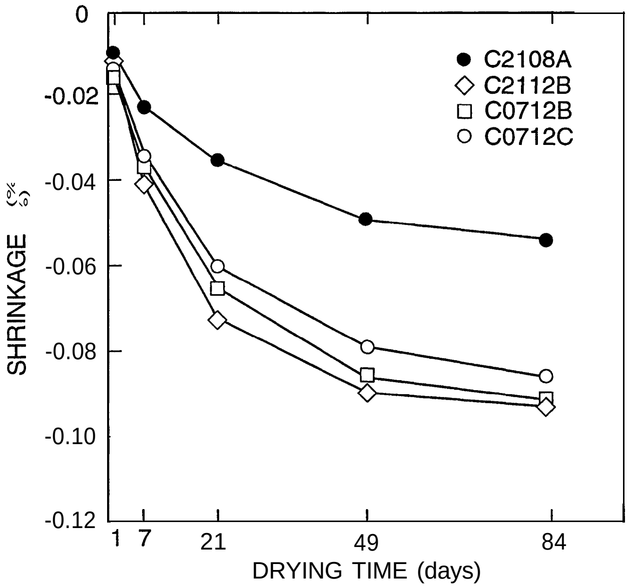

Figure 3. Drying shrinkage of RCA concretes

on RCA fines loading and, hence, water demand of the respective mixes. Compared to the control, shrinkage values recorded for concrete made with RCA coarse and fines at 91 days were 50% higher than control. Part replacement of RCA fines with natural fines marginally affected the shrinkage levels. These findings highlight the sensitivity of concrete drying shrinkage to RCA fines loading in the concrete mix.

It is evident from the results obtained that RCA fines have a significant influence on the drying shrinkage of concrete. This influence largely depends on the extent to which aggregates alter the water content of the concrete. Other RCA properties such as surface texture, grading, particle shape, proportion of fines and maximum aggregate size contribute to different extents to the drying shrinkage of concrete. It is essential also to monitor the absorption of RCA, since excessive absorption rates may produce concrete with very high shrinkage, especially for aggregates contaminated with clay fines.

Figure 4 shows drying shrinkage plots of the control mix and mixes incorporating fly ash. Comparing the shrinkage values of Figure 3 to those of Figure 4 indicates that variations in mix constituents have negligible impact on the overall magnitude of shrinkage for mixes containing RCA fines. It must be recalled that only marginal differences exists in the water to binder ratios of the mixes (Table 2). This trend suggests that while fly ash inclusion in mixes significantly alters later-age compressive strength, there appears to be no corresponding beneficial effect with regard to the drying shrinkage of RCA concrete.

From the shrinkage plots, it is further apparent that significantly higher shrinkage values are obtained for the RCA mixes with or without fly ash. The higher shrinkage values may be linked to the water content of RCA mixes, owing to the presence of excess fines. Thus, it is essential to establish an optimum fines content. Exclusion of RCA fines in concrete mixes has also been proposed in order to control excessive shrinkage [1]. However, the exact role of RCA fines on concrete performance may require further study, specifically the implications of grading and quality of such fines on concrete drying shrinkage and durability.

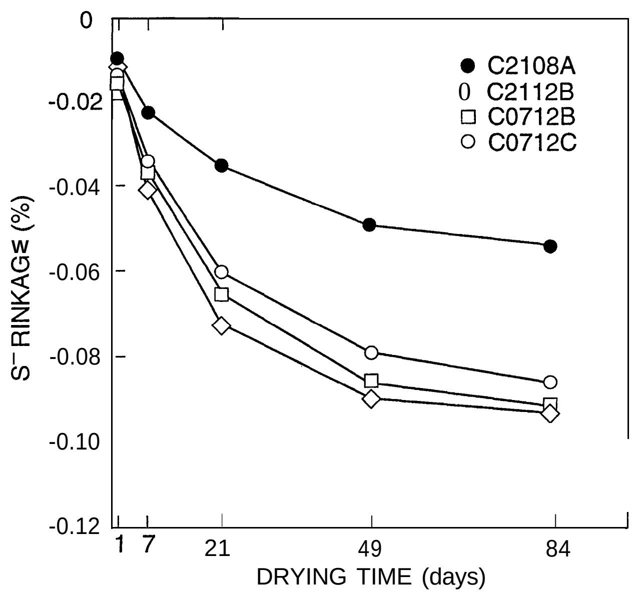

Figure 4. Drying shrinkage for RCA concrete containing fly ash

5 Conclusions

It is concluded from this study that although several fresh and hardened properties of concrete are altered with the use of RCA in concrete, the potential exists to offset some of these deficiencies through proper selection and grading of recycled materials and concrete mix design. The results further indicate that the compressive strength of RCA concrete may be enhanced with the addition of about 10% fly ash to the concrete mix. No corresponding benefits in concrete drying shrinkage were observed.

The extent of bleeding of fresh RCA concrete mixes was significantly lower compared to control mixes of equivalent workability, although setting characteristics remained comparable. However, owing to higher absorption rates of RCA fines, and consequently higher concrete drying shrinkage values, the use of RCA fines should only proceed with due caution and perhaps be limited to specified applications.

The Potential for Solar Powered Desiccant Cooling

S.P. Halliday
GAIA Research, Edinburgh, Scotland, UK
C.B. Beggs
School of Civil Engineering, University of Leeds, Leeds, UK

Abstract
The air conditioning industry has, in recent years, come under sustained attack from a range of economic, environmental and regulatory pressures. Global environmental concerns, improving standards of ventilation and increasing concerns about indoor air quality have all contributed to a sea-change in design thinking. Professional guidance is increasingly steering clients and consultants away from full air conditioning to natural ventilation and mixed mode solutions in new and refurbishment projects. Nevertheless inefficient lighting, increases in computing equipment, and architectural fashion mean that overheating is now the predominant design consideration for new offices in the UK. Older buildings often constrain natural solutions. The situation is likely to worsen if global warming scenarios are accurate. It is vitally important that the building industry seeks innovative methods of maintaining and improving the quality of the indoor environment, under potentially more demanding performance criteria, without increasing the environmental impact. Solar air conditioning potentially offers an elegant exemplar of a clean, sustainable technology which is consistent with UK and International commitment to Sustainable Development. By using solar/gas hybrid desiccant cooling and dehumidification technology it may be possible to offer a benign solution to cooling of buildings, in new as well as refurbishment situations, and significantly reduce greenhouse gas emissions. Desiccant cooling is a potentially environmentally friendly technology which can be used to condition the internal environment of buildings. Unlike a conventional air conditioning system which relies on electrical energy to drive the cooling cycle, desiccant cooling is a heat driven cycle. The feasibility of solar desiccant cooling in the UK is examined in this paper; an investigation on the possibility of using solar energy to drive the desiccant cooling cycle is conducted. Through the use of a parametric study, the energy consumption and costs associated with desiccant cooling are evaluated.
Keywords: desiccant cooling, heat driven cooling, heat powered cycles, solar

1 Introduction

Desiccant materials such as silica gel have long been used to dehumidify air. In such processes, moist air is passed over a surface which is coated with the desiccant substance. As the moist air passes across the surface the desiccant material absorbs moisture from the air, thus dehumidifying the air stream. In order to drive off the moisture absorbed by the desiccant surface, the desiccant then has to be physically moved into a dry hot air stream. In the case of desiccant wheels (one of the most commonly used desiccant systems), the moisture laden section of the wheel slowly rotates (i.e. at 16 revs/hour) from the moist air stream to the hot dry air stream where it is dried out in a process called 'regeneration'.

In a typical desiccant cooling system a desiccant wheel is coupled to a thermal wheel in a single air handling unit (AHU), to produce a system which is capable of heating, cooling, and dehumidifying air, with little or no need for refrigeration [1]. Because it is a heat driven cycle, such a system has the potential to reduce both energy costs and environmental pollution, when compared with conventional vapour compression based systems [2]. Electrical energy consumption is replaced by heat consumption, which in most countries produces much less carbon dioxide (CO,). In the UK the burning of natural gas in a boiler produces 0.21 kg CO_2/kWh whereas delivered electricity produces 0.68 kg CO_2/kWh [3]. In addition, the significant reduction in size, or elimination, of refrigeration plant, results in reduction in the refrigerant charge required. Desiccant cooling affords an opportunity to utilise waste heat and the regeneration temperatures required mean that theoretically they could be coupled to solar collectors to produce an extremely benign cooling system.

2 The system

A typical desiccant cooling system is illustrated in Figure 1, and comprises a thermal wheel and a desiccant wheel located in series. On the supply air side of the AHU, a cooling coil and/or an evaporative cooler is located after the thermal wheel. A heating coil may also be located after the thermal wheel, for use in winter time if required. An evaporative cooler is located in the return air before the thermal wheel to enhance the heat transfer across the wheel. For the purpose of driving the cycle and regenerating the desiccant wheel a heating coil is located between the thermal wheel and the desiccant wheel.

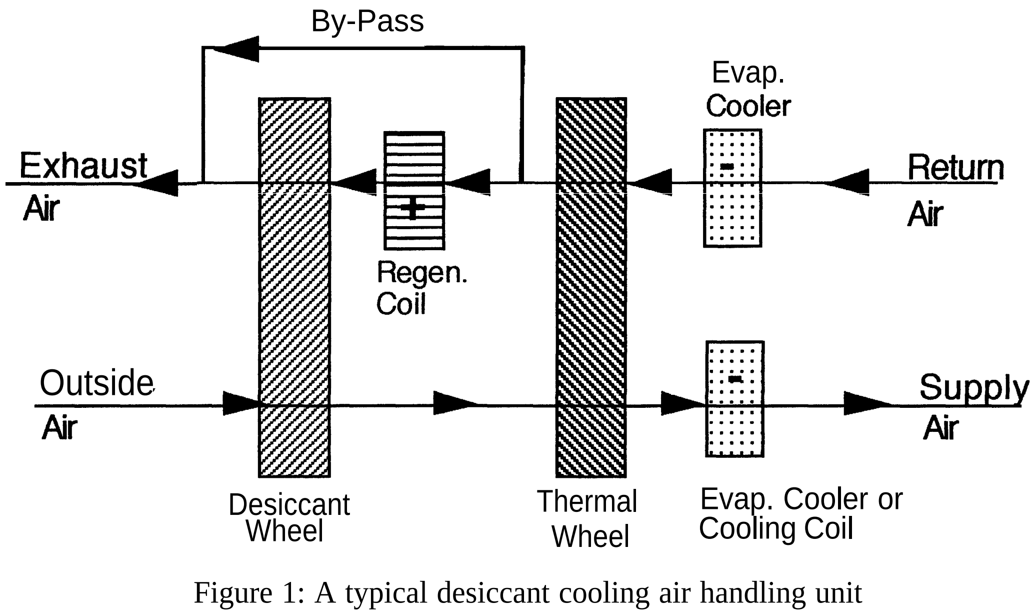

Figure 1: A typical desiccant cooling air handling unit

The cooling/dehumidification process is illustrated by the psychrometric chart shown in Figure 2. During the summer time, warm moist air at for example 26°C and 10.7g/kg moisture content is drawn through the desiccant wheel so that it comes off at say, 39°C and 7.3g/kg moisture content. The psychrometric process line for the air passing through the desiccant wheel on the supply side, has a gradient approximately equal to that of a wintertime room ratio line of 0.6 on the psychrometric chart. The supply air stream then passes through the thermal wheel where it is sensibly cooled to say, 23°C. The air then passes through a small direct expansion (DX) or chilled water cooling coil and is sensibly cooled to the supply condition of say, 17°C and 7.3g/kg moisture content. It should be noted that if humidity control is not required in the space, then the cooling coil can be replaced by an evaporative cooler with an adiabatic efficiency of approximately 85%. In which case, air may be supplied to the room space at say, 16.2°C and 10.2g/kg moisture content.

On the return air side, air from the room space at for example, 22°C and 8.6g/kg moisture content is first passed through an evaporative cooler so that it enters the thermal wheel at approximately 16.2°C and 10.8g/kg moisture content. As the return air stream passes through the thermal wheel, it is sensibly heated to approximately 35°C. The air stream is then heated up to approximately 55°C in order to regenerate the desiccant coil. It should be noted that in order to save energy approximately 20% of the return air flow by-passes the regenerating coil and the desiccant wheel [4].

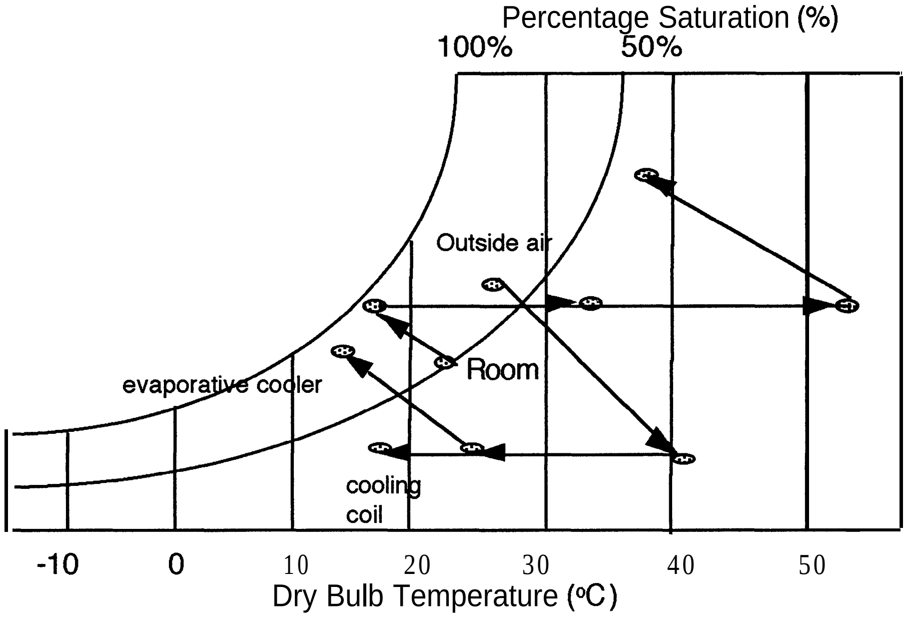

Figure 2: Desiccant system in cooling/dehumidification mode

3 Evaporative cooling

Through the use of a desiccant cooling air handling system it is possible to both dehumidify and sensibly cool the fresh-air supply. However, this often requires the installation of a chilled water cooling coil in the supply air stream. Whilst the installation of a cooling coil might result in an overall energy saving, the downside from the environmental perspective, is the introduction of refrigerants into the system. It is possible to avoid the use of a cooling coil, by installing an evaporative cooler in the supply air stream, to provide the required sensible cooling. However, this strategy has two major drawbacks:

- The air supplied to the room space is humid. Consequently, although the system might achieve the required degree of sensible cooling, it may not be able to provide adequate latent cooling, with the result that the occupants may find the environment uncomfortable. In addition, the high humidity in the room space is likely to lead to condensation problems.
- In order to achieve the required degree of sensible cooling, it is often necessary to perform a large amount of dehumidification on the desiccant wheel. This high level of dehumidification necessitates a high regeneration temperature, and consequently the energy consumption is increased dramatically.

The above drawbacks are significant and as a result most desiccant cooling systems incorporate some form of cooling coil. However, it is important to note that this cooling coil will be considerably less than that which would be incorporated into a conventional fresh air dehumidification system.

4 Solar application

Since desiccant cooling is a heat driven cycle, it would appear logical and synergistic that it might be powered by solar energy. However, the use of solar energy introduces constraints on the application of desiccant cooling. Assuming a ratio of solar collectors to building floor area of 1: 10, then the available heat (in northern Europe) to power the cooling cycle will be (conservatively) in the region of 25 to 50 W/m^2, depending on the climate, type and orientation of the solar collector. Consequently, the heat must be harnessed effectively. The desiccant cooling cycle is an open cycle, which rejects moist air at a high temperature, which is unsuitable for recirculation. Also the parasitic losses may be significant. The greater the air volume flow rate supplied to the room space, the greater the fan power required and the heat energy consumed. Therefore, if desiccant cooling is used in an all air application, the regeneration heat load is many times greater than the available solar energy. However, if the bulk of the sensible cooling within a space is carried out using a water based system such as a chilled ceiling, with the desiccant AHU dehumidifying and 'tempering' the incoming fresh air, then the air volumes handled will be much less and the 'solar energy' may make a significant contribution.

Theoretical work by Beggs and Warwicker has shown that desiccant cooling is best applied to installations in which the bulk of the sensible cooling is performed by a system such as a chilled ceiling [2]. In such an application the desiccant system treats only the incoming ventilation air. Because chilled ceilings are designed to have a dew point of approximately 17°C, it is possible to use low grade chilled water which can be produced using evaporative cooling towers. This avoids the need to install vapour compression refrigeration machinery,

5 The solar desiccant model

In order to investigate the potential for coupling a desiccant system to solar collectors in a European application, a solar desiccant computer model was developed at the University of Leeds. The model simulated the psychrometric and thermodynamic processes associated with desiccant cooling, using the following assumptions:

- The desiccant cooling system was employed solely to dehumidify the incoming fresh air supply, and to provide when required supplementary sensible cooling. It was assumed that the bulk of the sensible cooling would be performed by a separate water based system.

- The desiccant cooling system did not contain a cooling coil. The required degree of sensible cooling being achieved through the use of an evaporative cooler.
- The desiccant cooling system contained a solar heating coil located directly before the regeneration coil.
- The desiccant cooling system incorporated a 20% bypass on both solar heating and regeneration coils.
- Regeneration and supply air temperatures were specified, and the room condition was allowed to vary.

The solar desiccant cooling model considered only the primary and delivered energy consumption associated with the thermal aspects of the desiccant cooling cycle. The associated fan energy consumption was ignored.

6 Methodology

In the theoretical study, the system shown in Figure 3 was analysed in order to determine the running cost, primary energy consumption and CO, emissions attributable to a desiccant cooling system on a m^2 of floor area basis.

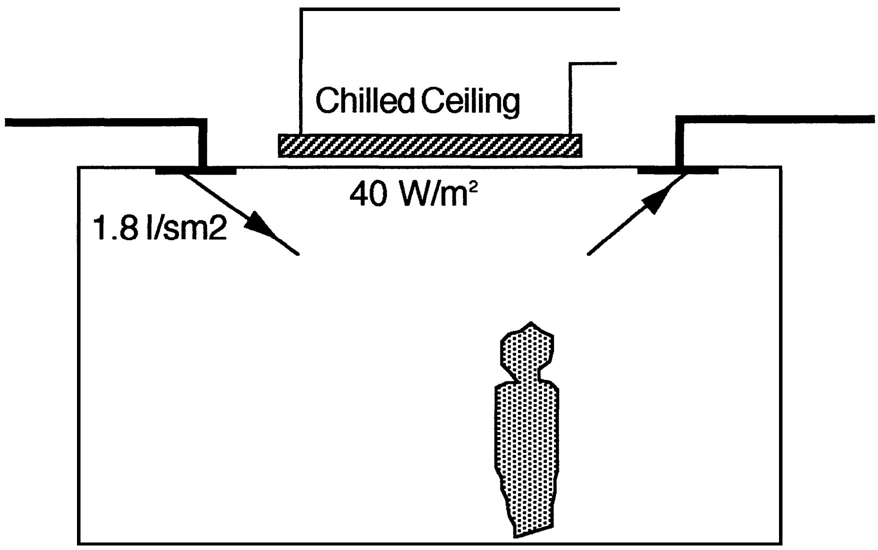

Figure 3: A chilled ceiling application in an office building where fresh air is introduced at high level

The system was analysed in cooling mode only, under the part-load conditions shown in Table 1. The study focused solely on the energy consumption of the desiccant fresh air system. In the study the energy consumption of the chilled ceiling was ignored, since this cannot be connected to a solar energy supply. The maximum sensible cooling output of the chilled ceiling was assumed to be 40 W/m^2. It was assumed in the study that under peak load conditions the desiccant cooling system would make-up the 10 W/m^2 short fall in sensible cooling. However, under part load the desiccant system would supply air to the space at room temperature. The psychrometric processes involved in the study are shown in Figure 4.

	Sensible Heat Gain (W/m2)	Latent Heat Gain (W/m2)	Outside Air Temp (0C)	Outside Air Percent. Sat (%)	Outside Air Moist.Cont. (g/kg)
Loading					
Peak	50	7	30	50	13.7
Mid	40	7	26	50	10.7
LOW	30	7	22	50	8.4

Table 1: Part-load data used in Parametric Study

Throughout the study it was assumed that the solar heating coil was connected to solar panels via insulated pipework, containing a glycol/water mixture having a specific heat capacity of 3.7 kJ/kgK. The glycollwater flow rate was assumed to be 0.0016kg/s per m^2 of floor area, which equated to a solar collector to floor area ratio of 1: 10. The glycollwater flow and return temperatures were assumed to be a constant 60.1°C and 53.9°C respectively, providing 36.7 W/m^2 of heat energy to the desiccant cooling system. In reality this value would vary considerably depending on time, solar insolation, orientation and collector type. However, the purpose of the study was to investigate the feasibility of using solar energy to drive a desiccant cooling installation, and so a constant relatively pessimistic value was chosen.

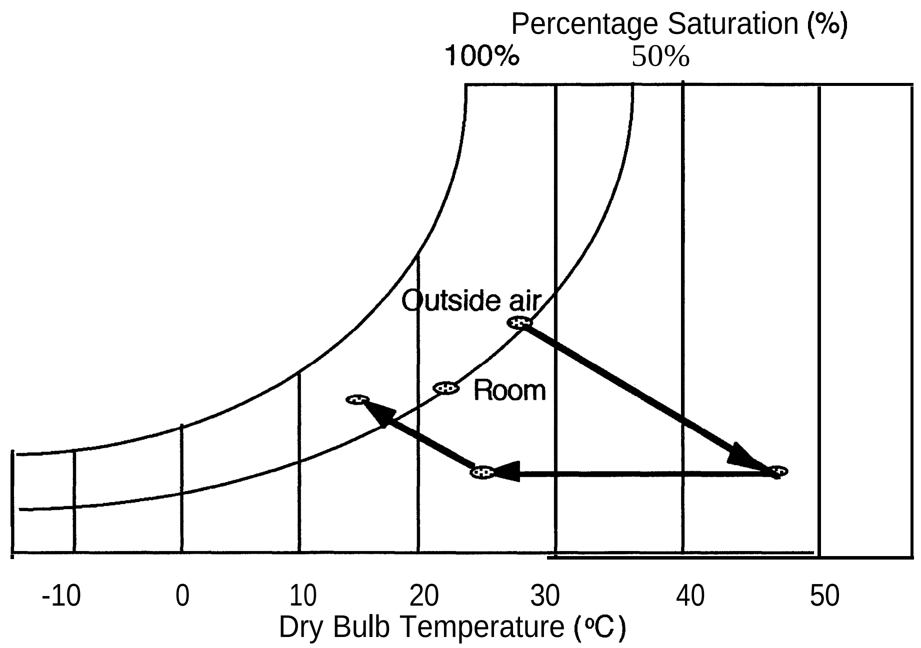

Figure 4: Psychrometric process (For clarity the return air cycle is omitted)

The operating data for the study is shown in Table 2. It should be noted that the degree of sensible cooling achieved by the desiccant cooling system is governed by the degree of dehumidification achieved by the desiccant wheel,-and that this in turn is governed by the regeneration air temperature. In short, the greater the regeneration air temperature, the lower the supply air temperature achievable to the room space. In order to determine the impact of varying the regeneration air temperature on the energy consumption of the cycle, the peak load condition simulation was carried out twice; once with a regeneration temperature of 55°C and a supply air temperature of 20.5°C, and once with a regeneration temperature of 75°C which enabled the supply air temperature to be reduced to 20°C. There was no benefit to be gained from raising the regeneration air temperature

- Section 7, and the remaining part-load simulations were undertaken using a regeneration air temperature of 55°C. The energy data applied in the study is shown in Table 3.

Loading	Supply Air Volume Flow Rate (l/sm 2)	Regen Air Temp. (°C)	Moisture Cont. Leaving Desic. Wheel (g/kg)	Ceiling Cooling output (W/m2)	Sensible Cooling From Desiccant Cooling System (W/m2)	Supply Air Condition Peak

7 Results

The results of the study are shown in Table 4.

System	Regen. Air Temp. (°C)	Supply Air Condition	Room Air Condition	Regen. coil Duty (W/m²)	Delivered gas (Wh/h/m²)	Cost per hour (p/h/m²)	CO_2 produced (kg/h/m²)
Non-solar (Peak)	55	20.5°C & 13.8 glkg	25.0°C & 15.2 glkg	30	43	0.07	0.009
Solar (Peak)	55	20.5°C & 13.8 g/kg	25.0°C & 15.2 g/kg	1	2	0.00	0.000
Non-solar (Peak)	75	20.0°C & 12.2 g/kg	24.5°C & 13.5 g/kg	54	77	0.12	0.016
Solar (Peak)	75	20.0°C & 12.2 glkg	24.5°C & 13.5 g/kg	25	35	0.05	0.007
Non-solar (Mid.)	55	22.0°C & 8.4 glkg	22.0°C & 9.7 glkg	38	54	0.08	0.011
Solar (Mid.)	55	22.0°C & 8.4 g/kg	22.0°C & 9.7 g/kg	9	12	0.02	0.003
Non-solar (Low)	55	22.0°C & 5.1 g/kg	22.0°C & 6.4 glkg	45	64	0.10	0.013
Solar (Low)	55	22.0°C & 5.1 g/kg	22.0°C & 6.4 glkg	16	22	0.03	0.005

Table 4: Analysis results (system incorporating evaporative cooler)

It can be seen from the results presented in Table 4 that coupling the desiccant cooling system to solar collectors produces significant savings in both running cost and CO, emissions. The greatest saving was achieved at peak load. This is because the return air leaves the thermal wheel at a higher temperature, and consequently, the solar heater is almost able to achieve an air temperature of 55°C without much help from the regeneration coil. However, despite the impressive energy savings achieved, based on these assumptions, the results indicate that operation of the system without a cooling coil is quite impracticable for most applications, since it results in high room air humidities. Indeed, for the installation shown in Figure 3 the results indicate that for much of the year condensation would occur on the surface of the chilled ceiling. However, this problem can be overcome by replacing the evaporative cooler by a small DX or chilled water cooling coil. If the study is repeated using a cooling coil instead of an evaporative cooler, then the results achieved are those shown in Table 5.

System	Regen. Air Temp. (°C)	Supply Air Condition	Room Air Condition	Regen. Duty (W/m²)	Delivered gas (Wh/h/m²)	Delivered electricity (Wh/h/m²)	Cost per hour (p/h/m²)	CO_2 produced (kg/h/m²)
Non-solar (Peak)	55	17.5°C & 10.2 g/kg	22.0°C & 11.5 g/kg	32.1	7.0	45.8	0.10	0.014
Solar (Peak)	55	17.5°C & 10.2 glkg	22.0°C & 11.5 glkg	2.5	7.0	3.6	0.04	0.006
Non-solar (Mid.)	55	22.0°C & 7.3 glkg	22.0°C & 8.6 glkg	38.9	0.4	55.6	0.09	0.012
Solar (Mid.)	55	22.0°C & 7.3 glkg	22.0°C & 8.6 g/kg	1.1	0.4	1.6	0.00	0.001
Non-solar (Low)	55	22.0°C & 5.1 g/kg	22.0°C & 6.4 glkg	45.0	0.0	64.2	0.10	0.013
Solar (Low)	55	22.0°C & 5.1 glkg	22.0°C & 6.4 glkg	16.0	0.0	22.9	0.03	0.005

Table 5: Analysis results (system incorporating cooling coil)

Table 5 shows that the inclusion of a refrigerated cooling coil increases CO, production under peak-load conditions, however for most of the year it will be inoperative and thus the overall increase in CO, would be minimal. It should also be noted that despite the removal of the supply air evaporative cooler, the solar collectors are still able to significantly reduce the overall energy consumption, and CO, emissions of the system.

The results in Table 5 indicate that for most of the operating year the conditions achieved in the room space would be acceptable. However, the peak load results suggest that condensation might still be a problem if a regeneration air temperature of 55°C is used. Consequently, under peak load conditions it would be advisable to increase the regeneration air temperature to say 75°C which would achieve an acceptable room air condition of 22°C and 9.1g/kg moisture content. If the operating conditions of the solar panel are optimistic then it is likely that these regeneration temperatures could be achieved during peak demand.

8 Conclusions

The energy study reported in this paper represents an initial study to determine feasibility of coupling solar collectors to a desiccant cooling system in an northern European application. To this end the study has been successful, since it has demonstrated that the inclusion of a solar heater into the desiccant cooling cycle can result in large energy savings. Indeed, under the mid and low load scenarios the thermal energy costs are negligible.

The main conclusions to be derived from the energy study are as follows:

(i) The inclusion of a solar heater into the desiccant cooling cycle can lead to significant savings in primary energy consumption and associated CO, emissions.

(ii) Due to desiccant cooling being an open cycle, solar energy can only be effectively used in applications where the supply air volume flow rate is small. This effectively limits its application to installations where the bulk of the sensible cooling system is undertaken using a water based system.

(iii) The regeneration air temperature should be kept as low as is practically possible, in order to minimise fossil fuel energy input.

(iv) There is little or no benefit to be derived from using an evaporative cooler on the supply air side. The inclusion of such a device can result in increased energy consumption and unacceptably high air humidities in the room space. It is preferable to include a small refrigerated cooling coil, which is only used under conditions of peak load.

The study is at an exploratory stage and further work will investigate the consequences of varying supply volumes and regeneration temperatures. Solar data from a sample site will be used to provide realistic profiles of water supply temperature.

Visualisation of 3-D city model on the Internet

Jie Shan , Michael Schmitz*
Department of Technology
University College Gavle
Gävle, Sweden

Abstract
In conventional GIS (Geographical Information System) technology and applications, the third dimension in reality is either ignored or treated as an attribute. Based on this methodology, only terrain surface can be incorporated and managed. However, urban planning and environment management demand the incorporation of, and interaction with man-made objects on top of the terrain, such as buildings in a GIS environment. The interaction and the analysis afterwards can only be best performed through effective 3 -D visualisation.

This article applies advanced Internet-based 3 -D visualisation technologies in visualising 3-D city model. In order to reach an effective visualisation, buildings should first be modelled in geometry, topology and appearance. This is done by using VRML, an advanced 3-D graphics standard for Internet-based visualisation and virtual reality. Textures and background images are also added to reach a photo-realistic effect. Because of the platform independence of VRML standard, any Web browser supporting VRML can be used to render the created world through the Internet.

In this article, a brief conceptual introduction to the 3-D city model is made, followed by an overview of visualisation technologies, where VR on the Internet and its development tool VRML are addressed. Methodology for modelling buildings with VRML in termes of geometry, topology and appearance are described with detailed examples. A virtual city environment for the campus of University College Gavle, Sweden is created and can be manipulated through the Internet. Further development towards an Internet-based desktop VR environment for virtual city is prospected.

1. Introduction

Geographical Information System (GIS) is nowadays widely applied in urban planning and environmental management, and is becoming essential in many quantitative analyses in these areas [1][5][6]. However, conventional GIS technique uses the 2-D map as a basis for managing 3-D geographical data and planning decision. In this methodology, the third dimension is either ignored or treated as an attribute. Though this is sufficient for describing physical terrain surface, man-made objects on top of the terrain in urban environment, such as buildings, traffic networks, i.e., a 3-D city, can not be managed. Advances in 3-D computer graphics and visualisation technologies are making it possible to model, manage and visualise the reality in a true 3-D mode.

The emerging of Internet technology and its spreading application are making the distribution, query, display and processing of geographical data possible through and on the Internet. The demand on visualising geographical data on the Internet environment is becoming higher. Although the geographical data can be visualised through the Internet via using different image formats (in 2-D), the interaction with the data and the stereoscopic effect are not possible without using advanced 3-D graphical tools running on the Internet.

This article applies advanced Internet-based 3-D visualisation technologies in visualising 3-D city model. A virtual city environment for the campus of University College Gävle, Sweden is created and can be manipulated through the Internet. The remainder of this article is organised as follows. Section 2 gives a brief conceptual introduction to the 3-D city model, followed by an overview of visualisation technologies in section 3, where VR (Virtual Reality) on the Internet and its development tool VRML (Virtual Reality Modelling Language) are addressed. Section 4 describes the methodology for modelling buildings with VRML in termes of geometry, topology and appearance. Sample results together with discussions are given in section 5, before this article is summarised in section 6.

2. 3-D city model

3-D city model is a three-dimensional digital description of an urban environment. Instead of conventional phenomena in physical geography depicted on topographical maps, such as terrain, vegetation area, water bodies, a 3-D city model is mainly composed of man-made objects, especially buildings, culture constructions, and traffic networks.

In order to establish a 3-D city model and manipulate it effectively, three fundamental issues are involved, namely constructing the models or modelling, managing the model based on database technologies so that spatial query is possible, and visualising the model [3][5][6]. 0nce the modelling process is completed, visualisation will be served as an interface for effective spatial query and analysis. This article will mainly discuss the modelling and visualisation issues.

A complete modelling should include geometric, topologic and thematic issues of the 3-D city. Geometry determines the size, shape and local or global location of any object in the 3-D city. The relative relationship among objects is described by topologic modelling procedure. Thematic modelling assigns the geographic objects with attributes. Besides, for visualisation purpose, objects in a 3-D city model will be given colour, texture, image etc. to model their appearance.

3-D city model is used in diverse areas. Urban planning needs 3-D city model for city development. Telecommunication industry is in need of 3-D city model to best locate mobile transmission stations in urban environment. A realistic virtual 3-D city can help architects with designing new buildings in an interactive mode. Tourists may experience the virtual 3-D scene before the on-site visiting.

3. Visualisation technologies

As a subject of computer graphics, visualisation has dynamically been changing its technologies in the past decades. 3-D graphical display and processing capabilities are now as a standard function in desktop environment, such as on workstation and high-end PCs. Industrial graphic libraries, like Open GL and Open Inventor, have functions to perform complex graphic processing tasks, such as shading and hidden element removal, which would otherwise be done only with lengthy codes.

Recent advances in computer graphics lead to a demanding research and application subject - virtual reality (VR) [4], which presents a compelling concept: a natural and effective interaction between user and computer through visualisation. The display of a 3-D city model, integrated with possible interaction, is called virtual city. Through an effective interface one can walk-through the city, go shopping and even chat with other people who are visiting the virtual city at the same time [5]. Thematic information about the current visiting place is available by clicking the mouse button on any interesting area. Once the 3-D city model is geo-referenced, it will act as a 3-D map with accuracy and realism, shared and connected locally and globally.

The integration of Internet and visualisation technology makes it possible to render the 3-D city model over the Internet. For this purpose, the VRML is developed, which is now acknowledged as an industrial standard for VR development over the Internet. The created VRML file can then be rendered via a browser, such as Cosmo Player, to get three dimensional effect and perform man-machine interaction. The current (1997.12) version VRML 2.0, released in August 1996 and revised as VRML97 in April, 1997, is capable of handling animation and integrating multimedia, such as sound, movie and image [2].

4. Modelling buildings with VRML

4.1 Introduction to VRML

VRML uses a hierarchical scene graph to describe the 3-D world [2]. Entities in the scene graph are called nodes. Nodes store their data in fields. Nodes can contain other nodes and may be contained by more than one nodes. By organising the nodes and specifying their values, one can model the geometry and topology of the geographical data. Illumination and appearance of the world can be defined by corresponding nodes as well. In addition , image textures can be transformed and added on top of the geographical surface, such as terrain and urban area. Another distinct characteristic of VRML is LOD (Levels Of Detail).The world is first defined in different versions of detail. VRML browser will automatically choose and display the appropriate version of the world based on the distance from the viewer.

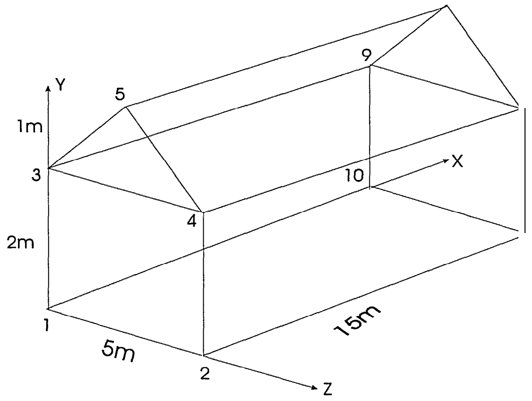
One can interact with the view so that any part of the world, as long as it is modelled by VRML, can be examined in any path at any orientation and at any scale. Textures can be pasted on the surface of the world as to obtain a photo-realistic result. In such a way one can experience the immersion into the geographical environment through navigating the virtual reality.

4.2 Modelling buildings

Modelling is to establish a description of the world based on a grammar which is interpretable for a visualisation system. It is the first step in visualisation. A comprehensive description should minimum include the geometry, topology and appearance of the world, illumination condition and viewer attitude.

Buildings should be modelled in geometry as well as in topology. In addition to giving the coordinates of vertices composing a building, their connectivity, namely how the faces are formed by which vertices, should also be specified. Following VRML codes are used to describe the building beside

```
Shape {
 geometry IndexedFaceSet {
   coord Coordinate {
    point [ 0 0 0
      0 0 0, 0 0 5, 0 2 0, 0 2 5, 0 3 2.5,
      15 0 5, 15 2 5, 15 3 2.5, 15 2 0, 15 0 0, ]
  }
   CoordIndex [
   1,2,4,3,-1,4,5,3,-1,2,6,7,4,-1,6,10,9,7,-1,7,9,8,-1
   1,3,9,10,-1,3,5,8,9,-1,5,7,8,5,-1,1,10,6,2,-1]
 }
}
```



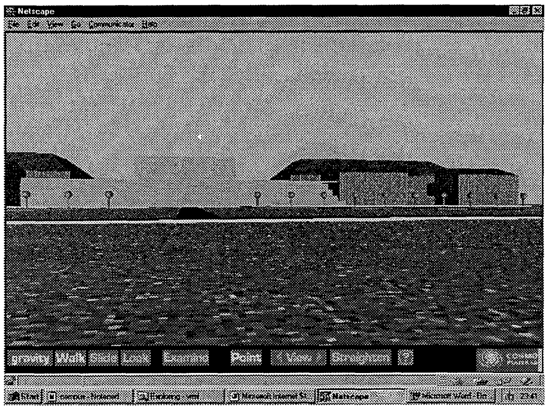
Modeling a building

4.3 Modelling the appearance

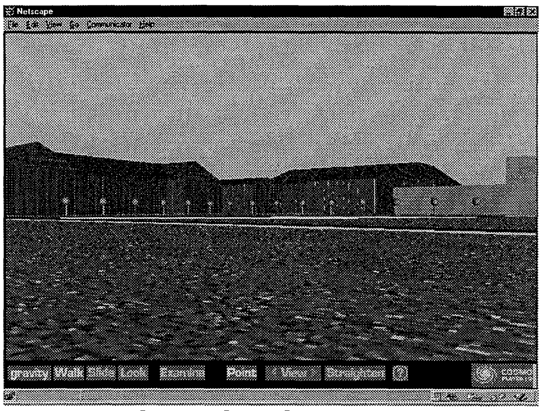
The appearance will affect the final effect of visualisation. There are various optional parameters to choose in VRML, such as the location, direction and type of illumination, reflection properties of the world, types of colour and texture, scale etc. To simulate the reality and the circumstances one views the object, directional light from upper-left (north-west) is chosen. The surface of the world is often chosen as having diffuse reflection. Initial attitude of viewing location is also carefully determined so that a proper initial view can be obtained.

5. Sample results and discussion

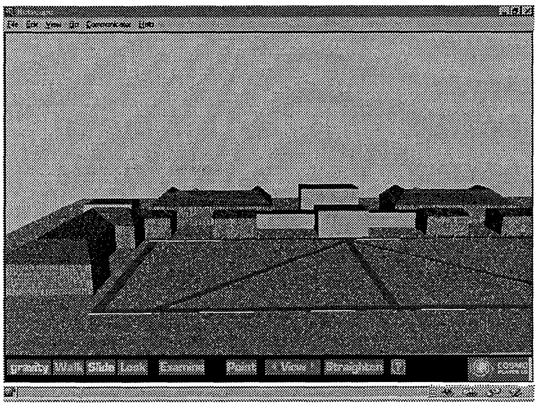
A VRML world for the campus of University College Gävle, Sweden is created. It includes buildings, trees and grasslands. The file is composed by text editor based on the building blueprint and aerial photographs. Sample results are given in following figures.



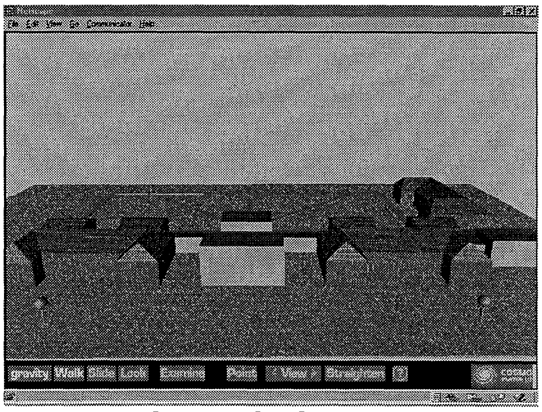
a. Back-left view



b. Back-right view



c. Back bird-view



d. Front bird-view

Geometric primitives, colours and textures are used in the creation of the virtual world. Cosmo Player and World View are chosen as browsers. By clicking interesting location on the view one can examine that spot at a larger scale, animate the scene via panoramic view and fly through the view.

There are optional parameters in the VRML for a programmer to choose proper appearance such as colour, intensity, illumination, initial view etc., however, they are hardly to determine with minor efforts. Creative author tool for this purpose is thus recommended to obtain optimal visualisation result.

6. Summary

3-D city model can be applied in, among others, urban planning, tele-communication, tourism, transportation, architecture and environment management. The integration of visualisation technologies and Internet enables the Internet-based visualisation. VRML offers powerful functions to model the 3-D city, which can then be rendered through a browser over the Internet. As for the future work, a VR system for integrating modelling, rendering and querying the 3-D city is expected to be developed in a desktop environment.

Functional analysis as a method to design new building components

P.N. Maggi, M. Rejna and F. Ravetta
Politecnico di Milano, Dipartimento di Ingegneria dei Sistemi Edilizi e Territoriali

Abstract
The paper presents a method to develop a functional analysis as a tool for designing new building components well balanced with respect to the different aspects of the technological quality: performances of a component at the beginning of service life, during service life and maintainability.

The analysis begins from a set of hypothesis of functional models which foresees different organisations of the distributions of functions through the structure of the component. These are the functions which the component must be able to develop in order to assure the technological performance goals, i.e. the functions strictly linked with the performances.

This analysis goes on through a set of actual models; every actual model comes from one of the previously set out functional models and foresees different choices of functional elements of the-component; every functional element will have defined values of the functional characteristics, i.e. the characteristics linked to performances, that must be held by the materials chosen to form the component (see paper "Methodology and experimental programme to evaluate building components and service life", Politecnico di Milano, DISET).

In this way it is possible to achieve the goals of a design of innovative building components within a policy of sustainable construction approach, which implies a balanced use of materials and natural resources without compromising the ability of future generations to satisfy their needs.
Keywords: Building components, durability, functional analysis, maintainability, performances, service life, sustainable construction.

1 Introduction

The paper's subject takes place in the general theme of the Symposium "Material and technologies for sustainable construction" and, in particular, in the main theme "Performance, durability and service life".

The problem's solution of the sustainable development in building sector passes through the individuation of the priorities in the choice of the materials to be used in the design and the production of building components. The choice of these materials must take into account their compatibility with the global equilibrium of use of natural resources. Therefore only the materials of which this compatibility is recognised should be taken into account for an environmental conscious building process.That is to say materials which minimise the intrinsic energetic waste of the involved raw materials, the energetic waste due to the transformation into building materials, the waste implied by an eventual recycling to reduce the environmental impact.

Within some years at DISET, Politecnico di Milano, it has been developped researches, coordinated by prof. P.N. Maggi, about setting up of evaluation methods for the three components of building components technological quality: zero time quality (characteristic quality) quality during service life (durability) and maintenance quality (maintainability).

This paper, related with other papers titled: "Methodology and experimental programme to evaluate building components service life" and "Experimental programme to evaluate building components service life: an application", reports about the functional analysis (see Figure 1 and Figure 2), as a building components design method; it allows to operate a choice in the following terms:

- at the beginning the materials selection and/or building components is based on a service life optimisation. In this design phase are calculated the real dimensions which avoid materials over-usage. The innovation which this paper, related with the two others, is proposing is the goal of a full rationalisation of the entire process, from the conception and design until the service life and the maintenance;
- in a second step will be operated, if necessary, a further reduction of the choices, considering only those materials recognised as compatible with a sustainable construction.

2 Building component functional analysis method

The functional analysis method allows to define during conception and design phase a building component belonging to a given class. In this way it is possible to define also its performances parameters values (characteristic quality, durability, maintenance quality and executive quality).

In the conception phase the design process can be controlled following the iter here indicated.

Given, for a specific list of building components classes, a fundamental functions package, individuated as those functions which generate the building components technological requirements, can be built the working model of the building component.

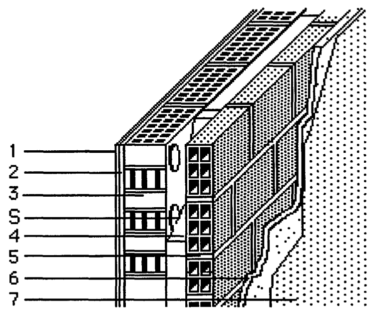

Figure 2: Building component design process

This model (functional model + actual model) individuates where are applied the specific functions which characterise the building component.

The fundamental functions of the functional model come from the technological requirements of the specific building components class and each of them consists in several analytical functions (see figure 3). The building component technological requirements compose the building component behaviour model.

To be noted that one behaviour model can generate several functional models which even if alternatives one to each other, are all coherent with the generator model.

The successive phase consists in an elaboration of alternatives of actual models all coherent with a given functional model.

For the elaboration of the alternatives of the actual models, starting from the spots of the corresponding functional model, these spots are transformed in a functional elements structure.

To each functional element are assigned the analytical functions groups to be accomplished and then the corresponding functional characteristics and the value ranges which these characteristics must show.

To be noted that for each functional model can be individuated several actual models, but coherent.

The successive phase consists in the design of a building component which for each actual model, previously identified, implies, for each functional element of the model, the choice of the materials which must meet the functional characteristics coherent with those admitted by the corresponding actual model.

To be noted that each actual model can generate several designs of building component (see Figure 1).

At this point of the functional analysis, the methodology allows to optimise the choice of the design of the building component either for durability or for maintainability.

For the durability optimisation will be chosen those materials which show the smaller functional obsolescence of their functional characteristics.

As far as the maintainability optimisation is concerned will be chosen those materials and the configuration of the building component which make easier the maintenance interventions, i.e. which maximise the value of the availability to maintainability and then minimise the average time of repairing.

Figure 3: Division of fundamental functions into analytical functions for external non-bearing walls

3 Conclusions

Applying the functional analysis methodology to the design phase of a building component it is possible, through successive approximations, to rationalise and optimise the process, obtaining a correct dimensioning of the single materials responding to the individuated functions, and which compose the building component functional elements.

The design development following the exposed criteria, if from one side allows to obtain a saving in terms of material resources, from the other side can become an instrument finalised to the design of innovative products in the respect of the sustainable construction.

It is actually possible, following the individuated design process, to orient the choice to innovative products already present on the market or to promote the conception and design of other ones, compatible with the functional models and with the durability and maintainability objectives established.

The conception and design of innovative products above prefigured, compatible with the global equilibrium of use of natural resources, can be operated by organisations coherent accordingly to ISO14001.

Environmental evaluation of external clay brick masonry

I. Oberti, A. Ratti, L. Roveda, S. Piardi
Politecnico di Milano, DITEC, Milan, Italy
L. Morfini
CNR ICITE, Milan, Italy

Abstract
The paper presents part of an ongoing research programme into the Environmental Impact of Buildings. It concentrates on environmental impact of external clay brick masonry, which is the most widespread technical solution in Italy. The aim of the study is to help designers in taking decisions about low impact building techniques. Eighteen clay brick masonry systems having the same thermal transmittance value have been studied. Each system has a different environmental profile and an attempt was made to evaluate them, according to the following parameters: resource quality, embodied energy, recycling possibility, environmental effects.
Key words: clay brick masonry, comparison among technical alternatives, design, environmental profiles, low impact building techniques, sustainable construction.

1 Introduction

The research deals with the problem of environmental quality of certain technical design solutions for external walls; brick technology has been selected as the prime focus of the study because it is the most widespread technical design solution used for buildings in Italy. The research was carried out through six phases:

1. Definition of technological solutions directory
2. Definition of functional unit
3. Drawing up of descriptive cards for the technical solutions and calculation of the included materials
4. Impacts inventories for the main materials: bricks and insulating materials
5. Implementation of an electronic sheet for the environmental effects calculation
6. Drawing up of comparative environmental profiles for the main solutions.

Each of these phases is described in detail below.

1.1 Definition of a technical solutions directory

Brick walls may be built using different solutions that vary from one another according to the kind of brick used, the kind of insulating material (fireboard, expanded materials - organic or inorganic), according to its position in the wall (on the outside face, in the cavity, on the inside face), as well as the different succession of elements in the wall and the possible presence of cavities. In this study the following functional models have been considered:

Functional Model	Technical Solution	Type of wall
Externally insulated wall	Hydraulic plaster on insulation	Single layer wall
Ventilated wall	Ventilated wall	Single layer wall
Insulated cavity wall	Double layer wall	Double layer wall
Internally insulated wall	Thin partitions	Single layer wall

Table 1. Functional models and technical solution analysed in this study

Altogether, 18 technical design solutions have been selected and each of them has been considered with seven different insulating material; such an inventory of 126 alternative technical solutions was analysed in this project.

1.2 Definition of a functional unit

In order to make a comparison between the various design solutions, the functional unit was fixed as follows:

- surface of external wall: 1 m^2;
- thickness and layers: to obtain, for each solution, a fixed thermal transmittance value: 0.375 W/m^2K;
- durability: 30 years.

To obtain the required thermal transmittance value thicknesses of different design solutions vary therefore in relation to the kind of bricks and insulating materials chosen

1.3 Description of design solutions and calculation material characteristics

Description of the chosen technical solutions have been worked out as shown for example in Figure 2. Each solution has been described in a format that takes into consideration the material properties, number of layers, their position, presence of an air gap layer etc.

which considers its materials, layers and thicknesses. Figure 2 shows an example of card.

1.4 Inventory of impacts for the most important materials: bricks and insulating materials

Information on bricks have been taken from an environmental analysis developed by ANDIL (Associazione Nazionale degli Industriali del Laterizio, Italy)[2]; information on mineral and natural insulating materials have been drawn from a bibliography on the subject; information on polymeric materials have been drawn from APME (Association of Plastic Manufacturers in Europe). The data were referenced to **1** kg of finished product considering its whole life cycle.

1.5 Calculation of environmental effects; implementation using an electronic 'sheet'

An electronic sheet was developed in order to collect inventories' data and to transform them into the specific contributions to environmental effects of each functional unit. The environmental effects that were considered are the ones given according to the CML methodology[4]: i.e., greenhouse effect, ozone depletion, human toxicity, photochemical oxidant formation, acidification and nutrification. Moreover, the sheet calculates the global energy consumption of a given solution as well as the quality of the resource.

VENTILATED WALL

Figure 3. Electronic sheet for the calculation of the contribution to environmental effects of the Insulated Cavity Wall (continued from previous page)

1.6 Comparative environmental profiles for the most significant technical solutions

In order to compare the different technical solutions, the contributions to environmental effects were transformed into graphic profiles, as show Figures 4a to 4f below.

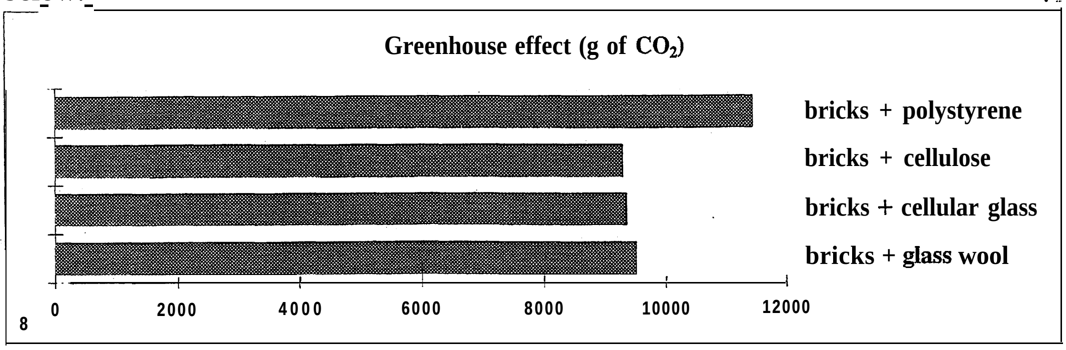

Figure 4a. Comparison among environmental profiles of insulated cavity walls having different insulating materials

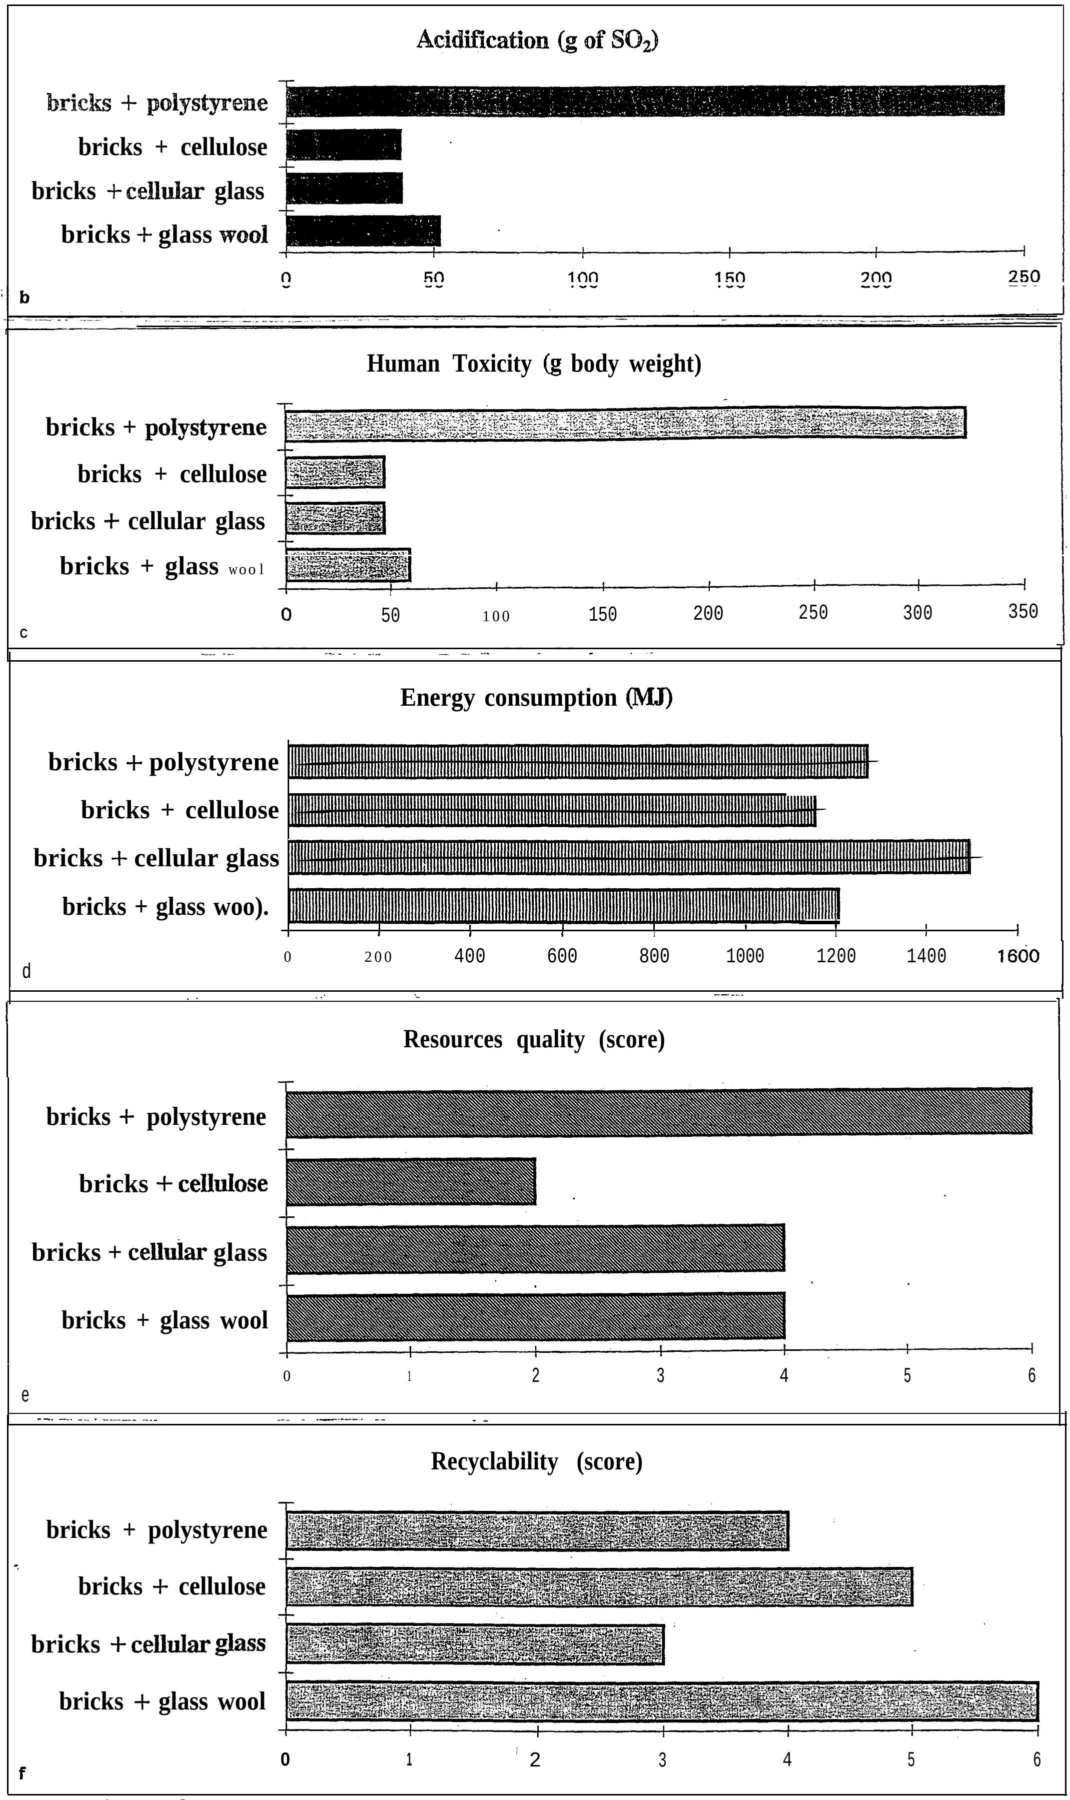

Figure 4b to 4f. Comparison among environmental profiles of insulated cavity walls having different insulating materials (continued from previous page)

2 Commentary on profiles

Profiles allow both to make a comparison among alternative technological solutions and to assess the consequences of different materials used in the same solution; in particular, the profiles reported in Figures 4a to 4f show how the use of different insulating materials within an insulated cavity wall modifies the contribution to the main environmental effects.

The analysis points out, for instance, that polystyrene implies more impacts as regards nearly all of the environmental effects (in particular, it proves to highly contribute to the greenhouse effect, human toxicity and photooxidation), yet it involves a more reduced energy consumption and a higher recyclability, since, through incineration, it is possible to recover the embodied energy.

Some remarks can be made about cellulose fibre. This material is considered to have a low environmental impact mainly because it is produced with recycled paper and in fact it has a low “quality of resources” profile; however, as regards environmental effects such as the “greenhouse effect” and “acidification”, cellulose fibre shows almost the same profiles as other insulating materials (excepted polystyrene).

3 Summary and conclusions

The results worked out in the research can be regarded as a contribution to designers’ choices, providing data and information in a readily available format that normally would be difficult to find and hence compared. Such results could be summed up as follows:

- implementation of a tool (the electronic sheet) for collecting, assessing and comparing environmentally relevant data; such a tool could be implemented for all the other technical solutions in buildings;
- comparison among 18 solutions of external vertical walls.

However, the analysis has revealed some difficulties: the availability of correct and comparable data, the unavoidable subjectivity of qualitative assessments, that can vary in relation to the context; the necessity to simplify the estimation of durability of the design solutions. The functional unit definition can also be improved, by introducing other parameters, in addition to the one of thermal transmittance: e.g., acoustic insulation, fire behaviour and mechanical performance.

This research should be implemented in order to deal with more reliable data and to be extended to other technical solutions of buildings. It is in fact increasingly urgent to provide designers with simple tools that improve their capability to make choices aimed at bringing about sustainable construction.

"Recoverability" of building elements in recovery intervention

E. Dal Zio and F. Vergine
Institute of Architecture and Urban Studies, University of Padua, Italy
R. Paparella
Department of Mechanical and Structural Engineering, University of Trento, Italy

Abstract

The present work takes in the themes about the rescue of building materials, i. e. the prevention and reduction of building debris and is founded on the concepts of sustainaible development and resource conservation.
The considerations from which the research presented during this article start, concern the difficulties in order to identify waste areas, and still less to assess the enviromental impact and the high cost for transport and dumping of the discarded material.
Therefore the expectation, since the planning phase, of what can be preserved and/or reused to reduce building debris quantity, becomes more and more important.
For us is also remarkable to deem many elements have to be preserved because of their intrinsic architectonic value or for their integration with the environment where they are put in or, still, like an historic evidence.
After the individuation of the necessity about the building elements evaluation, that serve by way of proem for each projectual choice, the work aim has been the description of a methodology that let to define in a well-pondered manner the "level of recoverability" of the element in order to be functional for the achievement of the set goals.
The worked-out methodology concern:
- the splitting up of the building into "intervention ambits", defined as a pool composed by elements and/or works, arranging in a common spatial ambit but having different functions and whose mutual interfacing relations have to be assessed;
- the accomplishment, for each intervention ambit, of an accurate investigation about health conditions and recoverability of the made-up building elements and their degeneration level;
- the accomplishment of an analysis concerning individual elements either under the valuation of the diagnostic angle fulfilled through the awarding of linked scores and the definition of a parameters sequence which enable the designer to decide whether to repair or to replace the element under consideration.
For each option a detailed form with related information is worked-out.
The originality of this work lies in the identification and definition of parameters and related scores that have to be specified in detailed forms and during the elaboration of the related forms. The parameters to be considered are not strictly referred to technological valuation, but they take into consideration also architectonic and operative aspect.
Keywords: Building recovery, recycling of construction materials.

1. Introduction

The present work stems from the necessity to single out tools able to manage the complexity of the problems related to recoverability of building materials in recovery interventions.
With the word “rescue” we refer especially to restoration and recovery interventions i.e. those are finalized to conserve the building and to assure that its function through a thematic pool of works which respecting the typological, morphological and structural elements permit a destination use compatible with it.
Such interventions include consolidation, restoration and renewal of building constitutive elements, introduction of accessory elements and plants requested by the modified use demands, removal of not related elements.
A building Knowledge phase [1], that we consider essential, must precede a rescue project it must be accomplished thoroughly and systematically.
Only the complete knowledge of the building as to specific historic, technological and functional references (construction techniques, materials, system types, construction date, original use, alterations, urban regulations, etc.) will allow properly oriented and timely arranged interventions , when necessary, for the maintenance.
A recovery project have to follow a precise path:
- the building knowledge through investigations in situ, surveys, etc;
- the determination of the building health conditions through specific procedures;
- the elaboration of specific forms related to health conditions of building in its complex and in its constitutive parts stressing the building pathologies and eventually their causes (etiology);
- the valuation of the convenience either to repair and/or to substitute damaged elements.

For a correct analysis the building have to be splitted up into “intervention ambits" defined as a pool composed by elements and/or works arranging, in a common spatial ambit but having different functions and whose mutual interfacing relations have to be assessed (i.e. in the intervention ambit “facade”, would be mandatory to valuate the interface problems between external frames and vertical external walls).
During the knowledge phase for each intervention ambit is necessary to accomplish an accurate investigation about the health condition and the level of recoverability of the constitutive building elements and their degradation level.
First of all, the concept of “recoverability” must be defined .
The word “recoverable material” is referred to material that can be reused and/or recycled.
From a conceptual point of view the two words “reuse” and “recycle” indicate two different concepts.
“Reuse” indicates a new use for the cast off product and is related to products or components that are reused as such, after verifications or functional control.
“Recycle” indicates the activity of processing debris.
It happens after plysical/chemical treatments in order to allow the production of secondary raw material, or energy or for purposes different from original.

2. Valuation of recoverability

The elements can be classified according to their recoverability level with regard to their recyclability o reusability,in the following way:
- constituent materials of not recoverable element, not recyclable and not reusable;
- not recoverable elements, not recyclable and not reusable;
- recyclable and/or reusable constitutive materials;
- recoverable elements for appearance not recoverable for performance;

- recoverable elements for appearance and for performance;
- recoverable elements , recyclable and reusable.

After examination of the recoverability degree of each element, the entire amb'it is evaluated to decide wich level of intervention will be chosen according to the specification of intervention types.

Building intervention levels are shown in hierarchical order from 0 to 6 and define what can be carried out at each level.

Level 0: Routine maintenance: internal and external paintwork, painting etc.;

Level 1: Remaking works of completion and finish materials: floors, sanitary wares, doors, windows, replacement of drain pipes, remaking of roofing, etc.;

Level 2: Complete remaking works of the plants included the replacement of waterpipes and under track elements (heating, wiring);

Level 3: Functional conforming works with displacement and addition of internal walls, bathrooms and services: remaking foundation, plants internal partitions, etc.;

Level 4: Strengthening works concerned loadbearing structures in situ (foundation, vertical, horizzontal and inclined structures).

Level 5: Replacement works of loadbearing structures (vertical, horizontal and inclined structures).

Level 6: Demolition and total rebuilding.

Once completed the procedure, it can be developed a technical-economic valuation of intervention, without forgetting the cost of waste disposal.

The related diagnosis, based upon the analysis of intervention ambit health conditions, and the valuation of different parameters will lead to define the intervention level.

The valuation whether or not it is convenient to repair and/or to substitute the damaged elements is not only based on diagnosys and economic data but it refers to others parameters.

For example after a building analysis, an element can be judged excellent regarding its performance but not proper for its appearance.

Viceversa an element below standard regarding its performance could not be substituable for its appearance.

Therefore we can conclude that substitution is not a necessary consequence of damage.

3. Parameters

The singled out tools are useful to reduce as much as possible the subjectivity of opinions related to elements health conditions based on use of words such as bad, middling, good; infact we think that such words are not able to describe the complexity of all factors involved.

Therefore a series of parameters have to be defined and used during analysis on each element through attribution of a combined score system; such scores will enable the designer to decide whether to restore or to replace the element under consideration.

The parameters to be considered will not only refer to technological valuation, but also to the architectural aspect.

Before evaluating the recoverability degree of building elements, the possible bonds (active) on the building have to be considered as determinant.

The analyzed parameters are part of a non exaustive list (open list) in which new specific parameters for a particular intervention can be later inserted.

The considered parameters are as follows:

- appearance: it is a parameter useful for valuation; in fact it can condition the decision because some elements could be not substituable for their intrinsic architectural value.
- use compatibility: the element must be compatible with its use.
- compatibility among materials; incompatibility among materials can produce pathologies of different importance.

- restoration and recovery costs: valuation of whether it is economically convenient to substitute or to maintain a degradated element should consider also the cost of transportation and dumping and/or storage of the replaced element; we should compare the cost of substitution of the element (interface problems included) with the cost of repair and maintenance of a new element with the cost of maintenance of a repaired element.
- morphological integration: the technical elements that are placed in the same intervention ambit must be adequate one with each other regarding their form;
- functional conformity: the element have to be conformed from the functional point of view to the new demands;
- enviromental respect: the element during its production whether in situ or when it is pulled down, must not damage the enviroment.
- correspondence to fundamental requirements such as: security, comfort, usability, integrability, appearance, management, enviroment protection.

Such requirements are related to fundamental specifications contained in Regulation CEE n. 106189.
Once completed the procedure, it will be possible to define wich level of intervention should apply and to determine a priori the quantity of discarded material should be dumped.
In any intervention ambit, each element will have score varying between 0 and 10 (0 = very bad condition; 10 very good condition), the addition will be done for each element and it could totalize a score variable between 0 and the maximum resulting from the number of parameters multiplyed by 10; it follows that, chosen the 50% value as a discriminant limit, the element will be substituted if the total score is under 50%; it will be maintened if the total score is over or equal to 50%.
After taking into account all parameters for each element, the intervention ambit, in its complexity, have to be considered.

4. Methodology

The worked-out methodology is based on the splitting up of the building into “intervention ambits" as these definied in the introduction and its development is composed. by three phases:

- decription;
- estimation;
- intervention.

For each ambit three forms sequenced with one of the three phases are looked on.
The first phase concern the development of an accurate investigation about the health conditions and recoverability of the constructive component element, and their degradation level.
The individuation and description form (Table 1) is related to this phase.
Instead the investigation/valuation form concern the second phase (Table 2).
In this form each element of the intervention ambit is inspected (directions are related to the inspection level and to the quantity to be inspected) and it is valued reused or not.
The valuation for each element, based either on value or diagnostic analysis, should be estimate by a score coming out from a total points for each parameters.
At the end to support the intervention phase an operative form (Table 3) is seen.
This form supply for indications concerned interventions and procedures for their execution.

5. Conclusions

The methodology described in the present work is applicable to recovery interventions and allows to determine in advance the extent of the demolitions and consequently the quantity of materials to be dumped, reused and/or recycled.
Moreover, such method let us relate quickly each project choice to the production either of debris or of recovery material. Such a result can be expressed in specific forms.
It is important to underline that it is an experimental method still in fieri that offers a wide list of parameters list; such parameter may allow the best project strategy.

Alternatives to Plasticized PVC for Flooring Tiles

J. Campanelli, M. Bani-Hani, D. Banu, D. Feldman
School for Building, Concordia University, Montreal, Canada

Abstract
Materials used in building applications are currently selected based on the principal criteria of cost and performance. However, sustainability is increasingly becoming an important selection consideration. The impact of a building material on the indoor environment must thus be addressed. For flooring applications, calcium carbonate-filled poly(vinyl chloride), PVC, has long been the material of choice for both flexible sheeting and tile products. PVC-based formulations have the necessary combination of physical properties and low cost to suit the needs of the application. However, these formulations must be processed with plasticizers, which have recently raised some concerns from a sustainability point of view. Plasticizers are low molcular weight additives that can contribute to the generation of volatile organic compounds, and to the growth of potentially hazardous microorganisms over the lifetime of the flooring product.

In the research work reported here, calcium carbonate-filled formulations based on polyolefin plastomers, POP, are prepared in a laboratory-scale mixer, and their physical/mechanical properties are studied for flooring applications. Plastomers are olefin copolymers synthesized using new metallocene catalyst technologies. These technologies allow the physical and mechanical properties of plastomers to be tailored to suit specific applications. The POP plastomer used in this research is a copolymer of ethylene and octene, and does not require any plasticizers for processing. The key physical/mechanical properties of the calcium carbonate-filled POP, which include tensile strength, elongation and impact strength, are found to compare very favourably to those of PVC formulations at filler loadings of 200 phr. In addition, the filled POP formulations are able to incorporate a significant amount of post-consumer recycle high density polyethylene while maintaining adequate physical properties. These results indicate that calcium carbonate-filled POP should be studied further as a more sustainable alternative to filled PVC for flooring applications.

Keywords: flooring tiles, plasticizer, polyolefin plastomer, poly(vinyl chloride), recycled high density polyethylene.

1 Introduction

PVC has a wide variety of applications. It is second in volume only to polyethylene, with sales in North America of 6.2 billion kg in 1995 [1]. Roughly 53% of PVC resin production is used in the building industry [2]. Indoor applications include wall coverings, coatings, flexible flooring, baseboards, blinds, and profiles for windows and doors. Unmodified PVC homopolymer is quite stiff and rigid. The same is true of the PVC copolymers used in flooring applications. These physical characteristics can be altered through the addition of plasticizers, low molecular weight additives that act to reduce molecular binding forces and increase flexibility. Typical families of compounds used as plasticizers include the phthalates and benzoates. The plasticizers are miscible with both homopolymer and copolymers, and can thus be present in a wide range of concentrations depending on the finished product. Extruded profiles require relatively low levels, while the plastisols used for flexible flooring, and the . organosols used for coatings, require much higher plasticizer concentrations. Plasticizers have been traditionally considered to be inert and non-volatile. However, there is growing evidence that plasticized PVC products can be a source of volatile organic compounds (VOC) in buildings [3].

Plasticizers are known to migrate to the surface of a PVC product over time. At the surface, they may become volatilized, or subjected to microbial degradation. This kind of degradation is especially prevalent in humid environments. As a result, plasticized PVC flooring products often suffer from discoloration due to unsightly bacterial and fungal growths. In addition to the esthetic drawbacks, microbial growth on plasticizers also presents a number of risks to human health and well-being. The microbes break down the plasticizer molecule into more volatile components, which are subsequently released into the enclosed building environment. Inhabitants may thus be subjected to long-term exposure of low-level VOC. The microorganisms may also increase the susceptibility of the polymer chain itself to biodegradation, leading to the possibility of volatilizing halogenated organics. Finally, the plasticized surfaces may provide a breeding ground for microbes, which can then spread throughout the building. These considerations point to the need for research into more sustainable alternatives to PVC-based indoor building materials.

In many ways, plasticized PVC is ideally suited to flooring applications. The PVC imparts excellent impact resistance, stiffness and toughness to the final product, even at filler loadings in the range of 200 to 300 phr (parts per hundred resin).

Conventional polyolefins, produced by Ziegler-Natta catalyst technologies, have been unable to match the balance of properties required for flooring applications. However, new families of polymers have recently been commercialized based on metallocene catalysis. Metallocene catalysts allow for site-specific polymerization of olefins and other monomers. The resulting polymers tend to have narrower polydispersity, a controlled degree of branching, a controlled length of the branches, and the ability to incorporate a variety of comonomers into the backbone. These polyolefin copolymers may be termed either a polyolefin plastomer (POP), or a polyolefin elastomer (POE), depending on whether the comonomer amount is low or high, respectively. Because of this flexibility in polymer synthesis, metallocene-based resins have a wider range of physical properties than traditional polyolefins [4]. The properties can also be carefully controlled to suit specific applications [5]. For this reason, the new resins are making quick inroads into packaging, wire and cable, and some specialty markets [6]. In the preliminary study presented here, formulations of filled POP have been produced at the laboratory scale, and tested for flooring applications.

POP-based formulations can have important advantages over PVC-based ones. The first advantage is that filled POP can be processed without the use of plasticizers, thus avoiding problems associated with VOC emissions and microbial degradation. The second advantage in using POP is the potential for incorporating post-consumer recycle. Over 75% of recycled plastics is estimated to consist of polyolefins. Incorporation of these materials into PVC flooring tiles would lead to large reductions in physical properties because of the poor miscibility between PVC and polyolefins. POP, on the other hand, is compatible with recycled polyolefin resins, which could thus be used as extenders to lower costs. The effect of recycle content on POP formulations is therefore studied as well in this work.

2 Methodology

The methodology section is divided into a description of the materials used, and of the experimental procedures for compounding and testing the physical and mechanical properties.

2.1 Materials

In order to evaluate POP relative to PVC as a resin for flooring tile applications, formulations were prepared using both types of resins. These formulations are indicated in Table 1.

The PVC resin, Oxy 1810, was obtained from the Occidental Chemical Corporation (USA). It is a PVC copolymer with vinyl acetate (VAc), having a specific gravity of 1.37, and a VAc content of 9.7%. The POP resin, Affinity PF 1140, was obtained from Dow Plastics (USA). It is a copolymer synthesized from ethylene and octene monomers, and has a specific gravity of 0.895, and an octene comonomer content of 14.0%. The calcium carbonate was obtained from Steep Rock Resources in Perth, Ontario. The grade used was Snowhite 12, which has a specific gravity of 2.71, and a mean particle size of 12 microns. For PVC formulations, a technical grade of dioctylphthalate (DOP) was used as a plasticizer, and dibutyltin dilaurate (DBTL) was used as a heat stabilizer. For both polymers, a technical grade of stearic acid was used as an external lubricant. Both stearic acid and DOP were obtained from Fisher Scientific. DBTL was obtained from American Chemicals Ltd.

Some formulations were prepared with post-consumer recycle high density polyethylene (PC-HDPE), obtained from Enviroplast Inc. of Ville d'Anjou, Quebec, and has a specific gravity of 0.93 and a melt index of 0.1 dg/min. Formulations were also prepared with both POP and PC-HDPE in concentrations totalling 100 phr. PC-HDPE contents of up to 80% were tested in these formulations.

Component	PVC Formulations	POP Formulations
	Concentration, phr	Concentration, phr
Resin	100	100
Filler, $CaCO_3$	**200**	**200**
Plasticizer, DOP	**35**	**-**
Stabilizer, DBTL	**3**	**-**
Lubricant, stearic acid	**2**	**2**
PC-HDPE	**0**	**20, 50, 80,** 100% of total resin content

Table 1. PVC and POP-based formulations prepared and tested.

2.2 Experimental Procedures

Raw materials were compounded in a Haake Rheomix 600 equipped with roller blades. The operating conditions for the mixer are summarized in Table 2.

Formulation	T, ^oC	Blade speed (rpm)	Mixing time (min)
PVC-based	140	**40**	**6**
POP-based	175	**60**	10

Table 2. Operating conditions in the laboratory mixer.

The compounded material from the mixer was then molded by compression using the following procedure. The sample was placed in the mold on the heated platens for **5** min. in order for the polymer to melt. It was then kept under pressure for 3 min., and subsequently air cooled under pressure at room temperature for 5 min. The platen temperature was 158 ^oC for PVC formulations, and 178 ^oC for POP ones. For POP formulations containing PC-HDPE, the molding procedures were modified slightly. The platen temperature used was 178 ^oC, but the melting time, the time under pressure, and the cooling times were 7 min., 4 min., and 10 min., respectively. From the molded samples, specimens were prepared for the tensile and impact tests. Specimens for tensile tests were cut with the Type V die specified in ASTM D638 [7].

Tensile and impact tests were performed for all PVC and POP-based formulations. The tensile tests were carried out in accordance with the procedures outlined in ASTM D638, using an Instron universal testing machine at a crosshead speed of 5 mm/min. for POP/PC-HDPE blends, 10 mm/min. for PVC samples, and 20 mm/min. for POP samples. Impact tests were carried out using the notched Izod procedure given in ASTM D256 [8] with a model 92T Tinius Olsen impact tester.

All the specimens for tensile and impact strength were tested one week after their preparation. They were conditioned at 23 ± 2 °C and 50 ± 5% RH for 48 hours before testing. All of the indicated values are an average of at least five determinations. The coefficients of variation inferior to 10% were taken into account for each set of specimens tested.

3 Results and Discussion

Table 3 summarizes the results obtained in the tensile and impact tests for the formulations described in Table 1.

Resin	Yield Stress, MPa	Break Stress, MPa	Elongation, %	Impact Strength, J/m
PVC	2.77	5.55	336	154
POP	3.92	**7.29**	1420	299
PC-HDPE	-		0	72

Table 3. Results of tensile and impact testing.

The tabulated data show that the physical properties of the POP-based formulations compare very favourably to the PVC-based ones. In particular, the higher values in elongation and impact strength point to superior toughness in the POP samples. This point is significant since high filler loadings have large adverse effects on the toughness of composites made with conventional polyolefin resins. The results also indicate that the POP resin can likely accomodate calcium carbonate loadings in excess of 200 phr while maintaining adequate physical properties.

Table 3 shows that formulations containing solely PC-HDPE as the resin have very poor mechanical properties. The calcium carbonate loading of 200 phr is clearly much too high for the PC-HDPE to function as an effective binder. Formulations using a blend of POP and PC-HDPE resins were therefore prepared and tested.

Mechanical properties were determined for the POP and PC-HDPE formulations containing recycle contents of 20%, 50% and 80% of the total polymer concentration, as indicated in Table 1. These results are presented below in Figures 1 through 4. Figures 1 and 2 show an increase in yield stress and a decrease in break stress with increasing recycle content. This behaviour is characteristic of a loss in the elasticity of the blend upon addition of the recycle resin, and is to be expected. The dramatic decrease in elongation shown in Figure 3 is also not surprising, since elongation is a property known to be sensitive to the previous thermal history of recycled resins. In fact, the incorporation of only 20% PC-HDPE leads to an almost threefold reduction in sample elongation. The loss of elastic properties due to the incorporation of recycled resins is well documented, and is frequently translated into a decrease in toughness. However, for the case of POP containing PC-HDPE, there is a notable increase in impact strength, as seen in Figure 4. In fact, there is an almost 40% increase in the impact strength when 50% PC-HDPE is incorporated into the POP formulation. This surprising result is due to the close chemical similarity of the HDPE and POP macromolecules - both being polyolefins. Thus, the PC-HDPE appears to be similar to an impact modifier in increasing toughness. The incorporation of post-consumer recycle into POP-based flooring tile formulations at fairly high loadings appears to be quite feasible based on this study of physical properties alone.

4 Conclusions

A polyolefin plastomer has been used to produce formulations containing 200 phr calcium carbonate. Similar formulations based on PVC copolymers are typically used in the flooring industry for flexible tiles and sheets. The POP-based formulations were found to have physical properties superior to the PVC ones. In addition, the POP formulations offer two significant advantages over PVC. Firstly, no plasticizers are required in their production, thereby eliminating a hazardous class of chemicals currently used in PVC-based flooring products. Secondly, POP formulations were shown to be capable of incorporating large amounts of post-consumer high density polyethylene with acceptable reductions in key physical properties. In fact, the impact strength of recycle-containing POP formulations was found to increase. Such a result would not be possible for the incorporation of recycled polyethylene into PVC-based formulations. It can thus be concluded that POP resins warrant further' detailed investigation as more sustainable alternatives to PVC in formulations for flooring products.

Application of aggregates out of construction- and demolition waste in road constructions and concrete

Ch.F. Hendriks
Faculty of Civil Engineering and Geosciences, Delft, Holland

Abstract

This paper describes the reuse of construction and demolition waste as aggregates in road constructions for subbase layers and in concrete. From the total amount of 14 Mton produced every year ca. 85% is recycled in this way. The applications are based on results of research programmes running since 1980. Also, specifications are made. In addition to the technical quality, the environmental properties of the aggregates were investigated. In The Netherlands these aggregates have to meet the demands in the Materials Order Decree. This concerns composition and leaching limits. To meet these limits the demolition process and the upgrading of the outcoming waste have to be executed in such a way that the recycled aggregates are not polluted with for example asbestos, heavy metals or PAH.

Therefore a quality certification system is developed which describes the process to be followed and the quality control of the resulting materials. The quality certificates integrate the technical and environmental aspects in one procedure.

Because of the good outlook for application of these aggregates in future the authorities decided that dumping of construction and demolition waste is forbidden in the Netherlands since April 1st 1997.

The economical aspects of the applications described in this contribution are until now in favour for use in road constructions. Replacement of sand or gravel in concrete is most of the time not cost saving until now.

Keywords: summary of certification, environment, recycled aggregates

1 Application of aggregates out of construction- and demolition waste in road construction and concrete

In the Netherlands, 85 % of construction- and demolition waste is processed and made suitable for application in road construction or in concrete construction. Asphalt too is largely reused.
Table 1 reflects the most important applications.

Table 1. Field of application of Recycled aggregates

type of recycled aggregates [1)] application	RCA	RA	RMA	RHMA	RSA	RCS	AG	BAG
road construction hardening layer out of stone-mixture	+	+	+	+	-	-	-	-
stabilised layer	-	-	-	-	-	-	-	+
sand for embankment and supplement	-	-	-	-	-	+	-	-

RMA = recycled masonry aggregate
RHMA = recycled hydraulic mixed aggregate
RSA = recycled sand aggregate
RCS = recycled crusher sand
AG = tar containing asphalt aggregate
BAG = bounded tar containing asphalt aggregate

1.1 Production of recycled aggregates

The care with which the producer accepts the construction and demolition waste and with which he then produces recycled aggregates is determining the quality of the recycled aggregates.
Procedure of acceptance and processing of construction and demolition waste into recycled aggregates and the delivery of these at the customer can be seen as a primary

process. To support this primary process other processes like for example, purchasing, selling, maintenance and management of the material, etc. have to be recognised.

Means for discussion of the subject is a clear, uncomplicated and by that fast accessible description of the primary process given in the form of an elementary process diagram (see fig. 1). With it the in enclosure A entered technique diagram has been used.

In the process diagram the elementary process is reflected with, directly linked, a verification of points in the process, whereas careless handling has a direct effect on the end quality of the recycled aggregates.

*Explanation of the in fig. **1** represented process diagram for the procedure at acceptance andprocessing of construction and demolition waste.*

1. **Inspection at location at source of supply**
   If possible, an inspection of the for demolition due object or building object has been performed by which one has registered the for reprocessing suitable materials.
2. **Arrival of construction and demolition waste**
   The construction and demolition waste will be evaluated.
3. **Identification at means of transport**
   The cargo then visually will be judged on quality and type. The acceptance regulation shows which requirements the incoming material has to meet.
4. **1” acceptance**
   If the cargo successfully has passed through the preceding phase further handling can follow.
5. **Weighing**
   The cargo will be weighed and administratively incorporated. Administration takes place according to an established procedure. The at least to be registered information’s are adapted into this guideline.
6. **Dumping of construction and demolition waste**
   The cargo will be dumped and then, in second place, visually judged on quality and type. The requirements the construction and demolition waste has to comply with are stated in the acceptance regulation.
7. **2^{e} acceptance**
   On account of the visual judgement the cargo can be approved or still be refused.
8. **Approved construction and demolition waste**
   The construction and demolition waste will be separately stored by sorts.
9. **Transportation**
   The construction and demolition waste will be transported to the processing site.
10. **Pre-sieving**
    The material with a grading < 10 mm can optionally be sieved, depending on the environmental quality of the fine fraction. The material, called crusher sieve sand, that hereby will be released, will separately be stored.

11. **Crushing**
The remaining material will be crushed.

12. **Selection**
During transportation to the main sieve installation, irregularities are removed out of the material (iron by way of a magnetic band, wood by way of air infuse or rinsing with water, other contamination's by manual selection).

13. **Sieving**
The material will be sieved on various fractions. Upper sieve (> 40 mm) will once again be crushed.

14. **Selection (separate)**
Wood and other light metals are manually and or mechanically removed.

15. **Recycled aggregates**
The generated recycled aggregate will be tested according to the requirements set in this regulation. If the lot will be rejected it can be retreated or separately stored and removed as rejected material.

16. **Storage**
The recycled aggregates will be stored separately, by type/class.

17. **Recycled aggregates in storage**
The storage is organised as such that mixture and/or contamination is impossible.

18. **Purchase**
During delivery various data's are registered according to set procedures. The recycled aggregate can, in accordance with the specifications of the buyer and corresponding with the requirements set in this assessment guideline, be delivered.

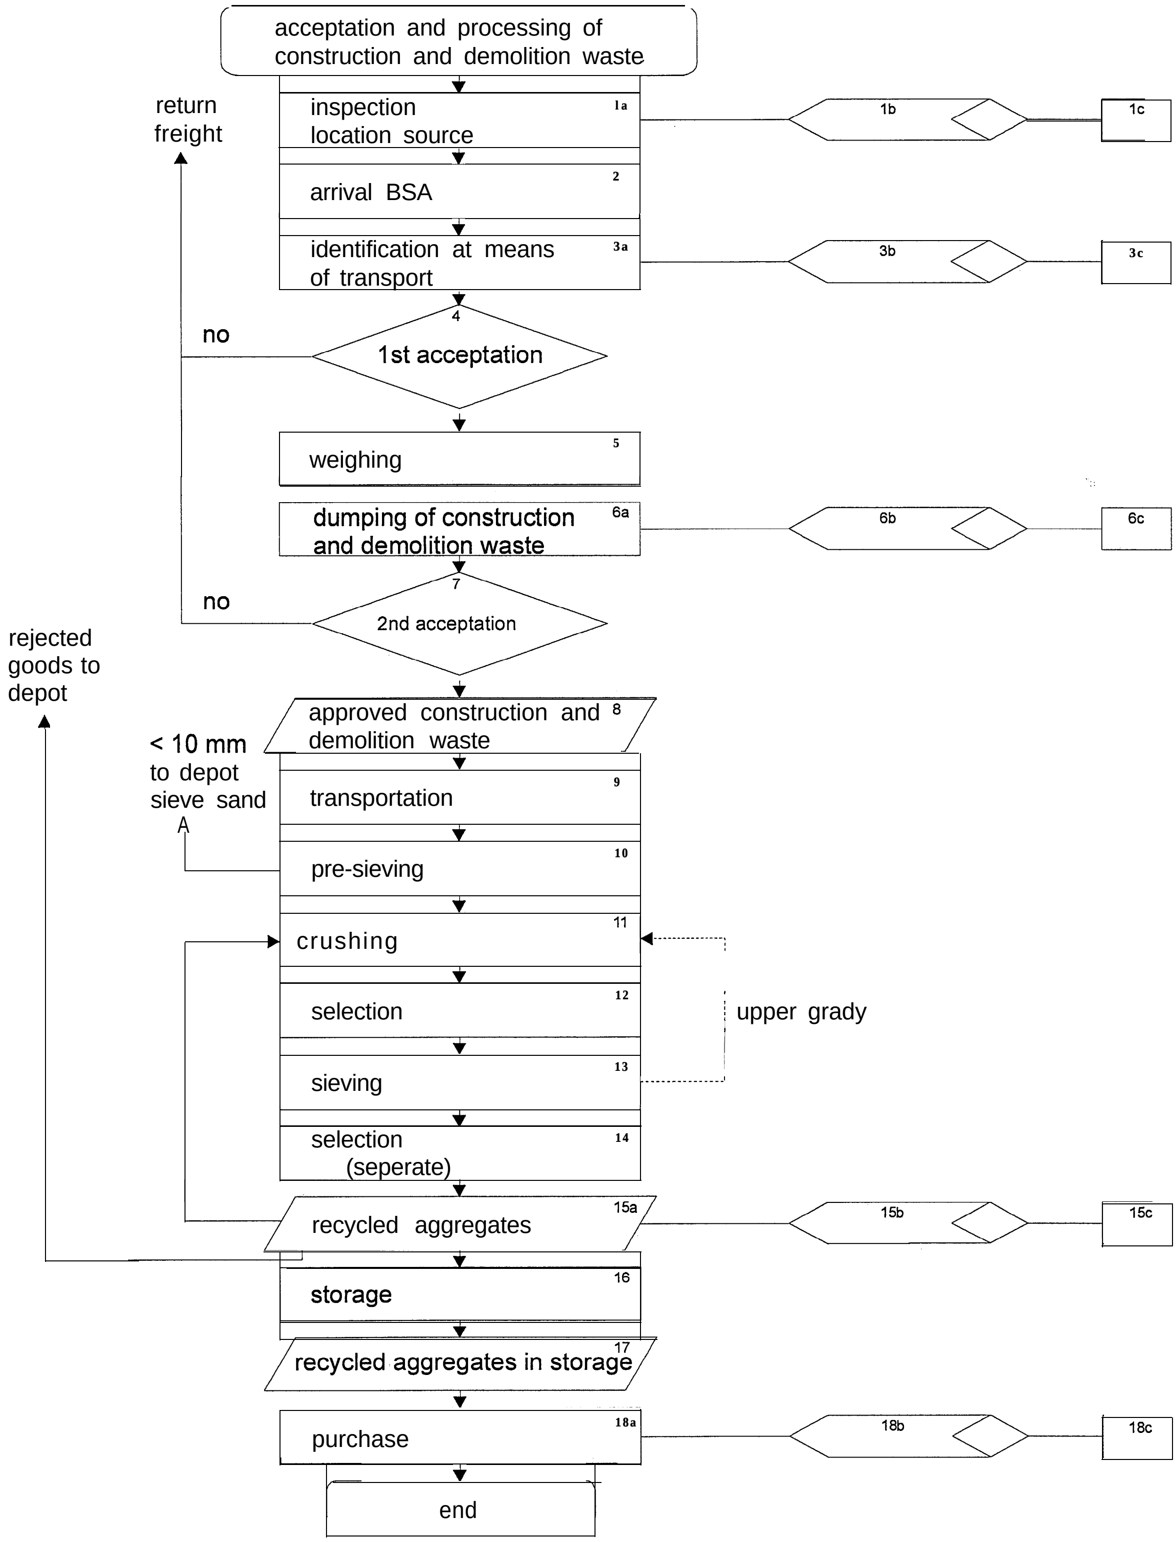

Figure 1. Example of a process diagram for the standard procedure during acceptation and processing of construction- and demolition waste.

1.2 Technical requirements road construction

A subbase of stone material has to improve the supporting power, must be good compacted and has to be resistant against action of moisture and frost. Recycled concrete- and masonry aggregates are, due to the thorough research and to an increasing degree of projects gained experience, fully accepted as qualitative high-grade stone subbases. Recommended is not to mix the recycled aggregates with other primary or secondary raw materials. Both from the engineering and environmental point of view this often is not leading to an improvement of the aggregates; through blending with the usually qualitative inferior products negative associations rapidly can occur. Furthermore there is a lack of experience with reference to suchlike mixtures which already has been gained with recycled aggregates. Incidental fantasy mixtures therefore have to be avoided. Application could, on term, bring the application of alternative materials in danger. Tables 2-4 summarise the most important Dutch specifications for recycled aggregates.

Table 2. Summary of requirements of compilation

	main component	**side component**
recycled concrete aggregate	min. 80% crushed concrete with dry density > 2100 kg/m^3	max. 10 % different stone and max. 5 % asphalt
recycled masonry aggregate	min. 85% crushed stone with dry density > 1600 kg/m^3	max. 15 % different stone and max. 10 % asphalt
recycled mixed aggregate	min. 50 % crushed concrete with dry density > 2100 kg/m^3 and max. 50 % stone with dry density > 1600 kg/m^3	max. 10 % different stone and max. 5 % asphalt

The technical qualities of recycled concrete aggregates practically are comparable with the recycled mixed aggregates. For application of stone mixtures as constructional road in subbases and as supplement and embankment, technical requirements are recorded in the so-called Standard specifications for roads (RAW).

Table 3. Requirements for subbases according to the Standard specifications for roads (RAW) 1995.

Requirements for subbases
• no foreign components • crushing factor higher the 0,65 • spreading of granules within limits, determined of sieves between C445 and 20 (m) • max. 10 % (m/m) round and unbroken pieces of sieve C4

Table 4. Requirements for materials on behalf of replenishment and embankment according to Standard specifications for roads (RAW) 1995

Requirements for materials on behalf of replenishment and embankment
• the materials has to be of mineral origin
• the material has to be inert that means for example not to dissolve in water
• the material may contain a portion of fine parts < 63 (m of 50 % m/m). In practice most of the times the requirement for sand will be handled for subgrade (max. 15 % (m/m) < 63 (m)
• the material may not contain more then 3 % (m/m) organic material
• in order to be used as embankment material the material has to be crushed to max. 45 mm. The created product has to have a regular distribution of granules in order to be able to compact. By reason of stability and possibility of compacting it seems to be advisable to handle, temporary, the distribution of granules of stone founding material 0/40 as basic assumption.

1.3 Technical requirements for application in concrete

Recycled aggregates have in comparison with gravel deviating properties. One has to consider these properties during composing of concrete blends and during processing of concrete mortar.
Recently the old NEN 5905: 1988 “Supplements for concrete, sand and gravel” was replaced through NEN 5905: 1997 “Supplements for concrete, materials with a volume mass with at least 2000 kg/m^3”.
In the revised version are for the application of recycled concrete aggregates and recycled masonry aggregates, respectively the CUR-recommendation 4 “recycled concrete aggregates as supplement of concrete” and the CUR-recommendation 5 “recycled masonry aggregates as supplement of concrete” written down.
Limiting values set to contamination have to do with various strength and durability aspects.

Among others:

- delaying influence on cement hardening;
- corrosion of reinforcement (chlorides);
- swelling under the influence of absorption of moisture (for example wood);
- formation of etringite (swelling through for example plaster);
- alkali – silica reactivity (for example Pyrex glass);
- decrease of pressure strength) for example asphalt.

In the table mentioned below a summarising of the most important requirements is given.

Table 5. Brief summary of the most important requirements made rule for aggregates at application in concrete according to NEN 5905.

Variable	Unit	Requirement	Definition method .
Distribution of aggregates		comparable with natural supplement	NEN 5916
Shape of aggregates		critical shape recommended	
flat pieces	m/m	< 40%	NEN 5935
supplement with round surface		limited % for use in concrete for roads and hardening	NEN 6240
shell extent	m/m	in coarse supplements percentage carbonates < 10% in fine supplements carbonates < 25%	NEN 5922
very fine material	m/m	aggregate group O-l mm: < 10% aggregate group O-2 and O-4 mm : < 4,0% coarse : < 3,0 %	NEN 5917
Physical properties and requirements			
Compound of aggregates	m/m/	recycled concrete aggregate: concrete percentage > 90 %, LA-value < 40 recycled mixed aggregates: concrete percentage > 50 %, LA value < 50	NEN-EN 1079-2/ visual
other not stony elements	V/V	5.4.2.1. bitumen, rubber, metals, glass, etc. <1,0 %	NEN 5942
Chemical requirements			
Chlorides	m/m	aggregate group O-4 mm; > 4 mm unreinforced : < 1 ,0%; < 1 .O % reinforced: ,0,1%, < 0,05% prestressed: < 0,03 %; < 0,015 %	NEN 5921
Sulphates	m/m	< 1,0 %	NEN 5930
total sulphur compounds	m/m	< 1,0 % < **2** % if dry supplement consists of slag	NEN 5936
spot causing iron and vanadium compounds		spot index may not become more then **20**	NEN 5923
fine organic material	**-**	discoloration not darker then standard picture A, or not satisfy standard picture B	NEN 5919 NEN 5920
soft components	m/m	< 0,5 **%**	NEN 5918
light material	m/m	< 0,1 %	NEN 5933

1.4 Environmental requirements

The environmental legislation sets requirements to maximum permissible percentages of organic contamination and leaching of inorganic contamination. Based on the possibility that a requirement (=testing value) will be violated, the products are divided into classes. These classes vary in possibilities that individual measuring values can exceed limit values (class 1 < 10 %, class 2 10 – 50 %, class 3 > 50%). For each class specific basic assumptions are obtaining with reference to the testing of critical components. For recycled masonry aggregates, recycled hydraulic mixed aggregates and crusher sieve sand the in table 2,3 mentioned basic assumptions are applying.

Table 6. Basic assumptions for testing of critical components (production control) category 1 materials according to the building materials decree.

Product	vicinity of application	class	critical components
recycled masonry aggregates	bottom fresh surface water	III	Antimonium Bromide Chloride Sulphate Poly Aromatic Hydrocarbon (10) mineral oil
recycled concrete aggregates	bottom fresh surface water	II	Barium Fluoride mineral oil
recycled mixed aggregates	bottom fresh surface water	II	Barium Molybdenum Fluoride Sulphate Poly Aromatic Hydrocarbon (10) mineral oil
moulded recycled hydraulic mixed aggregates	bottom	III	Bromide chloride Sulphate Poly Aromatic Hydrocarbon (10) mineral oil
unmoulded recycled hydraulic mixed aggregates	bottom	III	Barium Molybdenum Bromide Chloride Fluoride Sulphate Poly Aromatic Hydrocarbon (10)

			mineral oil
recycled crushed sand	bottom fresh surface water	III	Antimonium Fluoride Sulphate Poly Aromatic Hydrocarbon (10) mineral oil
asphalt aggregates as semi-manufactured product for asphalt	bottom	III	Poly Aromatic Hydrocarbon (10)
bounded asphalt aggregate	bottom	III	Poly Aromatic Hydrocarbon (10)

Testing on class division has relation to the last 300.000 ton product. This testing has to be performed once per 100.000 ton production. With this the component with the highest chance of exceeding is the one that will be normative for the class division of the product.

1.5 Frequency of testing

1.5.1 Compilation and emission

In table 7 it is indicated how frequently the products, minimally, have to be controlled, in principle, by the producer on compilation and emission.

Table 7. Frequency of testing / production control

class division of product	production control
class I	minimal 1 x per 15.000 ton
class II	minimal 1 x per 10.000 ton
class III	minimal 1 x per 5.000 ton

Table 8. Frequency verification investigation

national production	verification investigation
< 2 Mton / year	minimal 1 x per 50.000 ton
2 – 6 Mton / year	minimal 1 x per 150.000 ton
≥ 6 Mton / year	minimal 1 x per 300.000 ton

1.6 Adaptation of frequency of testing production control of compilation and emission

Depending on the results of the successive determinations, the minimal frequency of testing for the production control can be adapted. This can be evaluated per component. Herewith one can distinguish between a mitigate, normal and enhanced testing regimen (see table 9).

Table 9. Minimal frequency of testing / production control

class division	production control		
	mitigated regimen	normal regimen	enhanced regimen
class I	minimal 1 x per 25.000 ton	minimal 1 x per 15.000 ton	minimal 1 x per 5.000 ton
class II	minimal 1 x per 15.000 ton	minimal 1 x per 10.000 ton	minimal 1 x per 5.000 ton
class III	minimal 1 x per 10.000 ton	minimal 1 x per 5.000 ton	minimal 1 x per 2.500 ton

1.6.1 Mitigated regimen

If the preceding 10 consecutive determinations under normal regimen are approved and production continuously took place (no stop longer then one week), one can turn to the mitigated testing regimen. If under the mitigated testing regimen the last measured result leads to an exceeding of the testing criterion or after an interruption of the production for longer then one-week, one has to change to an enhanced testing regimen.

1.6.2 Enhanced regimen

If during the five preceding consecutive determinations under normal regimen two determinations are leading to exceeding of the testing criterion, one has to change to an enhanced testing regimen.
If during the enhanced testing regimen the five preceding consecutive determinations have not led to an exceeding of the testing criterion, one can change to a normal testing regimen.

1.6.3 Temporary stop of inspection

If during the five preceding consecutive determinations under enhanced regimen all five determinations have led to an exceeding of the testing criterion, a temporary stop of inspections has to be established and the producer has to take measures in order to improve the quality of the products. After implementing these measures one has to follow the enhanced testing regimen.

1.7 Poly Aromatic Hydrocarbon (10) percentage of the fine fraction of recycled aggregate 0/40

The Poly Aromatic Hydrocarbon (10) percentage of the fine fraction of recycled aggregate 0/40 has to be determined 1 x per 10.000 ton product.

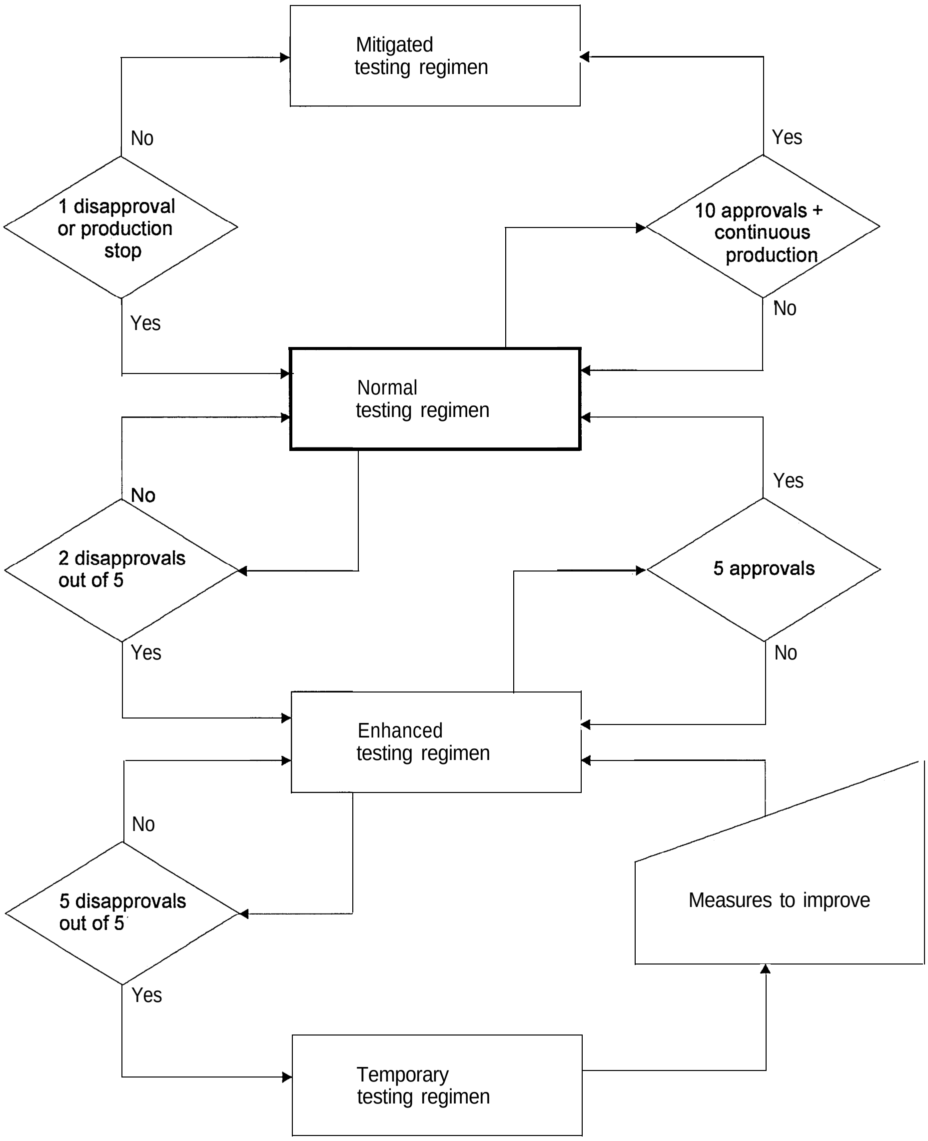

Figure 2. Adaptation of testing regimen

ABSTRACT

In the Netherlands, as well as some other European countries, recycled aggregates are applied increasingly. Recycled aggregates are obtained from the processing of stony building and demolition waste. Concrete, containing up to 100% fine and coarse aggregates may be utilised successfully. Significant savings on primary aggregates may be obtained, thereby contributing to closing the concrete life cycle. It is estimated that in Europe alone, about 200-300 million tonnes of building and demolition waste is currently landfilled or applied in road construction. However, recycled aggregates may also be applied very well as coarse aggregate in concrete, thereby upgrading its application.
In this paper, the practical experiences gained with the application of recycled aggregates in concrete in the Netherlands will be highlighted, starting with a brief historical overview of relevant actions taken in the past, and ending with a discussion of future trends.
Introduction of “new” raw materials in the building industry is only possible when there is no discussion on aspects such as the product quality and the ratio between price and performance. Therefore, this paper will give attention to results obtained in the mix-design, strength, durability as well as environmental performance and concrete with recycled aggregates. It will be shown that for the most common ordinary concrete, durability is not a topic for much concern, based on results of tests on chloride-ion ingress and freeze-thaw resistance.

Keywords: chloride ingress, concrete, freeze-thaw, recycled aggregates, specifications, quality control.

1. INTRODUCTION

For millennia, construction and the demolishing of constructions go hand-in-hand. Especially in densely populated countries or regions, an example being the Netherlands, the possibility to recycle stony “waste” materials derived during the process of building, renovation and demolition of structures, has been drawing particular attention since about two decades.
In the Netherlands, almost 15 million tonnes of building and demolition waste’is produced annually; this is equivalent to about 1 tonne per capita. A conservative estimate is thus, that within the EC countries alone approximately 200-300 Mtonnes of this particular kind of waste is produced annually. And just in order to visualise: this is roughly equivalent to an area of $400 km^2$, with a total height of 1 meter, given an average volumic mass of 1.500 kg/m^3.
The major part of building and demolition waste consists of stony components. These components are, upon recycling, generally referred to as recycled aggregates. According to the definition provided in reference [6], a recycled aggregate is a granular material, resulting from an industrial process involving the processing of inorganic materials, previously exclusively used for construction, applied again for construction purposes.
In the Netherlands, the major marked for recycled aggregates is found in relatively low-tech applications such as embankments, road foundations, etcetera. These low-tech applications are faced with an ever-increasing competition with other secondary raw materials, while at the same time demand is decreasing. However, it is very well possible to upgrade the application of recycled aggregates. It then becomes a potential raw material for the large market of “common concrete”, i.e. concrete which does not have to meet the highest standards with respect to workability, flowability, strength and/or durability. In the Netherlands, roughly 80% of the annual concrete production of about 16 million m^3 is used for ordinary concrete in the strength class up to 25MPa, i.e. almost 13 million m^3. The demand for stones and gravel (4 - 32 mm) and sand (0 – 4 mm) for this concrete is respectively about 14 million and 9.5 million tonnes. And although the production rate of this concrete far exceeds the production of recycled aggregate, the application of this material into concrete is - as a concept - interesting, since it contributes to closing the concrete life cycle, thereby contributing to a sustainable society.
So far however, in only few EC-countries a well functioning building and demolition waste recycling industry, actually producing recycled aggregates of sufficient quality, is present. Within Europe, this is particularly the case in the Netherlands.
In the following chapters a historic overview is presented, starting with a discussion of the meaning of the term “sustainable”, the basis of Dutch environmental policy, followed by an overview of Dutch- and EC-policy on recycled aggregates, legislation, standardisation and quality control, resources and types of aggregates produced, processing, practical experiences, ending with a discussion on future trends.

2. SUSTAINABILITY

“Sustainability” is the fundamental topic behind terms like energy conservation, recycling, efficiency improvement, etcetera. Many definitions exist. The Brundtland report of 1987 “Our Common Future”, published by the World Commission on Environmental Development, describes this term by formulating three aims, the first being an economical development, within the prior condition of ecological criteria.
The outlook for next generations (say in about 50 years) is that world population will approximately double, that this world population will have an average level of prosperity which is about 4-8 times higher than the current one, and that at the same time the pressure on the environment should be reduced with a factor of 2-4. For the building industry as a whole, this means that in 50 years we will have to able to build about 15 to 50 times more efficient.

In order to fulfil our common needs for building (housing, infrastructure, etc.), the building industry should contribute by increasing its overall efficiency in terms of raw materials and energy consumption, low emissions into the environment, ease of adaptability of constructions, an optimised durability (design for durability) and, last but not least, the recyclability of constructions (ease of demounting or demolition and recycling, preferably back into its own product chain). It is particularly this latter aspect which is addressed in this paper.

3. DUTCH- AND EC-ENVIRONMENTAL POLICY

As one of the reactions on the Brundtland report the Dutch National Environmental Policy Plan (NMP) was published in 1989. In this document, as well as the later published update of this plan, and in the "National package" on "Sustainable Building - Investigation into the future", intentions and guidelines were formulated with the aim to anchor the concept of sustainability into, amongst others, the Dutch building industry. A few years back this resulted in an "Implementation Plan on Building and Demolition Waste", with the aim to apply 90% of this kind of waste by the year 2000. In this plan, and its subsequent updates, no particular preference for any particular application was formulated. Integral chain management is considered to be one of the central themes needed in order to reach a "sustainable" way of building. Integral chain management may be considered as the closing of a product or material life-cycle is such a way that only a minimised amount of material needs to be landfilled or cornbusted, at the same time maximising product and materials reuse and recycling. Preferably, reuse and recycling should take place into the same application. The effect of integral chain management is considered twofold:

1. Materials recycling. This results in a decrease of emissions into air, water and soil (which would take place as a result of landfilling or combustion), as well as a reduction of the environmental impact related to land filling; and
2. Limited use of primary raw materials. This results in a reduced intervention into (scenic) landscapes and extended exploitation of -essentially finite - natural resources.

Within the Netherlands, a National Council for the Construction Industry has been established in order to provide for a discussion platform between building industry and government bodies.
On a much smaller scale, also an EC-building council has been operating. Both councils merely serve to provide a basis for formulating realistic goals, as well as performance related quality criteria.

4. LEGISLATION, STANDARDIZATION AND QUALITY CONTROL

In order to establish a normally operating market for recycled materials in the building industry, one of the major aspects was the formulation of appropriate guidelines. Since the early eighties several Rilem committees have been working in the field of recycling and reuse of secondary raw materials. Results have been presented at the conference proceedings of Rotterdam (1985), Tokyo (1989) and Odense (1993; 4). As a result, a Rilem recommendation was prepared with respect to the applications of recycled aggregates in concrete. This Rilem specification was based on experience obtained since the early eighties in The Netherlands, Denmark and Belgium. Since only few countries have substantial practical experience with the use of recycled aggregates in concrete, only few EC countries developed standards and regulations in this field.
At the same time, two CEN committees were already active in fields which could influence the use of recycled aggregates: CEN/ TC 154 "Aggregates for unbound and hydraulically bound materials for Civil engineering work and road construction" and several task groups within CEN/TC 227, focussing on materials for road construction.
A related, but important discussion was taking place within CEN/TC 229 "Characterisation of Waste".

In 1994 the CEN/TC 154 "ad-hoc group on recycled aggregates" was founded; prime task of this group was to advice TC 154 and its subcommittees on specification requirements and any additional tests required for recycled aggregates. The British Building Research Establishment handles the secretary tasks of this ad-hoc group. This resulted among others to a draft proposal for materials specification for unbound, hydraulically bound and bituminous bound recycled aggregates in 1996 [6].

On a national scale a division should be made between standardisation on the one hand, and legislation on the other hand. The process of national standardisation has been stimulated by the publication of the already mentioned Rilem recommendation. Since a couple of years, Dutch national standards (valid up to concrete with a compressive strength of about 65 MPa) allow for a replacement of 20% (m/m) of natural primary aggregates by either mixed recycled aggregate or concrete recycled aggregates, without the need for additional performance based tests. Mixed recycled aggregates are aggregates which have to contain at least 50% (m/m) of recycled concrete aggregate (and less than 50% (m/m) of recycled masonry aggregate); they should also fulfil other criteria, adressed later. In the recently published "National package for sustainable building in the Netherlands" the suggested standard for concrete was indeed to replace 20% of the primary coarse aggregates (4 – 32 mm), by secondary ones. Currently, there is debate on this 20% limit, since the majority of concrete produced may contain significantly higher amounts [1].

Natural aggregate replacement is allowed, provided legislative requirements are fulfilled. In the Netherlands, diffusion-leaching tests are considered appropriate to monitor this. By January 1999, concrete containing secondary materials, applied outdoors, will have to fulfil to limit values regarding the imission of specific elements into the soil and surface water (which differs from the emission from a building product), specified in the Dutch Building Products Directive. Starting point is the concept that only an increase of specified (an)organic elements by 1% over a period of 100 years is considered to be acceptable. This imission is calculated by taking into account the leaching characteristics of a variety of elements as well as the specific application. For indoor applications, legislation addressing radon emanation is currently in study [l].

Key quality control criteria for recycled aggregates used in concrete include of course grain size distribution, grain shape, the fines content, specific mass, chloride and sulphate content, alkali-silica reactive material (glass), organic components influencing setting and hardening time and "soft' components, such as plastics and wood. Essentially, specifications do not differ much from the specifications for natural aggregates. A summary is provided in table 1.

In the Netherlands, the producers of recycled aggregate carry out quality control; both recycled concrete- as well as recycled mixed aggregates are sold with quality certificates. Periodically, certification institutes carry out audits, thereby providing an external quality control assurance.

5. RESOURCES AND AVAILABLE TYPES OF AGGREGATES

In the Netherlands, each year about 120 Mtonnes of raw materials are used in the building industry; 85% of this quantity is actually produced in the Netherlands. As already stated, the amount of building and demolition waste is currently estimated at about 15 Mtonnes per year. Of these 15 Mtonne, 11 Mtonne is recycled, of which a majority of about 80% in "on the ground" applications; only 20% is applied in "above ground" applications.

In 1996 the total installed recycling capacity was about 16.3 Mtonnes. Total production in 1996 was less: 10.9 Mtonnes. 10.4 Mtonnes were actually applied. About 68 percent of it originated from demolishing operations, other sources being waste produced at large infrastructural projects, such as road construction (15 %) and building waste sorting installations (5%). Approximately 9% of it was produced at building sites, the remaining 3% from other sources.

Several qualities of recycled aggregates are currently available in the Netherlands. They are summarised in table 2.

Table 1. Specifications for recycled aggregates.

Table 2. Types of recycled aggregates produced in the Netherlands (1996; [I])

type of recycled aggregate	Mtonne/year (1996)
recycled concrete aggregate	1 .0 (+ 0.07 applied in concrete)
recycled masonry aggregate	0.9
recycled mixed aggregates	5.3 (+ 0.11 applied in concrete)
hydraulic aggregates (Korrelmix ®)	0.9
total	8,1 (+ 0.18 applied in concrete)

As can be seen from table 2, about 98% of these recycled aggregates are not applied as secondary raw material in concrete. However, the potential is clearly very high, even when it is considered that recycled masonry aggregates and hydraulic granulates as such can not be applied because of their too low specific mass and friable nature.

New developments include the production of secondary sand (0/4 mm) of various sources. Such sources include sand which comes available at the concrete crushing plant, sand which comes available from sieving operations at crushing plants, sand which originates from cleaned sandy soils and sand which comes available during river dredging operations. The current amounts produced are however small compared to recycled aggregates. Potentially, some 2 Mtonne may be produced of sufficient quality.

6. PROCESSING

Essentially, the processing of building and demolition waste does not differ from the processing of natural aggregates. In order to be economically feasible, plant size ranges typically between 100 and 250 ktonne. Important is that the demolition waste is separated as early as possible in the recycling chain; this should be achieved preferably at the demolition site, but it may also take place in so-called sorting centres.
Separation generally starts with a crushing action. Further sorting may be carried out by sieving, windsifting to separate light materials, a magnetic sorting to separate iron-parts and sieving. Especially when high quality granulates are needed, the material is subjected to a washing step. Disadvantage of washing operation is that in the end usually a polluted sludge remains, which has to be disposed of, at relatively high costs. Debate is currently going on to reduce these costs significantly, since it poses a significant burden on potential high quality applications, such as concrete.

7. PRACTICAL EXPERIENCES

7.1 Availability and price

Although in principle capacity should be sufficient, the market for low quality applications is still very large. Generally, recycled aggregates for concrete are produced on demand. Recycled concrete aggregate is rather difficult to obtain; because of the difficult applicability of recycled masonry aggregates, recycled mixed aggregate is the main product. Prices are similar to natural aggregates.

7.2 Replacement level of recycled aggregates in concrete

For over 15 years demonstration projects have been carried out in the Netherlands. Concretes with varying levels and types of recycled aggregates have been produced. A recent survey confirms that a replacement level of 20% (v/v) of recycled concrete- or mixed aggregates, for common strength classes such as B15 or B25, and likely up to B35, is very well possible without any performance loss [3;4].
Concretes containing significantly higher amounts of recycled aggregates (up to 100% replacement) may also be produced. Currently, in a housing project near Delft 100% mixed aggregates are applied in almost all precast concrete elements used (walls, floors, and foundations). A compressive strength of about 45 MPa was generally reached, exceeding specifications. Furthermore, an increase in noise reduction compared with traditional concrete was noted, apparently due to the use of the more porous mixed recycled aggregate.

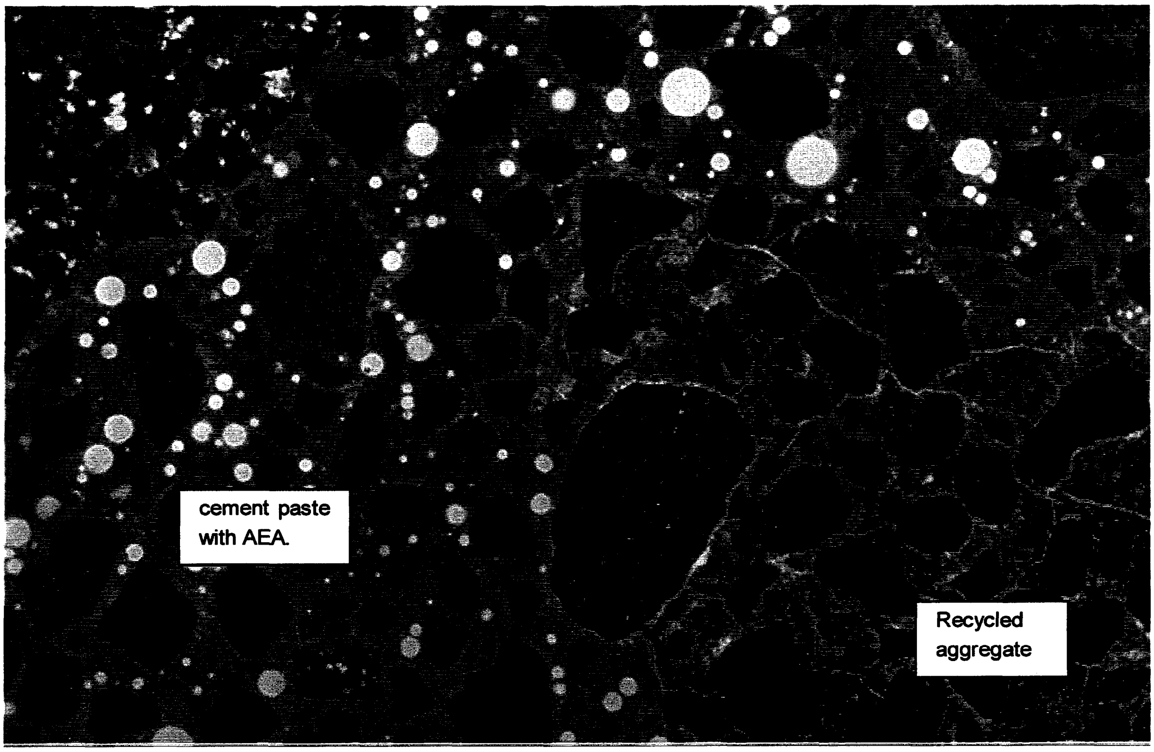
7.3 Mixdesign

In cases of high aggregate replacement levels, care should be taken to analyse the moisture content and adsorption potential of the recycled aggregates, since water demand is usually higher. This is particularly so for aggregates containing masonry or lime-sandstone brick. Three options to overcome this problem exist: the first consist of wetting the recycled aggregates prior to mixing, the second by simply adding more water during mixing, the third by addition of a superplasticiser and/or air entraining agents. Especially this last option is applied successfully in practise. Experiences with replacement of secondary sand 0/4 are still in an embryonic stage. One of the major problems may be, apart from increased water demand plus quality variations within one lot, the hydraulic behaviour, which may cause handling problems in storage bunkers (caking).

7.4 Strength development

Generally, concretes containing up to 20% recycled aggregates do not show a significant strength loss. Higher replacement levels of recycled concrete aggregates also do not seem to be problematic. Due to the hydraulic behaviour of recycled aggregates, as well as their comparatively high surface roughness, good bonds between cement pastes and aggregates exist. An example is shown in figure 1. This micrograph were taken from a (fluorescent) epoxy impregnated thin section.

Figure 1. Microstructure of concrete with recycled mixed aggregate (fluorescent light; 1 cm = 0.3 mm)



7.5 Durability

So far, no damage cases have been reported were the use of recycled aggregates itself was the likely explanation. In practice, no problems with frost-thaw action have occurred, although the porous nature of some recycled aggregates may be a problem in countries with more severe climates, compared to the Netherlands. Air entraining agents may be applied in such cases. In figure 2, some examples of the freeze thaw resistance of concrete with recycled aggregates are shown, based on the RILEM 4 CDC test [2]. Results from chloride penetration tests, according to APM 302, are shown in figure 3. In this test concrete is subjected to a highly saturated chloride solution; after 35 days the relative chloride ingress is analysed. It is an accelerated test. The composition of the concrete used in these tests is summarised in table 3. The water-cement ratio was 0.45. In all cases a superplasticiser was applied, within the allowed specifications. The recycled sand- and aggregates were all pre-wetted; the recycled concrete aggregate contained an additional 16 litres (1.45%), the recycled mixed aggregate 4/16 40 litres (3.6%) and the recycled mixed aggregate 4/32 75 litres (6.8%).
From figure 1 it can be seen that the recycled (concrete) aggregate displays a strong bond with the cement paste, as evidenced by a lack of defects at the interface. Generally, concrete aggregates

display micro-cracks, the significance of which is presumed to be little, as there is not interconnected three-dimensional network present.
The freeze-thaw results from figure 2 demonstrate that the saturation percentage above which "damage" may occur starts at a saturation level of about 77% (critical saturation level). Concrete displaying a critical saturation level over 85-90% may generally be considered to be fully frost-thaw resistant, since such high saturation only occur in special applications. Note that no air-entraining agent was present. The concrete with recycled concrete aggregate performed markedly better than the concretes with recycled mixed aggregates. However, all concretes displayed a performance at least equivalent to the reference concrete with natural aggregates.
From figure 3 it is clear that up to a depth of 12 mm the concretes containing recycled aggregates display a somewhat increased level of chloride ingress; thereafter no difference with reference concrete could be noted. The well-known fact that concrete based on blast furnace slag cement performs better in such tests is also demonstrated.

8. CONCLUSIONS AND FUTURE OUTLOOK

Application of recycled aggregates in concrete contributes to closing the concrete life cycle, and reduces the impact on the landscape due to the exploitation and quarrying of natural aggregates.

Recycled aggregates may be applied successfully in concrete. This is especially true for the majority of the concrete market, which consists of relatively low-demanding products. Coarse aggregate replacement levels of 20% to 100% are very well feasible, especially in case of recycled concrete aggregates. The durability of concretes with up to 100% recycled aggregates is, given the concrete quality tested, within range of concrete without recycled aggregates. Both frost-thaw resistance and chloride ingress levels are acceptable for normal use (in the Netherlands). Mix-design should be done with care and experience, since the water demand of notably mixed aggregates is rather high. Pre-wetting is one of the more practical precautions to be taken.

In order to obtain an effective building and demolition recycling industry, the technical- and possible legally required specifications should be made absolutely clear. The best way to obtain good quality aggregates is to work with strict acceptance criteria "at the gate" of a recycling plant. The better the quality and homogeneity of the input, the more easy it is to produce recycled aggregate of high and constant quality. External quality control has proven to be a key element towards a successful market introduction in the Netherlands. The same applies for a clear government commitment.

One of the current discussions in order to stimulate the application of recycled aggregates is to introduce a gate-fee for recycled aggregate, which should counterbalance the residue-dumping costs, which are unavoidable, when the recycled aggregates need to be washed. Currently, the costs of recycled mixed aggregates are approximately 20% less than natural ones, also depending on the building location. Other stimulating actions may consist of prescribing the use of recycled aggegates in buidling specifications. A clear insight in supply and demand of building materials is also needed in order to evaluate results of the stimulating actions taken.

On the long term, it is foreseen that the amount of building and demolition waste will decrease, as a result of renovation, a trend towards more flexible building and an extension of the service life of buildings and structures. From the point of view of integral chain management, application of recycled masonry aggregates in concrete is something that may be of importance when recycling for a second, third or fourth time. The authors are currently addressing this topic [l].

“Green Concrete” is as Simple as ABC

Larry C. Muszynski, M.E. Rinker Sr., School of Building Construction, University of Florida, Gainesville, FL 326 1 l-5703 USA

Abstract:

There is world-wide interest to develop advanced construction materials that are both cost effective and produced with a minimum negative impact on environmental quality. Recently, the Civil Engineering Research Foundation (CERF) organized an international research symposium on “Engineering and Construction for Sustainable Development in the 21st Century. One key element identified was the proper use of by-product materials that can enhance performance, reduce cost and environmental impact.

The interest in using recycled materials as integral components of concrete is well-documented. Recycled concrete, masonry block, brick, recycled post-consumer wood and rubber have been evaluated as “aggregates” and additives for concrete as a construction material. Fly ash, which is a by-product of the coal combustion process, has been used as a filler, cement replacement, and even pelletized as an aggregate for concrete.

ABC™ cement is a newly patented, cement binder, produced in the United States, having a composition of 95 per cent fly ash and 5 percent portland cement. Utilizing this 95 percent by-product, cementitious binder, will provide a “99% plus green concrete construction material when combined with other recycled products used as aggregate. Concrete produced with this “green” binder has been shown to produce excellent short and long-term strengths as well as excellent durability.

Keywords: cement, concrete, construction materials, fly ash, recycled materials.

Introduction:

ABC Cement™ is a patented hydraulic cement system marketed and sold in the United States, and is composed primarily of high-lime, alkali activated, fly ash, mineral additives, retarders, activators, and accelerators. [1] The source of fly ash is subbituminous coal, and is classified by ASTM as Class C. The material can be activated. by water addition alone or by addition of a chemical activator. The Class C fly ash makes up 77- 95 percent by weight of the total cement binder, the remaining part can be slag and/or portland cement. The binder used during this project consisted of 90 percent by-product fly ash, 5 percent portland cement, and 5 chemical additives. The product does not contain any toxic chemicals subject to the reporting requirements of Section 3 13 of Title III of the Superfund Amendments and Reauthorization Act of 1986 (SARA) and RCRA (40 CFR Part 372). [2]

Sustainable Development:

What makes this system so green are the following: The cementitious binder makes maximum use of recycled materials, fly ash from coal burning power plants, and slag from iron and steel making facilities; the material can be used with recycled concrete as coarse aggregate to produce a 99 percent recycled product,, that itself can be later recycled into coarse aggregate; the material appears to have improved durability characteristics that would enable the engineered product produced to endure for a longer period of time; and the material has the potential to reduce the amount of greenhouse gas, carbon dioxide emitted into the atmosphere, and reduce the amount of by-product fly ash that is landfilled.

Reducing the amount of greenhouse gas, carbon dioxide, may not be as obvious as the other three "green" attributes of this system. Worldwide cement production totaled 1.2 billion metric tons in 1992 according to the U. S. Bureau of Mines. [3] This would produce 1.5 billion metric tons of carbon dioxide released into the atmosphere, or 8% of the total carbon dioxide released. [3] The 1.2 billion metric tons of cement would produce approximately 4 billion cubic meters of concrete at a cement content of 300 kg per cu. m. ABC Cement™ binder would require only 60 million tons of portland cement to produce the same amount of concrete at the 300 kg per cu. m. therefore, reducing the amount of carbon dioxide emissions from worldwide portland cement production from 1.5 billion metric tons to 75 million metric tons released. The amount of by-product fly ash utilized worldwide from this endeavor would be a staggering 1 billion metric tons per year. In addition, 40 percent of the 75 million metric tons of carbon dioxide released would, over a period of time, be consumed back to carbonation products, by the 4 billion cu. m. of produced concrete. [5]

Experimental:

Experimental programs were developed by the Army Corps of Engineers at Waterways Experiment Station and Wright Laboratories at Tyndall Air Force Base, FL to develop a property database documenting workability, strength, and durability of ABC Cement™ based mortar and concrete [6 7] The fresh properties measured on the concrete mixtures were slump (ASTM C-143): unit weight (ASTM C- 13 8), air content

(ASTM C-23 1), and time of setting **(ASTM C-403).** Compressive strength testing was also performed on mortar cubes **(ASTM C-109)** at freezing, 0° C., and below freezing temperatures, -18° C. Tests on hardened concrete included compressive strength of cylinders according to **ASTM C-39,** freeze-thaw testing according to **ASTM C-666,** Procedure A, and rapid chloride permeability according to AASHTO **T-277.**

Results:

The results of the hardened concrete and mortar testing are shown in Figures 1-4. Figure **1** illustrates that concrete produced with ABC Cement™ produce compressive strengths at **1, 7,** and 28 days with both gravel and limestone coarse aggregates, comparable to Type III portland cement concrete produced with the same coarse aggregates. The compressive strengths ranged from 24 to 3 **1** MPa at **1** day age and **41** to 55 MPa at 28 days age.

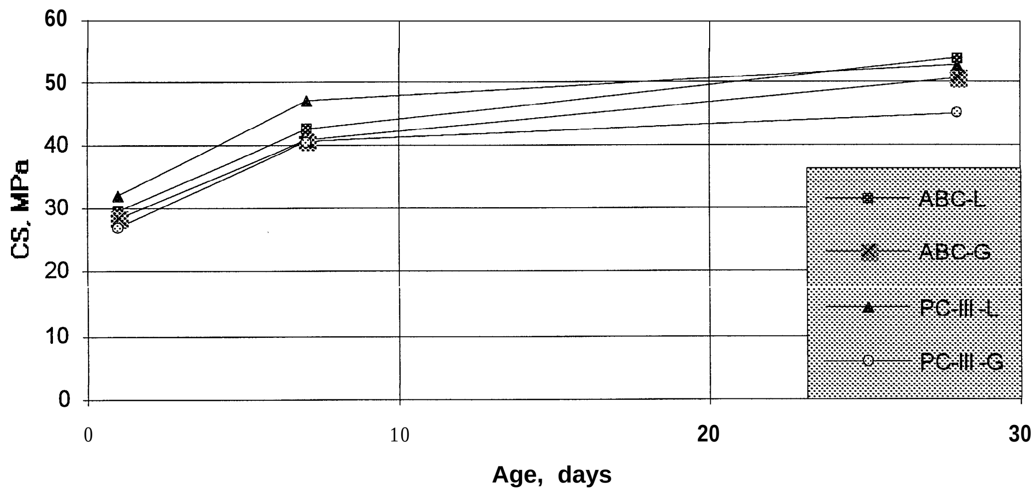

Figure **1.** Compressive Strengths of ABC Cement™ and Type III Cement Concrete

Figure 2 illustrates that concrete produced with ABC Cement™ produce good frost resistance with limestone coarse aggregates, comparable to Type III portland cement concrete produced with the same coarse aggregate. None of the mixtures produced with the natural siliceous river gravel exhibited good frost resistance even with air entrainment. This was not an unexpected result since the river gravel from this source has a history of poor performance in severe freezing-and-thawing exposure.

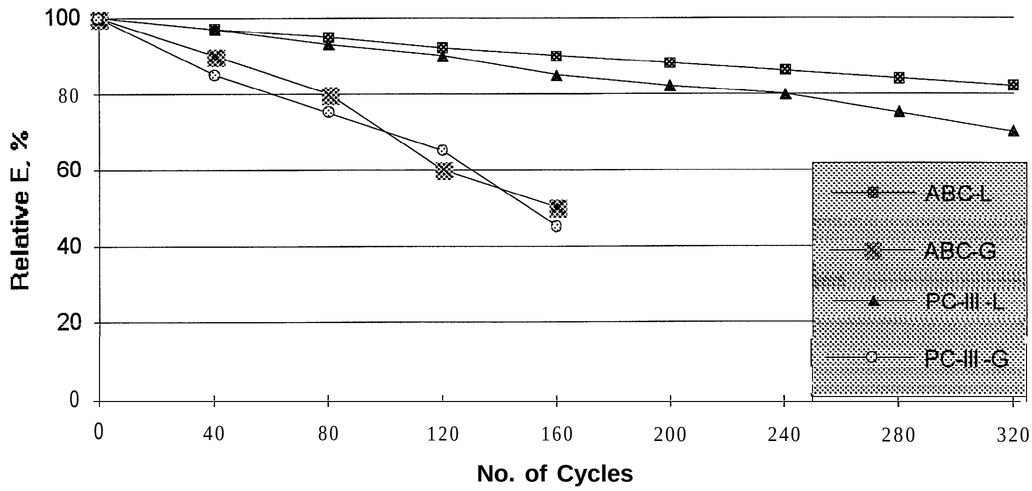

Figure 2. Freeze/Thaw Resistance of ABC Cement™ and Type III Cement Concrete

Concrete produced with the ABC Cement™ exhibited much better resistance to the passage of chloride ions than concrete produced with Type III portland cement. The average charge passed for the ABC Cement™/limestone concrete averaged about 700 coulombs, that corresponds to a very low chloride ion penetrability, and the ABC Cement™/river gravel concrete averaged about 1100 coulombs, that corresponds to a low chloride ion penetrability. Type III portland cement produced with limestone and river gravel coarse aggregates averaged about 2800 and 3000 coulombs of charge passed respectively. Both of which correspond to only a moderate chloride ion penetrability by definition (AASHTO T-277).

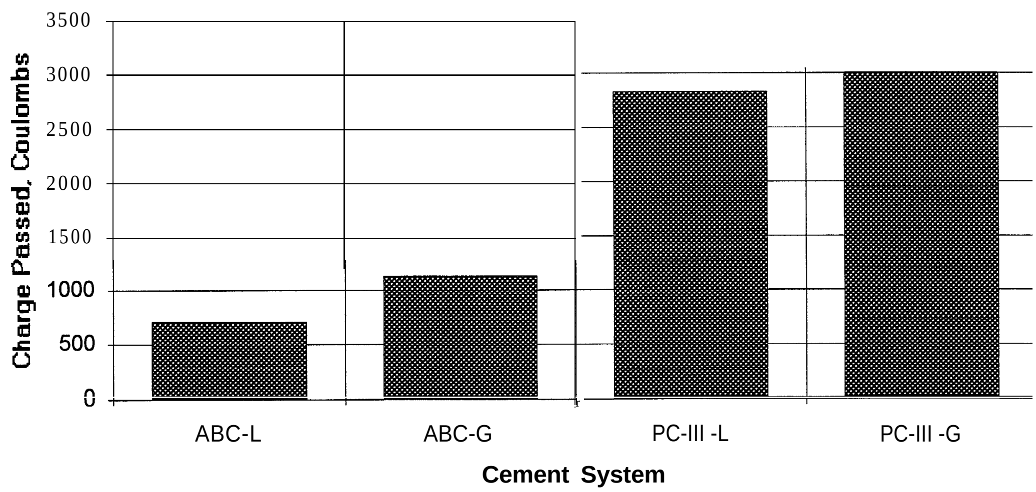

Figure 3. Chloride Permeability of ABC Cement™ and Type III Cement Concrete

Figure 4 illustrates the compressive strength gain of mortar cubes cast and cured at 0” C. and **-18”** C. The three hour strength of ABC Cement™ mortar at 0^o C and **- 18”** C. approached 30 MPa and 20 MPa respectively. The ability of the ABC Cement™ mortar to set and gain strength at these temperature without the use of antifreezing additives was remarkable.

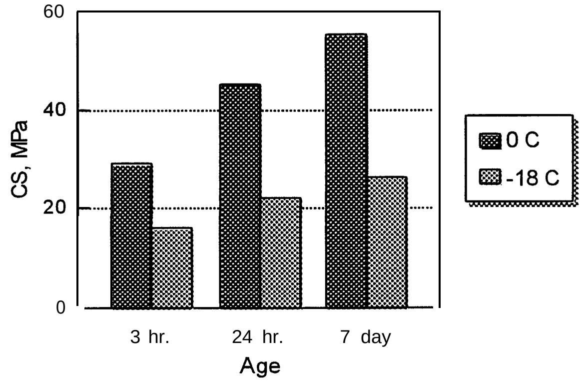

Figure 4. Compressive Strength of ABC Cement™ Mortar at Temperature

Conclusions:

- ABC Cement™ concrete makes maximum use of fly ash and other waste by-product materials.
- ABC Cement™ concrete has fresh concrete properties similar to those of ordinary portland cement concrete.
- ABC Cement™ concrete offers the advantage of improved performance in durability without sacrificing strength performance at early or later ages.
- ABC Cement™ mortar and concrete has the potential to be the construction material of choice in subfreezing conditions.
- ABC Cement™ mortar and concrete has a positive impact on the environment.

Acknowledgments:

The author would like to thank the inventor, W. D. Kirkpatrick for providing the ABC Cement™ material system for testing and evaluation purposes. The author would also like to thank the Army Corps of Engineers at Waterways Experiment Station, Wright Laboratories at Tyndall AFB, and Applied Research Associates, Inc. for providing test data relative to this new product.

Methodology and experimental programme to evaluate building components service life

B. Daniotti, T. Poli, F. Re Cecconi, G. Rigamonti
DISET, Polytechnic of Milan, Milan, Italy

Abstract
In the report we present a method to evaluate the service life of building materials and components, to support decision in design for durability and for a sustainable development.
The evaluation method starts from the concept of durability as the ability of building components to maintain performances and related functional characteristics over a specified limit during service life.
Then the method implies the functional analysis of building components, which let's know, for each material of the component, the functional characteristics that permit to develop the functions directly related to performances and to requirements.
The adopted functional analysis is described in the paper: "Functional analysis as a method to design new building components within a policy of a sustainable construction". The proposed method develops into three phases of analysis.
In the first phase one defines the list of significant agents, one gets from scientific documentation the information on the effects on the materials caused by the agents, and elaborates models to evaluate the "material sensitivity". The second phase, in co-operation with geom. M.Melzi and developed at Istituto Cantonale Tecnico Sperimentale della Scuola d'Ingegneria del Cantone Ticino (Switzerland), with Dr. A.Jornet and Dr. T.Teruzzi, consists of laboratory accelerated ageing tests on material specimens and building components. Characterisation testing will be executed before beginning ageing tests and then repeated periodically during ageing cycles to measure functional characteristics decay until the durability limit, which defines the end of service life. In the third phase one will elaborate the obtained experimental data, to support and conclude the initial methodology, leading to a quantitative evaluation of service life of building components. The information obtained by this method, will represent also a useful input for design and for maintenance management. Once defined the functional model which controls the performances behaviour, building designer will analyse different object models and will choose the optimised ones, from the point of view of service life, considering the real external site agents. The service life evaluation method permits then to choose solutions that will guarantee correct performance levels during predicted service life, and then contributes to optimise natural resources utilisation towards a sustainable development.
Key words : sustainable construction, building components, durability test, service life, maintainability

1 Introduction

The paper's subject takes place in the general theme of the Symposium "Material and technologies for sustainable construction" and, in particular, in the theme "Performance, durability and service life". The problem's solution of the sustainable development in building sector passes through the individuation of the priorities in the choice of the materials to be used in the design and the production of building components. The choice of these materials must take into account their compatibility with the global equilibrium of use of natural resources. Therefore only the materials of which this compatibility is recognised must be used, i.e. those materials which minimise the intrinsic energetic waste of the involved raw materials, the energetic waste due to the transformation into building materials, the waste implied by an eventual recycling to reduce the environmental impact. Within some years at DISET, Politecnico di Milano, it has been developed research work, co-ordinated by prof. P.N. Maggi, about setting up of evaluation methods for the three components of building components technological quality: zero time quality (characteristic quality)' quality during service life (durability) and maintenance quality (maintainability). This paper, related with other papers titled: "Functional analysis as a method to design new building components" and "Experimental programme to evaluate building components service life: an application", reports a method for the evaluation of building components service life.

2 Evaluation method for the sensitivity of building materials and components

The research aims at defining an evaluation method for service life of building components, within a particular class of building components. If exhaustive experimental information would be available, one could estimate building components durability, as the time of service life, after which performance levels decay under specified acceptability thresholds. Actually the lack of experimental information led us first to consider qualitative evaluations, about trends of "effect indicators": so in the first research phase we elaborated a method for the evaluation of durability, based on sensitivity to actions of building materials and components, constituting a catalogue of technical solutions; the component sensitivity is calculated on an absolute dimensionless scale, from the analysis of degradation effects reported by scientific and technical documentation. In the second experimental phase of the research we turned to evaluate the decay of functional characteristics of building components, during laboratory accelerated and outdoor natural ageing tests. To demonstrate the applicability of these durability evaluations we chose a catalogue of technical solutions of "Not-bearing external walls", while the methods may be applied to each class of building components [1]. We consider a "technical solution" as a complex product, composed by elementary products, (let's call them simply "products"), which can be materials, semi-manufactured or elements, at different technological complexity. Then for the sensitivity evaluation method, we consider the available experimental information on durability of such products constituting each technical solution, regarding agents and actions, which may cause degradation. The considered agents have been chosen among all natural and artificial agents [2], significant for the whole building, as the ones which may really stress the specific class of building components, considering external and internal surface exposure. An action is defined as the expression of mediation between one or more agents and the consequent effects: the action is taken into account when it's demonstrated, by technical scientific documentation, to cause some irreversible effect and then the degradation of the products; besides the intensity of significant actions must be comparable to building context. The parameter on which we evaluate product sensitivity to the action is the "effect indicator" defined as the characteristic that consents to measure the effect in testing, and then represents the effect in a synthetic way. Then starting from pertinent information, found in technical scientific documentation, about products durability regarding each action, we elaborate a method for the evaluation of product sensitivity parameters, based on the analysis of each final irreversible effect. The "product sensitivity to an action" , is defined as a function of the following parameters regarding each final effect: the mean time trend of effect (represented and measured by its indicator), the effect surface frequency, the effect depth progression, and the effect time trend regularity. So the "product sensitivity to an action" S_A, is calculated as the mean value of sensitivity evaluation on each final effect caused by this action:

$$S_a = \sum_{e=1}^{E} \frac{F_e \cdot P_e \cdot (T_e + I_e)}{E}$$

where:

E	is the number of final effects *"e"* significant to the action A
F_e	is the effect surface frequency parameter
P_e	is the effect depth progression parameter
T_e	is the effect mean time trend parameter
I_e	is the effect time trend regularity parameter

The mean time trend parameter is evaluated through four classes of increasing risk for the product due to the effect (see Figure 1).

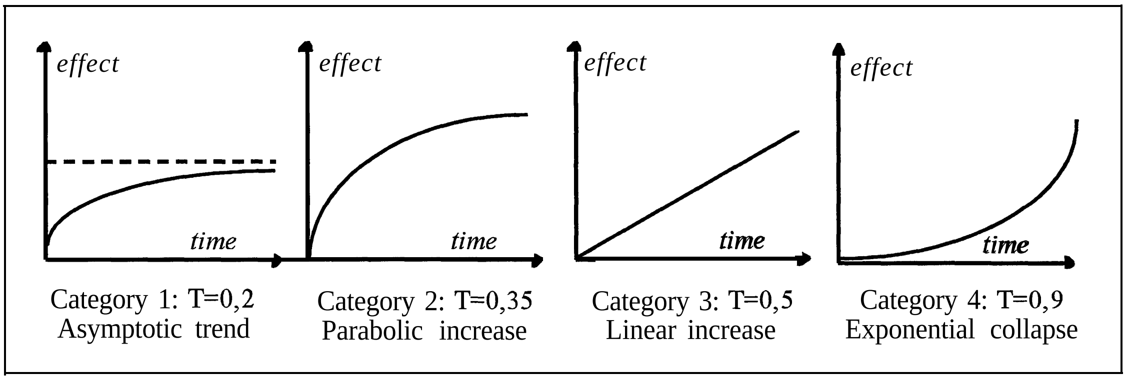

Figure **1.** Evaluation categories for the effect mean time trend parameter "T"

When the effect time trend has some significant irregularities, as fast trend variations or time steps the parameter of mean time trend is corrected by a term "I" called the effect time trend regularity parameter (see Figure 2); this has a positive value +O. **1** when the effect trend has fast worsening, corresponding to material crack or leaks, or it has a negative value -0.1 when the effect trend has some improvement.

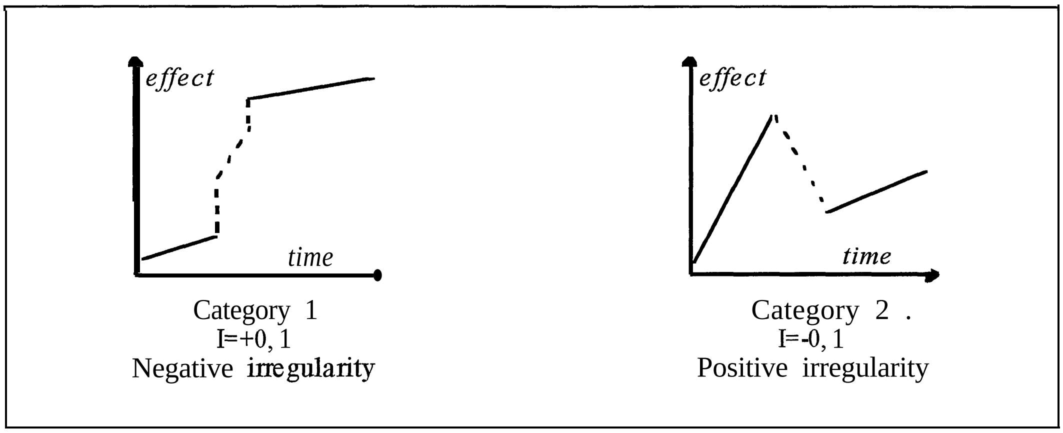

Figure 2. Evaluation categories for the effect time trend regularity parameter "I"

Besides these evaluations on time trend of effect the other parameters evaluate the space distribution of effect; the effect surface frequency parameter "F" (see Table 1) and the effect depth progression parameter "P" (see Table 2).

Effect surface frequency	**category**	**effect surface frequency parameter F**
Localised	1	0.8
Increasing frequency, from localised to uniform	2	0.9
Uniform with different decay start-up points	3	0.95
Uniformly distributed	4	1

Table 1. Evaluation categories for the effect surface frequency parameter "F"

effect depth progression	**category**	**effect depth progression parameter P**
Only surface effect	1	0.8
Depth progression effect	2	1

Table 2. Evaluation categories for the effect depth progression parameter "P"

After setting up the method to evaluate products sensitivity the research work was focused at he experimental validation of such method and in obtaining quantitative data about building components service life. The durability of a technical solution may be defined as the capacity to maintain substantially the initial performances during time. As the functional characteristics of the products in a technical solution are the vectors for the fulfilment of basic functions, related to requirements and performances, we may say that the performance decay of the technical solution depends on the variation of such functional characteristics.

Then the experimental evaluation of durability is based on measurement of time decay of functional characteristics of each product constituting the technical solutions, after laboratory (artificial) and outdoor (natural) ageing. The considered functional characteristics are correlated to technical solutions performances through the functional model, which can be obtained by the functional analysis explained in the report: "Functional analysis as a method to design new building components within a policy of a sustainable construction" presented by Politecnico di Milano, DISET.

3 Experimental programme to evaluate building components service life

3.1 General testing layout

In order to evaluate the durability of building components it was chosen to carry out a series of accelerated ageing tests in laboratory and in outdoor environment simultaneously. The choice to resorting to a double method of evaluation allows to correlate the different scales avoiding to produce unreliable results or, at least, some that are not traceable back to outdoor environmental stresses. As far as the tests in the environment are concerned two contexts with assimilated climate (Milano and Lugano) were chosen but with different levels of pollution. The samples are placed vertically and with an inclination of 45 °. This latter position allows submitting the building components to conditions of greater stresses than the natural ones to which a vertical external wall is subjected. Three types of tests were thus identified: laboratory accelerated test, outdoor accelerated test (45") and outdoor natural ageing test (90°).

3.2 The laboratory test cycle

In order to determinate the length and structure of a complex test cycle, which is able to give back to environmental agent conditions, the outdoor agents that can effect service life of the chosen building components, were first identified. To verify the stressing time and the likely synergies which can develop among the agents both the national standards supports (UN-I and ICITE) and international ones (Swiss standards - SIA 162/1 test n. 7, n.3, n.5 -, ISO/TC 59/SC 3/ N 296, CEN, ASTM E 632, ASTM G 26, DIN 1048 test 5, DIN 52617 -, AFNOR - NF T 30-049) were analysed as well as the documents concerning the testing climatic chamber. The equipment allows to simulate the following environmental conditions:

1. Temperature cycles from +20°C to -20°C in 4'
2. Maximum Temperature +90°C and Minimum Temperature -30°C
3. 15%< Relative Humidity <95%
4. UV Radiation (max 6000W, 90 Klux)
5. Artificial rain

The total cycle (about five and half hours) is divided in four partial cycles interrupted by times of transition (T) necessary to guaranty the passage and the following assessment of the proper condition of every partial cycle.
The test cycle has been so divided:

1. Artificial rain (30'). In this first phase the samples are washed away with water at a temperature of 20°C ±5°C. The climatic chamber is kept at a constant temperature of 20°C ±5°C and at a relative humidity higher than 90%; T_{12}=Transition time: 5'.
2. Freeze (60'). The wet samples are submitted to a temperature of -20°C; T_{23}=Transition time: 8 5 '.
3. Warm and humid condition (60'). The temperature is raised to 55°C with a likely oscillation of ± 2°C whereas the relative humidity must rich values of 95%; T_{34}=Transition time: 5 '.
4. Warm and dry condition with UV exposure (80'). In this last phase there must be a

relative humidity of **20%** in the apparatus with a range of 5% and a planar radiant temperature of 60°C±2°C; T_{41}=Transition time: 5'.

3.3 Laboratory test programme

To carry out the first surveys 28 samples have been prepared (14 protected and 14 unprotected). 8 of these were exposed to environmental stresses (4 in Milan - 2 protected and 2 unprotected - and 4 in Lugano - 2 protected and 2 unprotected) being placed both at 45° and 90°. The first preliminary phase actually consists in verifying if the planned cycle brings to right stressing loads on the samples through the constant measuring of the temperatures and humidity rates, at different depths of the sample, during the progress of the rain and freeeze cycles. Once the preliminary calibrating phase of the cycle is ended the 16 samples, which are pre-set to be introduced in the climatic room (8 protected and 8 unprotected), will be started to be tested.
The test will take 3 month. To reduce the testing time it has been defined a program, which could permit full function of the machine. In the ageing apparatus have been in fact inserted always first samples with higher time of exposition. The program permits to guarantee the same number of cycles and test (destructive and not destructive) for each sample.

3.4 Characterisation tests

All samples are subject to test of functional and dimensional characterisation at the beginning and the end of the pre-defined stressing cycles at different intervals for each sample. There are two types of test: not destructive with a span of a week or two weeks, or destructive with variable span in relation with exposure time (minimum 3 days, maximum 1 month and half). In the first case the measurement is done by observation and is documented by photos (1 photo general and 4 details). In the second case are used specifically instruments and measurements methods related to the characteristics to be measured.

Non Destructive tests		Destructive tests	
Characteristics	**Evaluation methods**	**Characteristics**	**Evaluation methods**
Colour difference	Spectrophotometer	Thickness	Electronic microscope
Specular gloss	Glossmeter	Young's modulus	SIA 162/1 test n.3
Weight	Precision balances	Absolute density	Picnometer
		Capillar absorption	Test as DIN 52617
		Vapour permeability	Test as DIN 52615
		Water permeability	SIA 162/1 test n.5 -DIN 1048 n. .5/ Directive EMPA
		Adhesive power	Tear test
		Specific heat capacity	Mixture method
		Thermal conducibility	Flowmeter method

4. First test samples of a traditional technical solution of external wall

4.1 The technical solutions and the start up of experimental tests.

The experimental tests programme will allow to evaluate the durability of 17 technical solutions of a catalogue of external walls, the most usual in Italian constructions. The technical solution chosen to start the experimental programme is a traditional wall composed by: external perforated bricks, thermal insulated layer, internal hollow bricks, externally coated with plaster and finished with an acrilical plastic coat and water painted. The test will tackle the external coat of the technical solution, so the samples will be only composed by the external coats, starting from the thermal insulating layer. The specimen will have two configurations :

1.NON PROTECTED SPECIMEN		2.PROTECTED SPECIMEN	
9	Perforated brick and mortar concrete	9	Perforated brick and mortar concrete
3 8	Plaster	3 8	Plaster
		8	Plastic coat with acrilical application (RPAC)
		7	Acrilical water painting

The comparison between the results of the non protected specimen and the protected one will show the protective performance of the external coats during the time.

4.2 The project and assembling of the samples

The samples are dimensioned to represent significant sections of the technical solutions and to fit the test chamber (radius: 40 cm ; chamber total dimension: 100x90x90 cm). The resulting sample has the following dimensions: 3 8.5x49x13.5 cm. The sample will be positioned in the test chamber as designed in the figure 3 below ; the four lateral faces will be protected from the water of rain cycle by a metal box, so the water will impact only the face that simulates the external face of the technical solution (Figure 3).

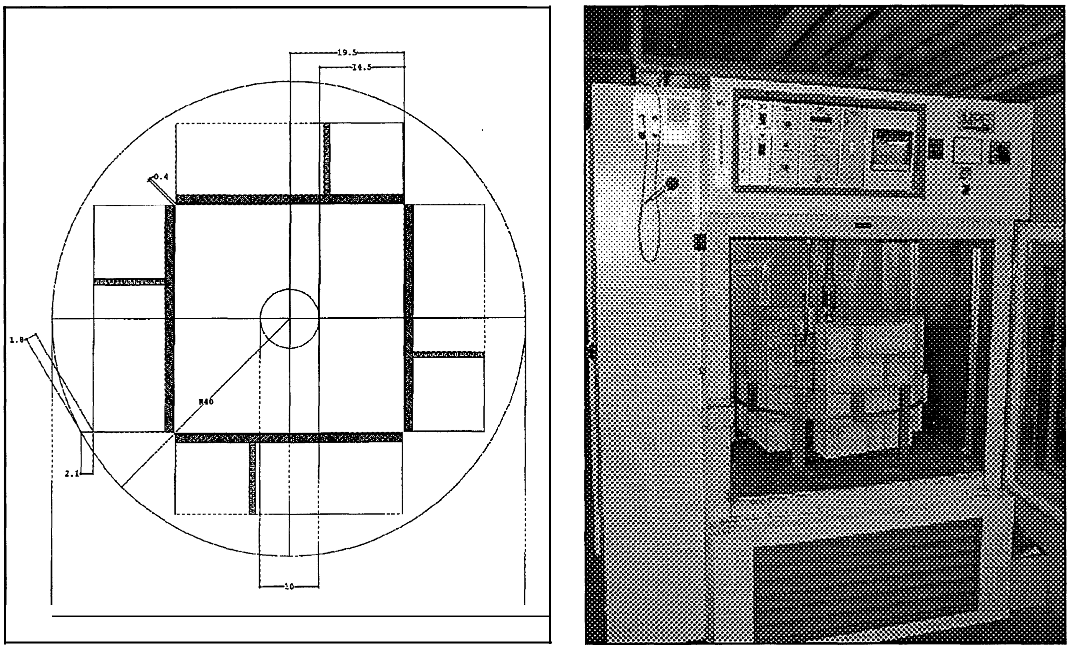

Figure 3 : Samples position in test apparatus.

4.3 The samples assembling

To choose the sand type we have tested some commercial sands normally used in building sites to produce mortars and plasters, and then we have reproduced this curve as sum of selectioned sands in percent.

The composition so defined, in accordance with the commercial and standard grading, will be reproducible as a constant in future tests.

Sieve spread (mm)	**0.063**	**0.125**	**0.25**	**0.5**	1	**2**	**4**	**8**
sands grading %	1.6	10.5	21.1	**39.3**	**58.3**	**82.9**	**99.4**	100

Defined the right sand grading curve, we started with the assembling of the components to produce mortar and plaster.

9	MORTAR	m^3	1
1	Cement Rbk 325	Kg	**450**
7	Sand	Kg	1450
6	Water	Kg	**250**

38	PLASTER	m^3	1
1	Cement Rbk 325	Kg	135
2	hydraulical lime	Kg	315
7	Sand	Kg	1450
6	Water	Kg	**300**

Before their application to produce the samples, some mortar prisms are characterised after a period of 7, **14, 21** days Curing in water positioned in a climatic cell at 20°C.

5 Conclusions

In these days the preliminary experimentation is just to begin: then we will be able to calibrate the experimental programme (see chapter 3); in the next months the testing programme will be executed and the first results will be available: with these data the methodology will be validate (see chapter 2); finally we will start with the experimentation on all the other technical solutions.
The results we will obtain about the building components durability, related with the reliability evaluations, reported in the paper "Method for reliability evaluation of building: application on a set of components" (CIB 1996 - "Applications of the Performance Concept in Building" - Tel Aviv), allow the designer to choose the optimised solution for the specific requirements of his project.
The service life evaluation method permits then to choose solutions that will guarantee correct performance levels during predicted service life, and then contributes to optimise natural resources utilisation towards a sustainable development.

Technological complex for utilization of high-calcium ash and slag for Abakan thermal power plant

S. Pavlenko, A. Shishkanov, and A. Soin
Siberian State Academy of Mining & Metallurgy, Novokuznetsk, Russia
Malyshkin V.
Khakasenergo, Abakan, Russia

Abstract
The Siberian State Academy for Mining and Metallurgy (SSAMM) and Uglestrinproject have developed a project for complex utilization of waste produced by burning brown coals from Kansk-Achinsk Power Complex at the Abakan thermal power plant. The project provides for total utilization of ashes and slags from the thermal power plant for producing finished 'cementless' binder and aggregate, finished 'cementless' fine ash/slag concrete and mortar, precast reinforced concrete structures and small products (silicate brick). Previous investigation of ash and slag from the thermal power plant and concretes on their base was completed in 1995. After grinding and introducing silica time, ash and slag to meet the requirements of State Standard 25818-91, concrete is in accordance with State Standard 26633-91.

The technological complex providing loo-percent utilization of waste products from the TPP includes departments for grinding ash with a storage, for producing sand from slag with a storage, molding with concrete mixers and premises for admixtures. The project has been approved by a nature committee of the Khakass Republic and is in accordance with the ecological standards. The construction of the complex is currently under way.
Keywords: High-calcium fly ash, slag sand, silica fume, cementless binder, technological complex.

1 Introduction

One of the trends towards the utilization of fly ash and slag waste products from thermal power plants, particularly those using brown coals, is the production of construction materials, mortars and concretes for various practical uses.

This work presents the results of a study and a project for a complex utilization of ash and slag from the Abakan thermal power plant, located in the Khakass republic, which is burning brown coals from the Kansk-Achinsk Power Complex. The project provides for the utilization of the total volume of high-calcium ashes and slags from thermal power plants for producing the following materials: finished binder and fine aggregate in the form of slag sand with the particle size of 0 to 5 mm, marketable cementless and lean mortar and concrete as well as precast structures and small concrete products.

Profitability of the project has been achieved through the use of cheap initial materials for the production of the above products.

2 Properties of materials used

2.1 Fly ash

The fly ash from the Abakan thermal power plant was investigated in accordance with two standard documentations:

1. Specification 34-70 10898-88 [1] developed by SibZNIIEP, IKhTTIMS of the Siberian Branch of the Academy of Sciences of the USSR NIIZhB Gosstroy USSR and Moscow Institute of Steel and Alloys;
2. State Standard 25818-91 [2] developed by the leading institutions of Russia with the participation of the first authors.

According to the requirements, physical properties of the ash from Kansk-Achinsk Power Complex were standardized by its fineness and residue on sieve № 008. The data obtained by the authors were compared with the data obtained by SibZNIIEP (Novosibirsk) who investigated ashes from the Kansk-Achinsk Power Complex coals burned at the Novosibirsk power plant and Barnaul thermal power plant №3 [3]. The physical properties determined in accordance with State Standards 3 10.2 - 76 and 3 10.3 - 76 [4,5] are given in Table 1.

Table 1 - Physical Properties of Ash from Abakan Power Plant

Properties	Standards			SibZNIIEP data, Ash from Novosibirsk TPP	SSAMM data, Ash from Abakan TPP
	Specification 34-70.10898		State Standard 25818-91		
	First Grade	Second Grade			
Surface area, no less than, cm^2/g	2800	2000	2500	2996	2358
Residue on sieve №008, no more than,	12.00	15.00	20.00	10.27	7.50

As can be observed from the data given in Table 1, the ash from Abakan thermal power plant can be referred to as a second grade ash due to its fineness, and as a first grade ash due to the residue on the sieve. It exhibited worse properties than the ash from the Novosibirsk power plant №3. For improving its characteristics, raising its chemical activity and eliminating irregular spreading, the ash needs grinding.

Chemical analysis of the ash for oxide and unburnt particles contents made in accordance with State Standard 5382-91 is given in Table 2. The results of the ash analysis can be summarized as follows.

Table 2 - Chemical Analvsis of Ash from Abakan Power Plant

Oxides	Standards			Ash from Novosibirsk Power Plant	Ash from Abakan Power Plant
	Specification 34-70.10898		State Standard 25818-91		
	First Grade	Second Grade			
SiO_2				20.93	39.45
incl. free SiO_2				16.87	24.20
Total CaO		-		31.95	31.20
incl. free CaO	6.00	9.00	5.00	5.51	8.91
MgO	3.00	7.00	5.00	5.96	6.31
Al_2O_3				7.64	7.11
$FeO+Fe_2O_3$				15.37	10.79
MnO				0.44	0.18
P_2O_5		-		0.23	0.06
SO_3	5.00	5.00	3.00	1.87	0.86
TiO_2				0.76	0.90
Na_2O+K_2O	-		1.50	1.80	1.10
Loss on ignition	3.00	5.00	3.00	3.45	1.85
Coefficient of quality, $c_q = \frac{CaO+Al_2O_3+MgO}{SiO_2}$ no less than	1.20	1.00	-	1.47	1.13

1. The coefficient of quality for determining binding properties of the ash [3] indicated that the binding properties of the ash from the Abakan power plant were less (more than 1 .O but less than 1.2) than those of the ash from the Novosibirsk power plant (1.3 times higher).

C_q = (31.20 + 7.11 + 6.317)/39.45 = 44.62 / 39.45 = 1.13

2. Due to calcium oxide (8.91%) and magnesium (6.31%) contents, the ash was referred to as the second grade.
3. Due to the contents of sulfate compounds and loss on ignition (0.86 and 1.85, respectively), the ash was referred to as the first grade.

Though the values of the first two indices were low, the ash had a potential activity reserve. A high percentage of the free silica content of the ash increased its binding properties after its grinding, subsequent treatment with water and heating. Magnesium-containing minerals were also activated after grinding. The data on the SO_3 content and loss on ignition were encouraging in terms of durability of the future concrete and protection of reinforcement from corrosion.

2.2 Granulated slag

The slag from the Abakan thermal power plant was studied in accordance with the requirements of State Standard 26644-U [6]. The glassy slag was separated into two grading fractions: 5 to 10 mm slag rubble (7.5%) and 0.14 to 5 mm slag sand (92.5%). While assessing the slag sand, the characteristics to be considered were bulk density, granulometric composition and chemical analysis. The bulk density determined in compliance with State Standard 9758-86 [7] was 1.58 g/cm^3 (1580kg/m^3).

Grain composition of the slag sand determined in accordance with State Standard 873 5-88 [8] is given in Table 3.

Table 3 - Grading of Slag from Abakan Thermal Power Plant

Sieve size, mm	Residue on Sieve	Cumulative percentage retained, %
5.000	75.0g 75.0%	75.0
2.500	56.2g 56.5%	64.0
1.200	21.5g 21.5%	85.5
0.630	55.0g 5.0%	91.0
0.3 15	50.0g 5.0%	96.0
0.140	30.0g 3.0%	99.0
< 0.140	10.09; 1.0%	100.0

The data on the grain composition indicated that the cumulative percentage retained on the sieve № 063 was 9 1% which was above normal (65%) while the fineness modulus was 4.3 5 which did not meet the requirements of fine aggregates for concrete (2.5 to 3.1 for denser packing). However, grading fraction of 5 to 10 mm revealed microcracks. Therefore, all the slag needed grinding to 0 to 5 mm particle size so it could be used in fine ash-slag concrete containing no natural aggregates. The absolute density of the slag sand was 2150 kg/m^3.

Frost resistance was determined is accordance with State Standard 9758-86 [7]. Before grinding, the frost resistance of slag was equal to 102 cycles of freezing and thawing, whilst after grinding to a particle size of 0 to5 mm, the frost resistance increased to 235 cycles versus 200 cycles according to a State Standard for a dense slag.

Testing for oxide contents was performed in accordance with State Standard 25589-83 [9,10]. The chemical analysis is given in Table 4. The data given in Table 4, showed that the slag sand meets the requirements of State Standards for use in concretes. Resistance of the slag to silicate and ferric decomposition was determined in compliance with State Standard 9758-86 [7]. The weight losses were 6.38 to 6.70% (up to 8% according to State Standard) and 4.42 to 4.60% (up to 5% according to State Standard) for silicate and ferric decomposition, respectively.

Table 4 - Chemical Analvsis of Slag from Abakan Thermal Power Plant

Oxides	Quantities, %	
	State Standard	Actual Sample
Total SiO_2	no standard	56.47
Free SiO_2	no standard	15.51
Total CaO	no standard	29.92
Free CaO	no more than 1%	
Al_2O_3	no standard	8.16
Fe0	no standard	8.20
Fe_2O_3	no standard	1.43
MgO	no standard	3.50
MnO	no standard	0.17
P_2O_5	no standard	0.05
SO_3	no more than 3%	0.11
Loss on ignition		
for dense slags	no standard	
for porous slags	no more than 3%	

2.3 **Silica fume**

Silica fume from the Kuznetsk ferroalloy plant was a fine powder (5 to 6 times finer than cement) of a light grey colour with a fineness of 2200 to 3000 m^2/kg. The data on test results are given in Table 5. X-ray diffraction and DTA showed the presence of silicon oxide mostly in the amorphous from, which increased the hydraulic activity of the silica fume while reacting with lime and binding free lime of a high-calcium ash. The hydraulic activity was assessed by determining the amount of lime absorbed by silica fume from a saturated solution at 85°C. It was 102 mg CaO/g.

Table 5 - Physical Properties and Chemical Analysis of Silica Fume

Physical Test	Results
Fineness	
-passing 45 mm, %	100
– Blaine, m^2/kg	2900
Specific Gravity	2.25
Colour	light grey
Chemical Analysis, %	
SiO_2 total, including	90.11
SiO_2 free	82.00
CaO total	0.71
MgO	0.97
Al_2O_3	1.93
$FeO+Fe_2O_3$	1.82
MnO	0.20
P_2O_5	1.18
Na_2O+K_2O	2.03
Loss on ignition	2.05

3 Optimum mixture proportions

Optimum mixture proportioning of an ash-slag-silica fume blend was obtained on the basis of previous studies [11, 12, 13] and new experiments using a mathematical method of planning [14]. Testing of structures and products (silicate brick in this case) were also made. The test results meet the requirements of up-to-date State Standards for concretes and silicate brick. The optimum mixture proportions for the ash-slag-silica fume blend were the following:

High-Calcium fly ash - 650 - 750 kg/m^3
Silica fume - 70 - 80 kg/m^3
Slag sand - 1000 - 1100 kg/m^3
Water - 180 - 210 kg/m^3
Superplasticizer - 0.7 - 2.0 kg/m^3 (0.1 - 0.3 % by weight of a binder)

As a result of the investigation and tests performed, non-autoclave ash-slag-silica fume brick has been produced with a compressive strength of 12.5 to 15 .0 MPa, frost resistance of 50 to 75 cycles and an average density of 1900 to 1950 kg/m^3 which meets the requirements of State Standard 379-89 "Silicate brick. Specification".

4 Technological scheme for utilization of ash and slag from Abakan thermal power plant

A technological scheme for processing ash and slag and a project of a technological complex for the Abakan thermal power plant have been developed. Collected by electrostatic filters, the high- calcium fly ash with a fineness of 2400 cm^2/g was ground in ball and tube mills to a fineness of 4000 cm^2/g in order to destroy agglomerated particles and fused surface of the ash and thus increase its hydraulic activity. Besides, the grinding stimulated interaction between free calcium oxide and the amorphous microsilica.

Slag from the thermal power plant in a melted state was granulated and then ground by roller crushers to a particle size of 0 to 5 mm. This procedure improved the granulometric composition of the aggregate, eliminated microcracks and stresses in the slag, improved its frost resistance and hence, the properties of the future concretes.

20 to 30 percent of the processed ash and slag is sold to builders while 70 to 80 percent is used for producing various types of concrete and products as well as used in concrete for reconstruction and expansion of the thermal power plant. The schematic diagram of the complex for utilization of fly ash and slag from the thermal power plant is given in Figure 1.

An ash-slag-silica fume blend was made in mixing-crushing runners or fixed-drum concrete mixers using hot water (60-80°C) at 12% relative humidity of the mixture. Brick was produced by dry pressing at 20 to 25 MPa and then was moist-cured in a steam-curing chamber at 95 to 100°C using a 3+10+3 h cycle. The use of 0.1 to 0.3% high-molecular S-3 superplasticizer greatly improved workability of the mixture and increased the strength and durability of the brick. With free CaO contents ranging from 5 to 15 percent the strength characteristics of the ash-slag-silica fume brick did not change greatly.

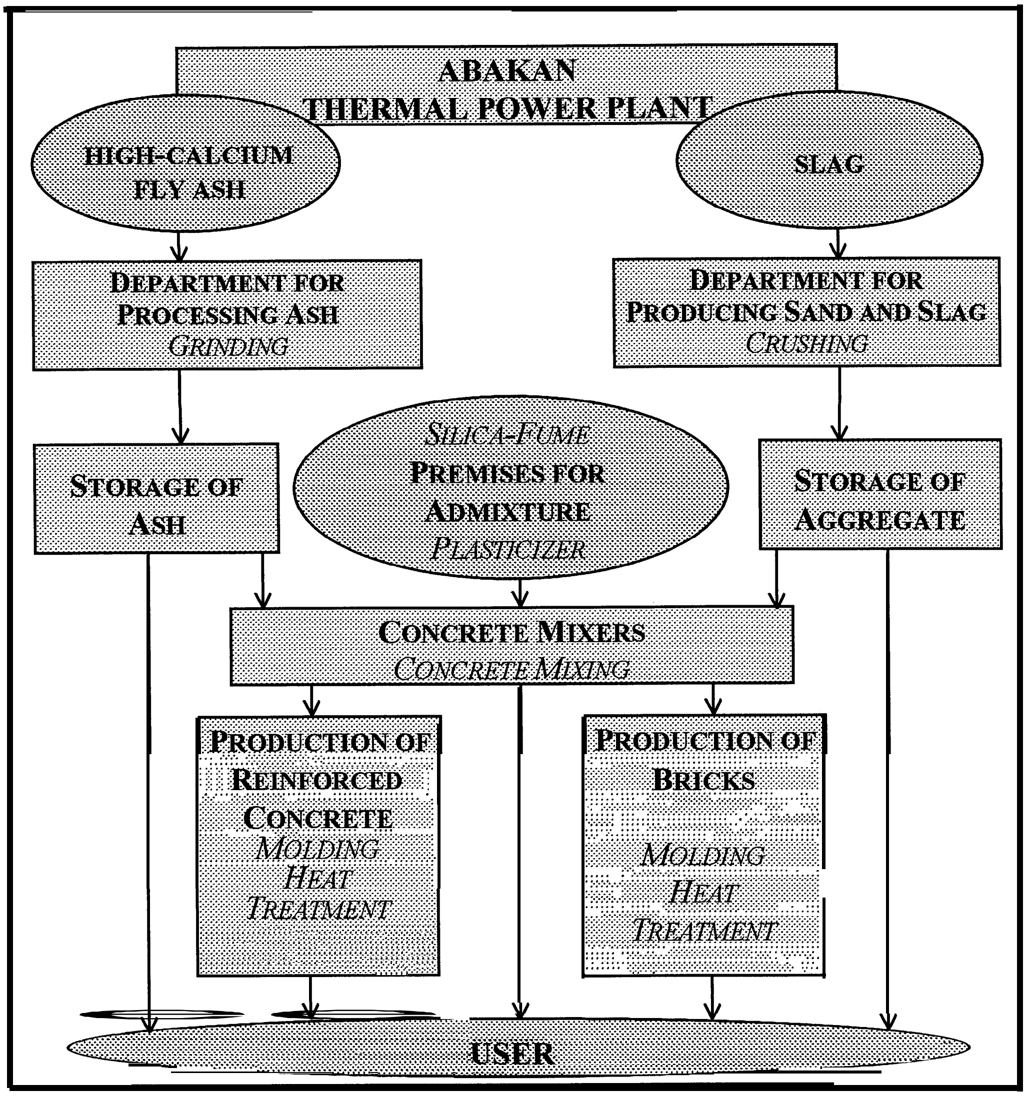

Figure 1 - Schematic diagram of total utilization ash and slag from thermal power plant

5 Technological complex for utilization of waste from power plants

The technological complex provides for the 100 percent utilization of wastes from the Abakan thermal power plant and includes the following facilities:

-the department for grinding ash with a store;

-the molding department with mixers, one of which is designed for the production of a ready-mixed concrete;

-the storage for finished products;

-the storage for admixtures, fuels and lubricants;

-the department for the production of sand from slag with a store for finished products.

6 Conclusions

1. The technology and a “Technological Complex for Utilization of Waste from Power Plants” project for producing ready-mixed concrete, reinforced-concrete structures and ash-slag-silica fume brick have been developed.

2. Organization of the production of ground ash, slag sand, structures and brick at the Abakan thermal power plant permitted the solution of the problem for the total utilization of wastes using steam and energy of the plant which reduced the cost of the products made of the wastes.
3. The cost of the production of a 'cementless' ready-mixed concrete and the ash-slag-silica fume brick are 60 and 65 to 70 % lower-than the production of a cement concrete and silicate brick hardened in an autoclave, respectively.

The effect of panelized single family residential construction on the environment

G.Z. Brown and T.E. Peffer
Energy Studies in Buildings Laboratory, Center for Housing Innovation
Department of Architecture, University of Oregon, Eugene, Oregon, USA

Abstract
The construction of single family housing in the U.S. is becoming increasingly industrialized with panelization emerging as the dominant form of industrialization. The question is whether this trend will mean that housing construction, operation, and demolition will have a greater or a reduced impact on the environment.

This paper analyzes the differences between low levels of industrialization, such as site-built wood framing or open wood-frame panels, and higher levels of industrialization, such as closed wood-frame or stressed skin insulating core panels, in terms of material use, waste generation in construction, and energy use in operation. One of the experiments cited compared the energy consumption of six units of housing built using various forms of factory fabrication — open wood-frame panels, closed wood-frame panels, and stressed skin insulating core panels. These tests indicated that the more completely components are factory fabricated, the less energy a house built from these components will consume, resulting in reduced CO_2 emissions from burning fossil fuels. The units built with the more industrializedpanels had a more completely insulated envelope and half the air changes per hour. Another experiment compared conventional onsite construction (wood frame) to stressed skin insulating core panel construction. Stressed skin insulating core panel construction used 5% less total wood and 50% less framing lumber, indicating the consumption of fewer trees. A similar experiment comparing the side-by-side construction of a wood frame house to a panelized house showed that the panelized house construction used less solid sawn lumber and generated less waste onsite. A recent prototype panelized floor/foundation system showed promise as a lower cost alternative to concrete slab construction with its high embodied energy. The on-grade panel floor system has better thermal performance than a typical slab floor, and the panels can be reused upon demolition. These examples show that high levels of industrialization can potentially result in less environmental impact from construction, operation, and demolition.
Keywords: energy, environment, industrialized housing, material use, panels

1 The current state of industrialized housing in the U.S.

Valued at $179 billion in 1994, the housing industry in the United States has an enormous impact on the economy and environment. The 1.6 million housing units constructed in 1995 (about 1 million of which are single-family units) consumed large quantities of raw materials and energy, and represent future demand for resources for operation and demolition [1].

1.1 Types of industrialized housing

Over the past 40 years, the production of houses has increasingly included more industrialized components and processes, ranging from dimensional lumber and prefabricated walls to completely prefabricated homes.

Datacollected on industrialized housing can be divided into four groups (listed here from most to least industrialized): HUD code, modular, panelized, and production-built housing. Houses completely built in the factory are considered to be the most industrialized, and those built primarily on site are the least industrialized. The most industrialized type of housing, HUD code housing, is built to a preemptive national code. A *HUD code* house is a movable or mobile dwelling constructed for year-round living, consisting of one, two or more manufactured units each towed on its own chassis, and connected on site. *Modular* housing is built from self-supporting, three-dimensional house sections intended to be assembled as whole houses. *Panelized* houses are built from manufactured roof, floor and wall panels designed for assembly after delivery to a site. The least industrialized are *production-built* houses, whole houses produced "in situ" using rationalized and integrated management, scheduling, and production processes, as well as factory-made components. Rather than the house constructed in the factory and moved to the site, the building site is the factory — an open-air assembly line of walls, floor or other building components [2].

1.2 Market share of industrialized housing

The last decade of industrialized housing production has shown a growing strength in the *more* industrialized modes of housing. From 1985 to 1995, HUD code, modular, and panel producers captured some of the market share from the less industrialized productionbuilders (including those that use only a few industrialized parts) (Figure 1). Panelized housing (including domes, precuts and log houses) showed the largest increase in market share over this period, expanding from 37% in 1985 to 47% in 1995, and shows promise of increasing growth [3].

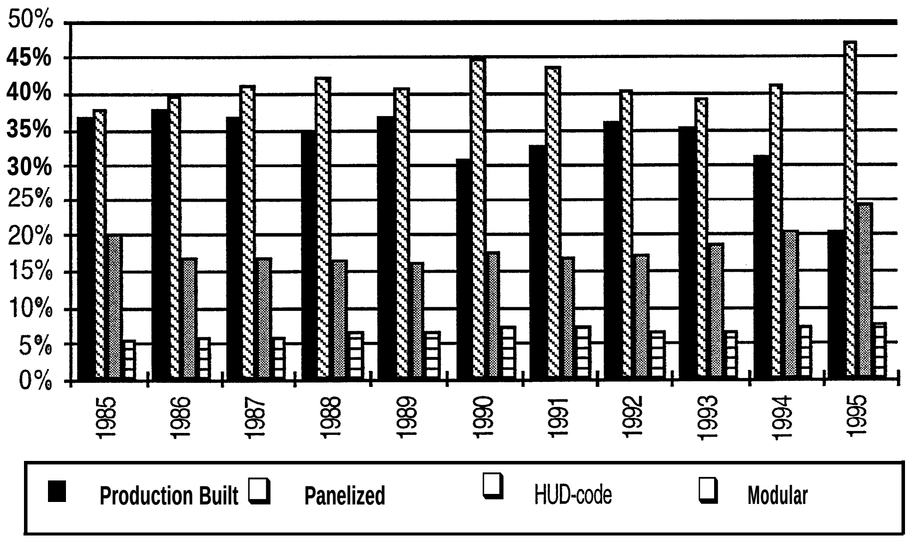

Figure 1: U.S. housing production by market share, 1985–1995 [4]

2 The impact of residential construction on the environment

The cost of housing can be measured in its effects upon the natural environment as well as on the economy. Houses impact air, water, and land quality, require raw material extraction, create waste in construction and demolition, and demand energy in operation. The choice of construction material — wood versus concrete, or engineered wood versus solid sawn lumber — affects the energy used, pollutants emitted, and waste generated during initial fabrication, and represents a potential waste hazard at the end of the building's life.

2.1 Construction material

The construction of houses requires a substantial amount of raw and manufactured materials that affect the natural balance of the environment. In the United States, a typical 194 m^2 (2085 sf) single-family house requires 3 1 m^3 (13,127 board feet) of lumber, 577 m^2 (6212 sf) of sheathing, 12,685 kg (13.97 tons) of concrete, 216 m^2 (2325 sf) of exterior siding, 225 m^2 (2427 sf) of roofing material, 194 m^2 (2085 sf) of flooring material, 284 m^2 (3061 sf) of insulation, 57 1 m^2 (6144 sf) of interior wall material, 257 L (68 gal) paint/coatings, as well as doors and appliances [5]. Since 90% of single-family houses are constructed of wood, housing greatly impacts the quantity and quality of living trees. Single-family homes create the largest single market for solid wood products in the United States. "In 1992 an estimated 41.3 million cubic meters of lumber, 9.0 million cubic meters of structural panels, and 3.0 million cubic meters of nonstructural [panels] were consumed in the construction of just over 1 million houses" [6]. Although-current annual tree growth is greater than harvest, logging practices of road construction and clearcutting lead to erosion, irreplaceable loss of topsoil, and the pollution of rivers and streams [7]. The demand for sustainably harvested wood in the U.S. has led to the growing number of sustainable forests, currently about 3.5 million acres of forest land [8].

The choice of material used in construction affects the degree of environmental impact. For example, when prefabricated panels are utilized as a treated wood foundation for basements, "the use of wood rather than concrete reduces the amount of embodied energy by about 30%" [9]. Concrete requires 1453–1589 kg (3200-3500 pounds) of raw material for 908 kg (one ton) of finished cement, produces CO_2, NO, and S gases, and requires 2344 MJ/m^3 (1,700,000 BTU/yd) of energy [10]. Wood, on the other hand, is a renewable resource, with low embodied energy, and shows promise of sustainable harvesting. Wood uses the least embodied energy of any building element at 2.5 MJ/kg (639 kilowatt hours per ton). (For comparison, brick uses four times this amount, concrete (5x), plastic (6x), glass (14x), steel (24x), and aluminum (126x) [1 1].

While wood has less environmental impact than other materials, using fewer trees and producing less wood waste can further reduce this impact. Engineered lumber consumes fewer trees to fulfil1 the same structural function as solid sawn lumber. Although lumber and timber consume half as much energy (7.38 MJ/kg) as veneer and plywood (14.62 MJ/kg) [12], the manufacture of engineered wood is highly efficient, using wood scraps and sawdust, so it saves trees. One manufacturer uses engineered lumber made from fast-growing trees like aspen or yellow poplar; the technology allows for use of "logs that are not large, strong or straight enough to be of structural value in conventional wood products" [13]. For structural engineered lumber, three-quarters of each tree is used, resulting in less waste than when using solid sawn lumber. Another example is the use of Oriented Strand Board (OSB) sheathing instead of plywood; OSB uses 59% less embodied energy than plywood because it makes better use of wood fibers [14].

2.2 Waste and air pollution

Building houses creates scrap material and other waste products that require time, energy, and means of disposal, whether by recycling or landfill dumping. A typical 186

m^2 (2000 sf) home generates the following construction waste: metals: ***68*** kg (150 lbs); drywall: 908 kg (2000 lbs); solid sawn wood: 726 kg (1600 lbs); vinyl: 68 kg (150 lbs); engineered wood: 635 kg (1400 lbs); masonry: 454 kg (1000 lbs); cardboard: 272 kg (600 lbs); containers (paints, caulks, etc): 23 kg (50 lbs); and 476 kg (1050 lbs) miscellaneous waste. This combined total of 3632 kg (four tons) of construction waste averages about $5 11 paid per house for disposal [15]. Wood products account for 40–50% of the residential construction waste stream.

Residential construction not only has an impact on the environment in terms of raw materials but also because of the transportation of materials to the site. An estimated 20–25% of the total energy for construction is due to transportation, which contributes to global warming via carbon dioxide emissions. One fifth to one quarter of total annual U.S. CO_2 emissions are generated from the manufacturing of buildings [16].

2.3 Energy use in operation

The composition and quality of construction of a house's exterior walls, roof and floors — the building envelope — substantially affects the energy consumption and cost over its lifetime. A Norwegian study found that the "[operational] energy use in buildings during the service life (50 years) accounts for more than 95% of the total energy consumption throughout the life of these houses" [17]. Residential buildings account for about one fifth of the United States' primary energy consumption, with 46% of this energy used primarily for heating and cooling [18]. Since energy use primarily requires burning fossil fuels, a more energy-efficient house is kinder to the environment in the long run. Heating and cooling residences in the U.S. accounts for 2 1% of the total U . S . CO_2 emissions from fossil fuels, producing 268 million metric tons of CO_2 per year as well as other gases detrimental to air quality and the atmosphere [19].

3 Less environmental impact with more highly industrialized panels

The growing use of panels in housing construction implies a varied impact on the environment through material and energy use depending on the type of panel. The panelized housing industry spans the spectrum of levels of industrialization, defined as the degree of completion of a panel when it arrives on the job site. Less industrialized panels need a moderate amount of finish work on the site, and more industrialized panels require less work on site (Figure ***2). Framedpanels,*** either open framed or closed framed, are prefabricated components replicating traditional stick framing and displaying low to moderate levels of industrialization. These panels consist of dimensional wood studs attached to wood sheathing such as Oriented Strand Board (OSB) or plywood. Framed panels carry structural loads through a stud frame as well as the sheathing. Predominantly used are the less industrialized ***open wood-framed panels,*** which are sheathed on the exterior only and completed on site with vapor barriers, interior finishes, and electrical and mechanical systems. More industrialized are the ***closed wood-framed panels***, which are shipped to the site sheathed on both the exterior and interior, and are sometimes pre-wired and plumbed. The most industrialized panels, the ***Stressed Skin Insulating Core panels,*** have a core of expanded polystyrene rigid foam insulation sandwiched between two sheathing layers that carry structural loads. These panels represent a new building component that cannot be fabricated on site, but requires a factory setting for production.

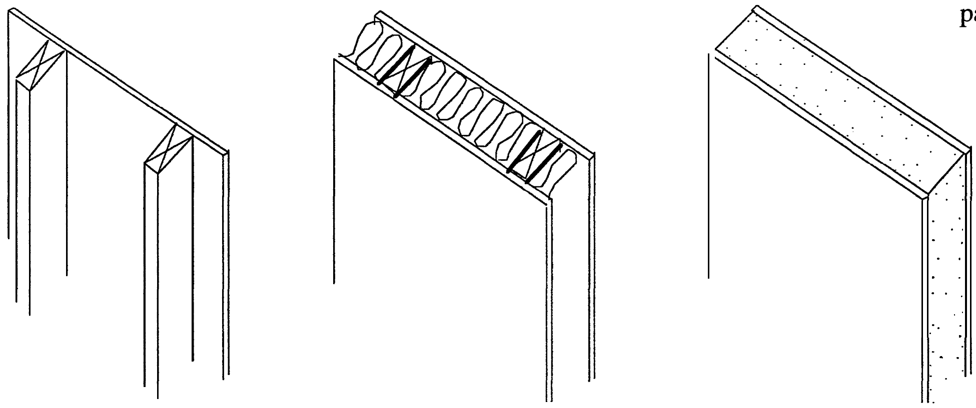

Figure 2: Types of industrialized panels

3.1 Fewer trees consumed with stressed skin paneled housing

Evidence shows that housing built with stressed skin insulating core (SSIC) panels consumes fewer trees compared to housing constructed with less industrialized methods. In an experiment conducted at the University of Oregon, the construction of an SSIC panel demonstration house was compared to that of a reference house of the same design and energy performance, but built with conventional onsite wood frame construction, The SSIC panel house used 5% less total wood, and 50% less framing lumber [20]. In another study, a stressed skin panel house and stick framed house, identical in plan, were constructed in a side-by-side comparison at the 1996 National Association of Home Builders (NAHB) convention. The more industrialized stressed skin panel house consumed the same amount of sheathing material, but 26% less framing lumber (35.6 m^3 or 15,100 board-feet) compared to the traditionally constructed stick frame house (48.1 m^3 or 20,400 board-feet) [21].

Using less framing lumber reduces the total number of trees required for the SSIC house and lessens the impact on the environment. Only 63% of a tree can be manufactured into solid lumber. However, more than 95% of a tree can be utilized when producing composite wood products such as plywood and OSB [22].

3.2 Reduced waste with panel construction

Housing built with panels can reduce the amount of wood waste entering landfills, since panels use primarily OSB and are factory produced, centralizing waste. Composite sheathing plants such as those that produce OSB divert about 8.2 x 10^9 kg (9 million tons) of residual wood from North America's landfills every year [23]. Highly industrialized processes such as panel production benefit from the centralized function and economies of scale of a factory, especially when directing waste. "Materials which are assembled into finished components under factory-controlled conditions usually make more efficient use of resources, and disposal of waste from a factory is more easily controlled" [24]. When waste is centralized and consolidated, it is more likely to be recycled properly instead of buried in a landfill. In NAHB's side-by-side test, the stressed skin panel house produced 76% less waste on site (3 m^3 or 4 yards) than the less industrialized wood-framed house (13 m^3 or 17 yards) [25].

A centralizedproduction scheme also reduces transportation. For example, a stick-built house requires separate transportation of relatively small amounts of drywall, studs, and sheathing. A panel produced in a factory means larger shipments of these items, capitalizing on the economy of scale. The standard 1200 mm x 2400 mm (4'x8') size of panels originated because "the economical transport of a factory-built house suggested the dimensions of a standard trailer truck as a design criterion — the 2400 mm (eight foot) width being particularly crucial" [26].

3.3 Less energy consumed in operating a stressed skin panel house

The more highly industrialized the panel, the better the energy performance of the panel-built house due to the quality of the insulation installation and the thermal performance of the insulation type. A study performed at the University of Oregon compared the thermal performance of six housing units constructed with open wood-framed panels, closed wood-framed panels, and SSIC panels. The units constructed of closed panels (Unit 2, Unit 5, and Unit 6) and the SSIC panels (Unit 1) were more airtight and had fewer thermal defects in wall insulation than the units constructed with the less industrialized open panels (Unit 3 and Unit 4).

Fan depressurization results suggested that the more industrialized panel construction achieved tighter construction resulting in reduced infiltration. The air changes per hour (ACH) measured 0.16 for the SSIC panel unit, 0.27–0.28 for the closed panel units and 0.34-0.39 for the open panel units [27]. Constructed a year later, the Demonstration House (DH) built with SSIC panel floor, walls, and roof showed even tighter construction at a measured 0.09 ACH (Figure 3) [28].

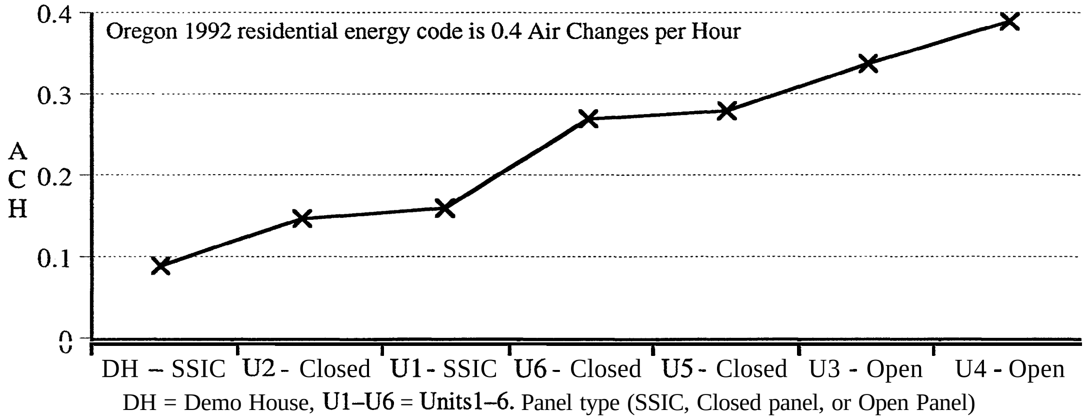

Figure 3: Tighter construction with more highly industrialized panels.

The results from thermographic imaging and coheating tests indicated that a higher level of quality control is achievable in the factory when installing insulation. The infrared imaging detected thermal weak spots caused by missing or poorly installed insulation in the site-installed insulation, predominantly in the open panel units. The open frame and closed frame panel units showed more heat loss through thermal bridging due to studs than the more highly industrialized SSIC panel unit, where the thermally broken splines were only detectable at building corners. Coheating tests indicated that the more industrialized closed panel units had lower overall thermal transmittance (UA) than the open panel units [29]. The 1280 sf SSIC demonstration house had a measured UA value of 133 BTU/h °F compared to 198 BTU/h °F for Unit 3 (800 sf) built with open panels.

Two identical houses were built in Louisville, Kentucky, one constructed of SSIC panels and the other using conventional site-built wood framing. The SSIC panel house outperformed the wood-framed house by 12–19%, mostly due to reduced loss from infiltration and thermal bridging. The air changes per hour (ACH) of the SSIC house were measured at 0.21 compared to 0.4 to 0.7 ACH for the conventional house [30].

4 On-grade floor panel system consumes less energy

The foundation and floor of a typical residence affects the environment through the materials used in the initial construction phase, through its energy performance in operation, and by its disposal at the end of its lifespan. A recent experiment using SSIC panels at the University of Oregon combined floor and foundation to reduce the cost of construction and the amount of concrete used, maintain energy and structural performance in operation, and provide easy dismantling and recycling upon demolition of the structure [31]. The prototype floor/foundation system uses one-sided SSIC panels on a compacted gravel bed, using engineered lumber as the perimeter beam (Figure 4). This floor/foundation system can potentially replace concrete slab floors — which represent 42% of the new single-family residences in the U.S. in 1995 [32] — with materials having lower embodied energy and cost. The on-grade panel floor costs 18% less than an equivalent slab-on-grade foundation and 40% less than a crawl space foundation. Thermal analysis indicates better energy performance than a slab-on-grade floor, with a measured F value of 0.1, compared to 0.5 required by code for a concrete slab. The ease of dismantling the structure also indicates potential in recycling and reuse at the end of its lifecycle.

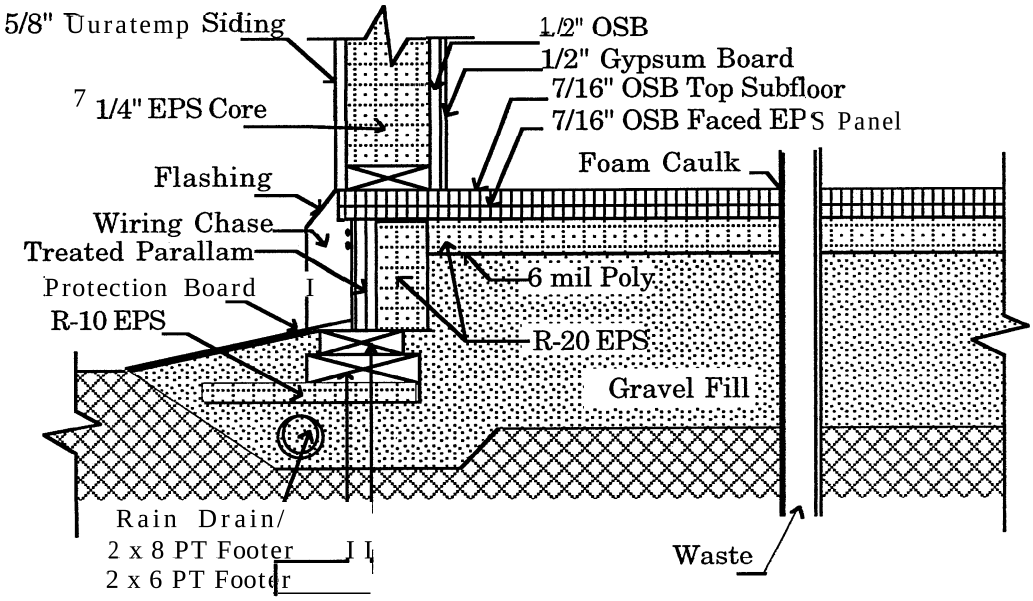

Figure 4: On-grade insulated panel floor system

5. Conclusion

This paper demonstrates the potential of industrialized panel construction in housing in reducing environmental impact by using fewer trees and creating less waste in construction, consuming less energy in operation, and showing greater potential for reuse at the end of a house's service life than conventional stick frame construction.

Many critics contend that industrialization is the antithesis of environmental regard. In residential construction this translates into a movement towards building products that have less processing and use more labor. While this low-tech approach has value it is clear that higher levels of industrialization at least in housing can also lead to reduced environmental impact.

Service Life Planning in Building Design

G. Hed
Centre of Built Environment, Royal Institute of Technology, Gävle, Sweden.

Abstract
Service Life Planning can be used in all phases of the design of a building. It can be used to set a time scale into the design as well as to consider the environmental aspects of the choice of materials and it can also give information to the consumer about the product he is going to buy and his investments performance over time.

In a research and development project carried out at the Royal Institute of Technology, Centre for Built Environment Materials Division, in Gävle the Service Life Planning is integrated in the design of a building. It is carried out according to the draft ISO-standard IS0 TC59/SC14 Design Life of Building, Part 1 [1]. It is an experiment to test and evaluate the standard. Also guidelines and requirements for further development and research are established.

Keywords: Service Life Planning, building design,

1 Introduction

Service Life Planning is to make plans for the intended use and performance of a building over its whole lifetime. It is a way for the actors in the building industry to reduce lifetime costs and meet environmental requirements.

The research in this area is intended to give a safer and more reliable prediction on how, when and under what conditions a building material or component will deteriorate, thus give a more reliable input for the Service Life Planning. With the knowledge available today in research institutions, universities and building material industry it is possible to make predictions on the behaviour of a number of building materials. An important issue therefore is to transfer this knowledge to the actors of the building market: clients, consultants, architects and contractors etc.

The standard IS0 TC59/SC14, Building Service Life Planning gives a generic description of how to plan for the service life of buildings and its components. Part one [1] deals with specific buildings and part two [2] with test of components in specific environments.

The following definitions are given in the standard:

Service Life	Period after installation during which all essential properties of a material or product meet or exceed minimum acceptable values.
Design Life	Period after installation during which all essential properties of a material or product are **intended** to meet or exceed minimum acceptable values.
Degradation Agent	Whatever acts on a component to reduce its performance

2 Service Life Planning

For a building component the requirements of properties, inherent properties and the degradation environment form the base for the Service Life Planning , se figure 1.

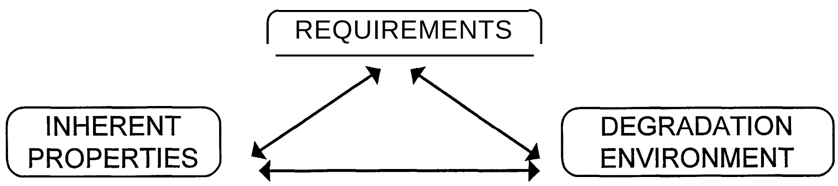

Figure 1. Basis for the Service Life Planning.

The requirements of a building component can be set up by national building codes and/or demands from the customer. Typically demands in a building code are issues dealing with personal safety like load bearing capacity, safety of fire etc. Customers demands could be economic and aesthetic. Demands of environmental safety are of increasing importance.

The requirements of properties are closely linked to the inherent properties of a component e.g. heat insulation, paint, load bearing member etc. But to estimate the behaviour over time one also have to consider the degradation environment i.e. all factors that will have an influence on the functionality of the building component as: wear and tear, mechanical impact, wind, rain, temperature, and air pollution.

The degradation environment can be described in four levels: **macro-region** country, **meso-**urban area, local-road/building and **micro-building** component [4], [5].

2.1 Scope, Method and Result

In a project where a modular building system in high performance concrete is developed the scope is to, in accordance to the draft standard IS0 TC59/SC14, Building Service Life Planning, part 1:

- Integrate Service Life Planning in the design of a building.
- Establish Design Life of Components, DLC.
- Make estimations of the Service Life of Components, ESLC.
- Evaluate the result

The Service Life Planning for each phase in the design is carried out in three phases in an iterative process: **planning** where requirements are set, **estimation** where the performance is checked whether it meets the requirements or not and **evaluation, see** figure 2.

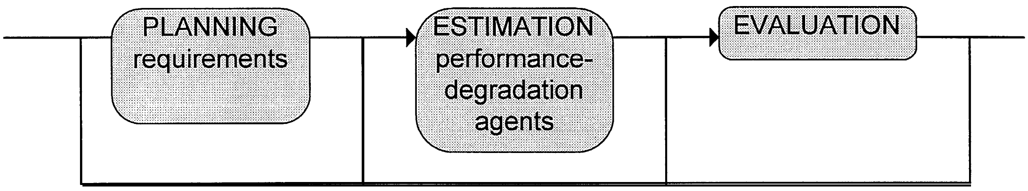

Figure 2. Service Life Planning in an iterative process in all phases of design, initiation, briefing, conceptual and detailing.

The results of the Service Life Planning are meant to be used primary to improve the design process and the design in:

- choice of components and materials
- exterior and interior detailing
- detailing of services

and in addition for:

- maintenance plans
- Life Cycle Assessments, LCA
- Life Cycle Cost, LCC calculations

2.2 Service Life Planning in Design

In the design of a building the documents, written and drawings, will turn to a higher grade of detailing as the process goes on. An assumption is therefore made that the Service Life Planning also has to be performed in that order. Table 1 gives an example on how Service Life Planning will fit into the design of a building. The design process is described in four phases: initial, briefing, conceptual and detailing.

	DESIGN		SERVICE LIFE PLANNING	
Phase in design process	*Drawings*	*Written documents*	*Service Life Planning*	*Degradation environment*
Initiation of a building project.		Short description of the project	Intended use of building	Macro- northern Europe Sweden
Design brief	Briefing sketch	Design brief	Set Design Life of Building, DLB.	Meso- urban area
Conceptual design	Drawings scale 1:200 plans and sections.	Function description Performance requirements	Set Design Life of major Components, DLC.	Local- location in city, wind, driving rain
Detailed design	Plans 1:100, 1:50 Facades Sections 1:50 Details	Building description Specifications of materials	Calculate the Estimated Service Life of the Components, ESLC.	Micro- degradation agents affecting a component

Table 1. Links between the Design and the Service Life Planning.

2.3 Initiation - Design brief

The thoughts of which service life a building have, has to be dealt with in the initial stages of a building project. The actual use of the building if it is a museum, small industrial building, temporary shelter, dwelling the planning of its lifetime use is an essential part of, or should at last be, of the initial process.

In the design brief for a new building generally no decisions on the layout and material choice are taken. The location, the intended use and the expected or desired lifetime of the building have to be formulated. This will give an input for the further going process of the design.

Use of building	Dwelling
Design Life of Building, DLB	The intended time for using this building is 60 years.
Criteria for reach of Service Life	Major refurbishment of the building.

Table 2. Result of Service Life Planning in briefing.

What is then the service life of a building? It could be this that several major changes of systems like service, roofing, facade etc. will take place at this time. All systems will during the lifetime be maintained, but on a certain stage the maintenance cost will be to high compared to the value of the building. It could also be that the function of the building is obsolete i.e. the building does not meet the demands of its time. See also figure 3.

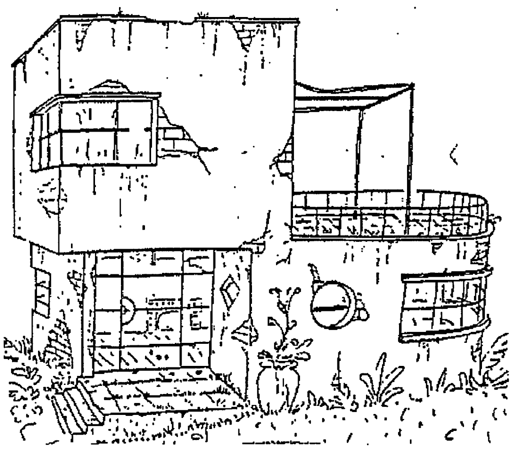

Figure 3. When has a building reached its Service Life.

2.4 Conceptual Design

2.4.1 Planning

Requirements for main assemblies: structure, inside and outside envelope and service systems are set up and evaluated at this stage in the design process.

One of the requirements is the Design Life of the Components, DLC. These are at this stage assumptions based on order of appearance in the building and previous knowledge and experience. Different components that meet the requirements will have different DLC. Example roof: felt, concrete tiles and zinc plates meet the requirements but will have different DLC.

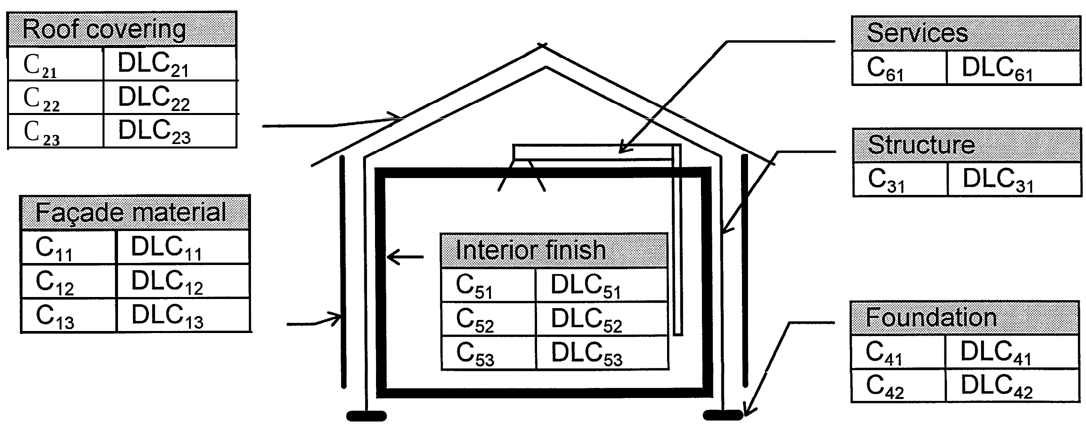

Figure 4. For different assemblies that meet the requirements, appropriate DLC´s are assumed. Examples, where C_{IJ} is a component and DLC_{IJ} its Design Life.

DLC's have also to be set according to the expected lifetime of the function of the component and possibilities to change systems in the future maintenance. It means that DLC is lowest for the interior finish and highest for the structure.

A quality approach to the Service Life Planning is to set the demands to the right service life, i.e. the service life which will give the best value for its purpose. A too long or too short service life will likely add extra cost. The long, in too high investment cost and the short in too high maintenance cost. Maybe these costs in a long term will level out.

2.4.2 Estimation - Evaluation

The DLC's are now treated as a requirement among others when different systems are evaluated.

In the actual case the structure is built from three dimensional elements made of high performance concrete. Therefore detailed estimations on the service life of these parts can bee done already at this stage. The 3-d volumes are also designed to be moveable. This will add the opportunity to reuse the building in an other place as it is likely that the technical service life will exceed the DLB.

In the design of the external wall a there have been discussions on the choice of façade system, or the role of the façade. The following standpoints have been taken into consideration, in addition to the demands of the building code.

- investment cost
- maintenance cost
- architectural expression
- environmental impact
- functionality, flexibility
- service life

From this a matrix discussion is set up on a limited number of solutions. This wav to discuss is set up for a number of main assemblies se figure 4.

External Wall - Façade

Function	Monolithic		
	Stratified		
Production	On site built		
	Factory made		
Material	Plaster	Plaster direct on insulation	
		Plaster on ventilated board	
	Boards	Fibre cement	fit on wood
			fit on metal
		Fibre cement, type Glasal	fit on stainless steel
		Ceramic plates	fit on stainless steel
		Coil coated steel	

Figure 4. Principles for matrix discussion on choice of façade.

The result of the discussion, from a Service Life Planning point of view, is summarised as follows:

- It is easier to describe the degradation environment for a stratified wall i.e. each layer has few functions.
- With factory built materials more reliable predictions of the service life can be made as it is not affected by the weather conditions on site.
- For the production, with moveable units, a reusable factory made plate facade is more suitable.
- A facade with ventilated plaster has a more predictable behaviour than a non ventilated.
- A facade with plates fit on metal bars will have a longer service life then plates fit on wood.
- Ceramic plates fit on stainless steel will have the longest service life, but does it have the right?
- Plates will be easier to maintain if single plates are fit to be able to change.
- A metal facade is recyclable.

The statements above are not objective truths based on scientific evidence but are evaluations based on experience. They can also be seen as guidelines for future research in the fields of durability and service life. E.g. ageing or long term tests on assemblies of components.

Anyway these discussions will end up in a table of DLC´s, table 3.

Building assemblies		***DLC Minimum***		
		alt 1	alt 2	alt 3
Load bearing members	foundation	DLB		
	vertical structure	DLB		
	horizontal main structure	DLB		
	stabilising members	DLB		
Non load bearing partition wall		25		
Roof	covering	15	25	40
	structure	DLB		
External finishing	facade material	25	40	DLB
	heat insulation	25	40	DLB
Fixings	external	40		
Services	ventilation	40		
	water	40		
	sewer	40		
Drainage	below ground	25		
External works		25		

Table 3. Design Life for major Components.

The values in the DLC table will in the next phase of design be compared to more detailed estimations on the service life of components.

3 Detailed Design

Here is given a brief description of the detailed design A separate report will later be prepared to present the detailed Service Life Planning.

In the detailing phase of the service life planning, estimations of the service life of the components are made. The estimations are based on the requirements, the inherent properties and the degradation environment and will be carried out with the factorial coefficient method proposed in IS0 TC59/SC14, Building Service Life Planning, Part 1, [1].

The equation for calculating the estimated service life of a component is given below:

$$ESLC=RSLC*A_1*A_2*B*C*D_1*D_2*E*F$$

Where

ESLC = Estimated Service life of a Component

RSCL = Reference Service life of a Component, which is a result of a test in a specific condition. The ideal is that these test are carried out according to IS0 TC59/SC14, Building Service Life Planning, part 2.

Factors A to F are described below:

F-actors related to nherent quality characteristics	4_1	Performance of Materials	Material type or grade. Manufacture, storage, transport.
	A_2		Durability features: Protection system.
	B	Design level	Details of construction: Joints fixing, incorporation, sheltering by rest of structure.
	C	Work execution level	Site work: Quality to standard or manufacturers specifications. Level of workmanship, climatic conditions during execution work.
Environment	D_1	Indoor environment conditions	Condensation, aggressiveness of environment, ventilation.
	D_2	Outdoor environment conditions	Elevation of the building, micro environment conditions, traffic emissions, weathering factors. Marine or polluted.
Operation conditions	E	In use conditions	Mechanical impact, category of users, wear and tear, vandalism.
	F	Maintenance	Quality and frequency of maintenance, accessibility for maintenance.

The ESLC´s will thereafter be compared with the DLC´s of table 3 and different actions will then be taken if ESLC differs from DLC. These actions could then be anything from just accept the difference to make a complete re design. It all depends on the cause and the consequence of the difference.

The quality of the estimation will be totally dependent on the input. Sources for input will be

- planning material manufacturers
- estimation reports from research
- experience from practice

4 Conclusions

The Service Life Planning can not be separated from the design of a building. This paper will show how this concept can fit in to the design process of buildings and how it can be used to improve the design.

The paper will also show that there is not only need for service life data of materials. It is also necessary to discuss general principles like

- factory built material - in situ built material
- stratified assemblies - monolithic structures

how they behave in the long term and how they affect the ability to predict service life.

System applied in Poland for assessment of products and technologies for sustainable construction

S.M. Wierzbicki
Building Research Institute - ITB, Warsaw, Poland

Abstract
The paper examines the principles of products and technologies for sustainable construction, applied in Poland. The assessment is carried out for two stages.

The first phase encompasses designing and the stage at which the building is constructed, taking into consideration the consequences of acquiring raw materials and the process for producing the materials and products.

The second phase of the assessment is the assessment of the building during its period of exploitation, which includes the living conditions of people in the building, the impact of the building on the environment and the service life of the elements and the whole building.

The basic elements of assessment and their systematics are given for these two phases.

The paper presents the provisions of the basic Polish building regulations affecting sustainable construction, i.e. the acts on environmental protection, on spatial management and the building law act. The acts are supplemented by executory ordinance issued by the appropriate ministers.

An important role in the system of these regulations is performed by the regulations determining the principles for assessing the innovative and non-standardised building products.

The paper informs about scientific research connected with sustainable construction, conducted in the Building Research Institute. The systematics of this work is to a large extent based on the set-up of basic requirements according to Directive 89/106/EEC.

Key words: assessment, buildings, products, sustainable construction

1 Introduction

If we agree with Bruntland's definition of sustainable development as ,,Development that meets the needs of the present without compromising the ability of future generations to meet their own needs", then one of the basic elements of such development is sustainable construction.

The Polish act on environmental protection states that sustainable development means such socio-economic development, in which in order to balance out access to the environment of various societies or their citizens - both present, as well as future generations - there occurs a process of integrating political, economic and social activity, maintaining an equilibrium in nature and the durability of the basic natural processes.

The building industry, in all of its phases of construction and exploitation of the building, is one of the basic factors affecting sustainable development.

Assessing building activity from the point of view of sustainable development we stress two aspects of this problem:

- the necessity of satisfying the needs of the present generation, requiring making short-term decisions i.e. for the contemporary users of the building and
- the requirement to act in such a way, so that today's activity does not prevent the fulfilment of the needs of future generations, and this means an assessment of the long-term effects of the investment decisions made today.

Construction which is conducted in accordance with the principles of sustainable development may be defined as sustainable construction.

The system of assessing construction products and technologies and buildings which considers the principle of sustainable construction includes its three phases:

- programming and designing,
- realisation,
- exploitation.

It is the task of the state authorities to create such a system of regulations, which would place the duty on all of the participants of the investment process to follow the principles of sustainable development and provide the basis for carrying out objective assessments by independent organisms.

Programs for educating building specialists should include knowledge enabling assessment of the designed and applied functional and technical solutions for sustainable construction.

The Building Research Institute - ITB conducts scientific research aimed at formulating the technical-service requirements for building products and buildings, as well as the criteria for fulfilling these requirements. This work takes into consideration the principle of sustainable construction.

2 Elements of assessing materials and technologies for sustainable construction

2.1 The investment process

In designing the first element of assessment is the building's location in the area, taking into consideration first of all assuring harmony with the environment. We consider rational use of land, including investing in areas with the lowest land class and ensuring the lowest degree of devastation of the natural environment, including water and air protection, taking into account the local climatic and geopatic conditions

The adopted set-up of building complexes, the accompanying municipal and internal transport systems, the municipal infrastructure and the correct insolation, ventilation and protection from noise conditions all take part in creating sustainable construction.

Adopting technical-service requirements in the design set for buildings, given in the national regulations in force, should not solely have a formal character, as the regulations set the requirements at a minimal level. They should only be a reference point for the solutions adopted in the design. Building designing cannot omit planning the service life of elements and entire buildings as the period of service usefulness of various elements and the entire building is not the same, and the end of service usefulness of the various elements does not signify the physical destruction of the building.

The production of building products significantly affects sustainable construction. The first element of assessment involves the way in which the raw materials, to a significant extent of natural origin, are acquired. This is connected with the need to conserve natural raw materials, utilising unused raw materials and recultivating post-mining areas.

Assessment of industrial production of building materials considers the physical and chemical factors connected with the technological process, such as air pollution, noise emissions, building industrial waste landfills. The following elements should also be considered: decreasing the energy consumption of production processes, decreasing the amount of technological wastes produced, and the possibility for recycling them, or utilisation for producing other materials.

When assessing the process of constructing a building we consider the temporary impact of a similar type as in the case of industrial production, e.g. energy consumption or noise emissions, and permanent consequences causing the degradation of land, such as a change of water conditions and destruction of trees.

2.2 The building during exploitation

The basis for creating sustainable construction is the correct formation of mans environment in the building. Analysing the biophysical reactions of the human organism, factors which decide on man's environment in the building include:

- temperature of the surroundings
- air humidity
- air circulation in rooms
- chemical and dust air pollution
- noise in the audible range
- ultrasounds
- vibrations
- effect of the electromagnetic field
- ionising radiation
- effect of micro-organisms

The selection of appropriate technical solutions for entire buildings, their elements and the used materials prevent the negative consequences of the factors mentioned above. A fragmentary approach to these issues, by specialists from different areas, is insufficient, as creating a building which would be „friendly" for humans requires all of these factors to be taken into account.

Elements which assess the service values of buildings also include safety and convenience of use (according to Directive 89/106/EEC) and the possibility of functional transformations of the building in the future.

When assessing the building during exploitation, its impact on the environment should also be considered, and in particular:

- emission of gasses
- emission of noise and vibrations
- method of disposal and treatment of sewage
- method of storing and utilising municipal wastes.

The service life of the building is not only an economic factor, but it has significant influence on creating a sustainable construction, as assuring the necessary service life of the building, materials and products decreases the amount of waste which may cause environmental pollution. The building's durability well serves, among others, the ease with which the good technical state may be maintained and the reliability of protective insulation. The service life is also connected with the results of renovations, modernisation and demolition of buildings and the possibility of recycling in-built materials.

The main elements of assessing materials and technologies are presented in Table 1.

Table 1 Elements of assessment of materials and technologies for sustainable construction

Assessed period	Problems	Elements of assessment
Investment process	Designing the building	• location of the building - harmony with the environment • rational land use • protection of water and air • technical-service requirements for the building • planned service life of elements and buildings
	Production of materials	• acquiring raw materials • environmentally-friendly industrial process
	Building process	• temporary impact during building • permanent effects on the environment
Building during exploitation	Man's living conditions in the building	• physical factors • chemical factors • biological factors • safety and convenience of use • ease of functional transformation
	Building's impact on the environment	• emission of gasses • emission of noise and vibrations • disposal and treatment of sewage • storing and utilisation of municipal waste
	Building's service life	• ease of maintaining good technical state • reliability of protective insulation • results of renovations, modernisation and demolition of buildings • possibility of recycling in-built materials

3 Polish regulations regarding sustainable construction

The act on protecting and forming the environment (amended in August 1997) introduces the principle of sustainable development, defining its aims. The act gives a series of requirements connected with environmental protection, which greatly influence the creation of sustainable construction. These requirements refer to:

- protecting the surface of land and minerals
- air protection
- protection from noise and vibrations
- protection from radiation

- impact assessments of investments or buildings on the environment.

In the act on spatial management amended in September 1997 the principle of sustainable development is adopted as the basis for activity connected with spatial management. This has direct effect on determining the conditions for land development and for locating areas for acquiring mineral building raw materials.

The act on the building law (amended in September 1997) creates a good basis for assessing materials and technologies for sustainable construction. The act states that a building should be designed, built, exploited and maintained in accordance with the regulations, in a way conforming with, among others, the basic requirements (according to Directives 89/106/EEC), the service conditions and protection of the justified interests of third parties. The building law requires that when carrying out construction works building materials should be used which would enable correctly designed and built buildings to conform with the basic requirements - formally permitted for turnover and use in the building industry. The procedure for allowing building materials in turnover and use lies in confirming the confirmity of the properties of the materials with properties given in the Polish Standard or technical approval provided for innovative or non-standardised materials. The technical approval according to Polish regulations gives the service properties and technical properties of the material and is a positive technical assessment stating the material’s usefulness in the building industry.

For most building materials the technical approval is issued by the Building Research Institute, which is a member of UEAtc.

The certificate issued by the unit authorised by the Polish Centre of Research and Certification or a declaration of confirmity issued by the producer confirms confirmity with the Polish Standard or the technical approval.

The following elements are determined on the essential of the building act by instructions of the respective ministers:

- technical conditions, with which buildings should comply and their location
- technical conditions for exploiting buildings
- acceptable concentrations and intensity of factors harmful to health emitted by building materials.

On the basis of the act on standardisation the minister responsible for the building industry prepares a list of Polish Standards which must be adhered to.

The presented system of the regulations in force in Poland forms a broad legal basis for:

- formulating requirements for building materials and technologies for sustainable construction,
- assessing whether these requirements are fulfilled.

4 Research conducted in the Building Research Institute - ITB

In the framework of statutory activity of ITB financed by the state budget work is currently being carried out on researching the problem of sustainable construction. This work is encompassed in problem groups. Six problem groups, partially referring to sustainable construction, encompass issues resulting from basic requirements given in Directive 89/106/EEC, for buildings, i.e.:

- mechanical resistance and stability
- safety in case of fire
- hygiene, health and the environment
- safety in use
- protection against noise
- energy economy and heat retention.

A very important requirement taken into consideration when assessing building materials and entire buildings, connected with sustainable construction, is the service life. This is why one of the problem groups is devoted to service life (including corrosion, chemical and biological protection, protection from humidity).
Two problem groups are connected with the specific character of exploited buildings and refer to:

- diagnosing the technical state of the building
- the technical aspects of maintaining and modernising the existing building resources.

The problem group called „ecology of the building industry" is directly associated with sustainable construction. This group includes mainly research topics regarding the surroundings of buildings, such as:

- soil and water protection when building municipal waste landfills
- building industrial ash disposal sites
- derelict land management
- the consequences of the vicinity of facilities generating vibrations
- methods for rationalising and utilising energy in buildings due to dust and gas contamination in the environment.

Ecological, Low Energy and Low Cost Housing Possibilities for Latvia

V. A. Lapsa
Ecological & Low Cost Housebuilding Center,
Riga Technical University, Riga, Latvia.

Abstract
The goal of this work is the minimization the housebuilding and maintenance costs and to create a possibility to obtain the dwelling for the families with a middle and low income. The main reserves for this goal are as follows:
- The optimization of the geometry for the load bearing external structures and their materials properties for reduce their size and the prime cost of the construction.
- Essential improvement the heat insulating properties of the windows, external walls and roofs by use cheap an efficient insulating materials.
- Utilization the mass industrial pollutants, coming out from the paper, wood and some other non-toxic chemical industries for production the cheap and high-effitive building materials and elements.
- The harmonization the housing architecture with the economy of the construction and with the non-expensive long-time maintenance.
Keywords: Ecology, external walls and roofs, heat losses, industrial pollutants, load-bearing capacity, thermal resistence, low-cost housebuilding, middle class, structural optimization.

1. The Problem

The dwelling-house building in Latvia during the past 5 years is almost stopped because the Government has no finances for this purpose, but the housing indigence for the people is still remained. Our new peasants often must start their life in an unhabitated field because during the Soviet occupation time the individual farms are destroyed or collapsed.

Only some new private companies have **built** new dwelling-houses and here two directions are obvious:

- The building company have bought from the municipality an unfinished government multistory dwelling house or only the foundation. The layout than is quite transformed - the number of the flats is reduced and their dwelling space is essentially increased (5...7 rooms and more). The comfort level is enlarged - the fireplaces, saunas, swimming baths, interior gardens and studios are built. The dwelling price in such houses is very high, it is about 250-350 Ls per.sq.m (430-600 USD per sq.m).

- The building the one-family houses according to the individual design. They are built very large (2-3 storey and more) with two and more car-ports, saunas,closed or open-air swimming pools, gymnasiums, sporting grounds, high reinforced concrete fences, and different safe-quard systems. The comfort level than is much higher like in our average dwellings, and the building price is about 400-500 Ls per sq.m (690-860 USD per sq.).

These **said** two versions, and the second especially, are available for the small quantity of our new riches only. So the requirements of the big amount of the majority population families with middle and low income are quite ignored. The approximate distribution of the potential and non-potential dwelling buyers is showed on the enclosed diagram (see fig. 1) in dependence of the 1 sq.m.price in USD. It is obviously how with the lowering the price the total amount of potential buyers could grow essentially. The white area here is the potential buyers of the middle class not yet very developed in the post-Soviet liberated states. Also it is obviously the greatest part of the people could not buy a dwelling, because the lowering the price less than 100-150 Ls per sq. (170-260 USD per sq.m) is very problematic for the construction. Exactly this diapason is the research field for our Center.

2. The Reserves

What is the real possibilities for building new type affordable dwelling-houses **with** normal comfort level **but** cheap in **the** construction and **in the** maintenance also?

The investigations done in **the** Riga Technical University show **us** four reserves:

1. We have stated the fact in the real house structures the strength of the materials is not completely utilized and the hidden reserves of their load bearing capacity are very large. For the mainly amount of the dwelling houses the ceiling and roof reinforced concrete slabs **about** 50% **of** the concrete volume is placed in the tensile zone and here the concrete does not work, here is working only the reinforcement only. The compression stress in the brick masonry or in different block walls for five storey houses is less than **40% of** their compression strength, but in 1-2

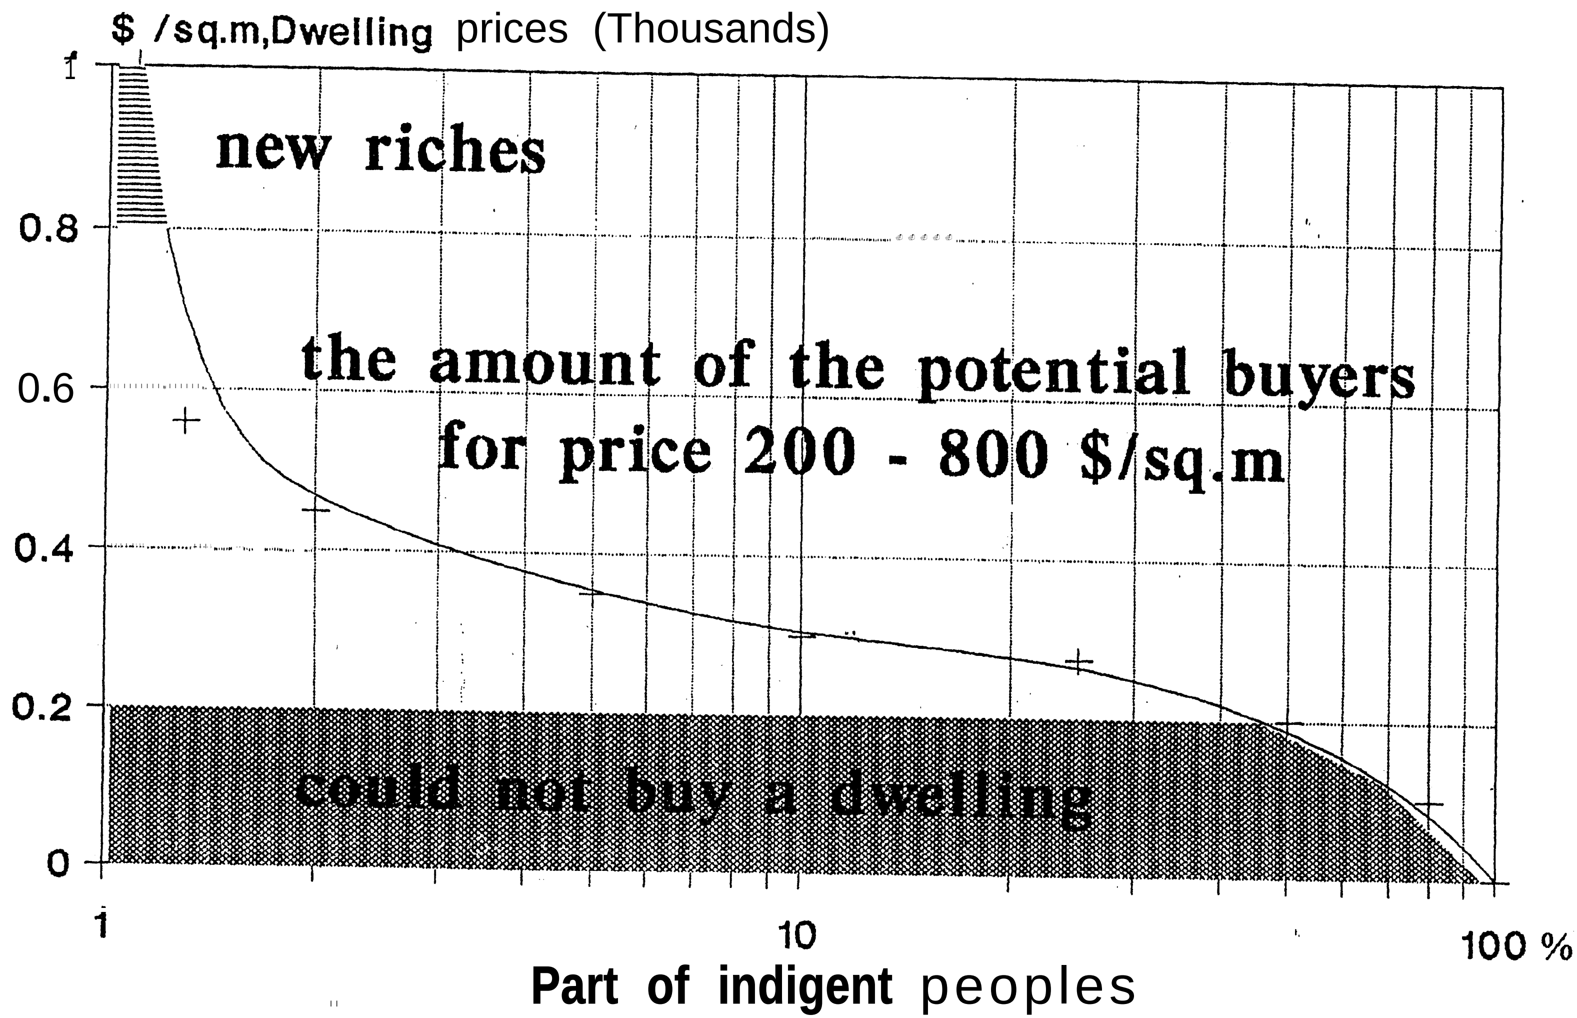

Fig. 1. The result of a social questioning about the distribution the potential house–byers and dwelling–byers depending of the one sq.m. dwelling price.

floor house it is about 6-10 % only. It is due the contradiction between the external wall big thickness necessary for the heat resistance and very small thickness which is necessary for the load-bearing function. In the foundation structures the situation is very worse - the stress is only 4-8 % of the concrete compression strength and is closely at the stress in the soil.

All other amount of the load bearing material is an expensive worthless stuff, but in the case of external walls and other outside structures, it is a very harmful ballast of the masonry or the concrete which is conducting the heat out from the house interior.

As it is indicated, these reserves could be converted into a very great economy if use new types of rational designed load bearing structures with the optimized sections and homogenized compression stress distribution.

2. Our new buildings, and these ones builded in the Soviet time especially, are not economical not only for the construction but for the maintenance also. Their heat losses (the u-value) through the walls, roofs and windows are 2,7-3,1 times more than the recent Building Codes of the North European States (Finland 1985, Denmark 1995) have permitted. For the existing external walls the real heat losses are 1,0-1,2 W/K.sq.m. But during the last 3 years the fuel prices in Latvia are raised catastrophically - for the earth gas the price have raised more than 600 times.

For the new building these reserve could be turned in an economy when in the rationally designed outside structures for walls and roofs the most part of their volumes will be replaced with high effective heat insulating materials.

For the existing buildings an effective additional heat insulation for the external constructions and triple-glass windows must be applicated. Always must be accounted fact that during the long life of the house the prices for the heat will grow up more and more, and the Building Code requirements will become stronger like nowadays.

These arrangements will give not only the economical, but an ecological benefit also, because the air pollution with the combustion products - the oxides of the sulphur, carbon and the azote, will be minimized.

3. It is a very big amount of different industrial wastes and pollutants coming out from the Latvia industry. In our investigations it is created simple technological processes for produce cheap heat and sound insulating building materials, the lignocomposites included, on the basis of the full utilization the wastes of the cellulose, paper, woodworking, forestry and timber industries. No one other branch of the industry can "swallow" so large amounts of the mass industrial pollutants like the building materials industry. So the ecological benefit here is the prevention the pollution of the rivers, forest and soil. For making cheap heat insulating composite materials in the technology could be utilized also some by-products and cheap local raw materials like the straw, boon, waste-paper, peat and low grade clay. The amount of these raw stuff in Latvia is more than sufficient. Wery actual for Latvia could be the production and use also the Eco-Fiber insulation made by utilizing the recycled waste paper.

Also special heat insulating materials, like plastic foams, rockwool, glaswool, aerated gypsum and others could be here used, but the practical utilization of the said ecological reserve could be essential cheaper.

4. The harmonization the housing architecture with the economy of the construction and the 1ong-time maintenance. It means the use the modulus-systems of load bearing structures for reduce the prime-cost of industrial house building. It means also the location the warmer parts of the house - the bath, sauna, stove, fire-place in the middle of the layout. The solar energy and the green-house effect for the external walls and roofs also could be used here as an important additional heat source. For the windows it means the use of the third-pm oriels. The ceiling must be joined together with a good insulated roof. The additional heat insulation for the soil will allow to use shallow and cheap foundations. Often the houses have very broken layout, stepvise vertical sections and unnecessary complicated rofs. So such houses obtain a very big external cooling surface, which must be essentially minimized. For exclusion the wind air infiltration the facade must have a simple and aerodynamic shape.

3. The way out of the situation and proposals

For evolution the scientific basis for the ecological and economical house-building, at the Riga Technical University an Ecological & Low Cost Housing Center in the 1994 was founded. We have elaborated some amount of real technologies and proposals for effective realization the said reserves in the building praxis, and here are 16 Latvian patents.

They are new ecological and cheap heat insulating materials (Ligno-Concretes and others). They are also new external wall structures - the Thermo-Blocks and Thermo-Panels and methods for heat saving in existing precast concrete houses. In each case the prime-cost of the constructional utility function (strength, bearing capacity, thermal resistance) for the new materials and building elements is very cheaper like for the traditional ones.

Thermo-Blocks are a new type external wall elements predestinated for 1-3 storey single-family houses. In contrast to the traditional one-material homogenous blocks made from lightweight aggregate or cellular concrete, wood concrete a.o., the Thermo-Blockes /1/ consist from two components - the load-bearing material part and the heat insulating material part. The load-bearing material - usually the concrete, must have the highest compression strength possible for each real producer, because in this case the cost of the strength will be the lover. The load-bearing material in the volume of the Thermo-Block is located accordingly to the following requirements:

1. The maximal moments of the inertia must be obtained with simultaneus minimization the horizontal load bearing section.

2. A homogenous (rectangle) distribution for tie compression stress in the load bearing horizontal section must be so obtained. Therefore the axis of inertia of the load bearing section are located in the some vertical flat where the resultant loads acts. Only in this case the full utilization of the concrete bearing capacity will be ensured.

3. The horizontal section of the load bearing material, and consequently, the concrete volume and expense are directly so great as it is necessary for the load bearing function in accordance to the Building Regulations, and no more.

4. To ensure the easy, high productive and cheap technology for Thermo-Blocks casting.

Only the respect of the requirements 1, 2 and 3, and when the maximal strength is warranted, give us a possibility to minimize the volume and the cost for the load-bearing material's part. In this case we can include in the other part of the wall volume the maximum amount of the cheaper heat insulating material, which is choosed with the minimal density, i.e. with the minimal thermal conductivity. The heat insulating materials (plastic foam, rock wool, ligno-composite and alike) usually are very cheaper than the high-strength concrete, and in such a way the cost of 1 wall cub.m. could be minimized, but the quality - the thermal resistance, will be increased essentially.

For example, when the wall thickness is 30 cm, the specific heat losses (the u-value) could be easy decreased till 0,25 W/sq.m.K. So effective result could be compared with a cellular concrete block wall with thickness 70-80 cm, or 115 cm thick expanded clay (Leca) blocks masonry,or the clay brick wall with 2,95 cm thickness.

This means the reduction the heat losses for about 4 times, and a similar decrease the cost of the heat resistance, what is the main external wall's function.

In a specific conditions, for example, in country-side, for the heat insulation stuft main components in the Thermo-Blocks could be used some wastes or local raw materials: the conserved and prepared with binder straw, boon, saw dust, bark, waste-paper, pit and alike For this goal also the Ligno-Concrete /2/ is elaborated. It is an ecological building i t -insulating material produced from the mass wastes coming out from the cellulose and paper industry. The density of Ligno-Concrete range from 350 to 850 kg/cub.m, the compression strength is from 1,8 to 3,0 MPa and the heat conductivity range from 0,08 to 0,18 W/m.K. The heavy weight classes of the Ligno-Concretes could be used for usual wall block casting, but the light weigh classes could be very cheap and effective filling for Thermo-Blocks. This also could essentially reduce the prime cost of the external wall construction.

The technology of the Thermo-Blocks is very simple, and the ordinary building material and detail making machines here could be used.

4. Conclusions

The practical results of the investigations could be as follows:

1. Economical - to essential reduce the house building expenses and to save the heating costs.

2. Social - to solute the cheap shelter problem for the families with low and middle. income and to raise the number of the working places.

3. Ecological - the prevention of the pollution for the environment with industrial wastes and the air with combustion gases CO, CO_2, SO_2, NO_x a.o.

Acknowledgements

These investigation was developed on the basis of the Latvian Government budget grant in the 1993-1997, and now the E & LCH Center of the Riga Technical University is looking for a Government grant in 1998 for the further development and for the realization the practical results of the investigation in the construction.

Design guidelines and life-cycle-cost analysis for the use of recycled plastic lumber (RPL) in structures

P. Krishnaswamy
Polymer Center, Battelle-Columbus, Ohio, USA

Abstract

Significant process improvements have been made in recent years to enhance the quality and consistency of recycled plastic lumber (RPL). Also, standard methods for testing and determining the performance of RPL are being developed by American Society of Testing and Materials (ASTM) Committee D20. The next step involves acceptance of RPL as a structural material in the marketplace. For this to happen, design guidelines must be established to account for the differences in mechanical properties of RPL as compared with wood. This would enable the use of RPL in construction applications where its corrosion and insect resistance, non-polluting properties and low maintenance aspects would make it a useful material. In a pilot project supported by the State of Ohio, Department of Natural Resources and the U.S. Department of Energy the structural aspects and economics of using RPL for shipping pallets were studied. A procedure to integrate field performance with laboratory evaluation was established. Typical properties of RPL were then used to predict the performance of structural components used in construction using advanced numerical techniques. A life-cycle cost analysis (LCCA) procedure developed by the U.S. Department of Energy (DOE) was adopted to investigate the economics of using RPL pallets versus other options at the DOE site. Plans to' expand this pilot project into a multi-client program to develop standards, generalized design guidelines, product specifications and a database of information for RPL in structural use are also discussed.

Key Words: Recycled Plastic Lumber, Life-cycle cost, design guidelines, shipping pallets

1 Introduction and background

Over the last decade recycled plastic lumber (RPL) has been a very key product in converting waste plastics into useful, high-valued, end-products. The manufacturing methods have been shown to be *both technically feasible and economically viable*. RPL can consume large quantities of mixed, waste plastics; is relatively insensitive to manufacturing variables as compared with other processes used to make plastic products; can tolerate high degrees of impurities and contaminants; can be reinforced with other recyclable wastes such as fiberglass or wood flour; and, requires low capital investment in equipment. RPL, which is currently used primarily in non-load-bearing-applications has not fully realized its potential as a structural material.

Even with limited applications, RPL production stands at about 16 million board-feet (5 million board-meters), or 20,000 tons of waste plastics, per year. More importantly, the growth rate of this industry in the US has been about 40 percent per year in the last few years and there are now over 25 manufacturers. The manufacturing processes and types of RPL have been discussed in detail by Krishnaswamy et al [1] and for brevity will not be included here.

2 Objectives

The objectives of this project were to: (1) determine the technology needs for using RPL in structural applications, (2) define a methodology to establish performance based standards for RPL, (3) validate the methodology through experiments, analysis, and field evaluation, and (4) conduct a life-cycle-cost analysis (LCCA) for assessing the economics of use of RPL in structures. The pilot project used shipping pallets manufactured using extruded RPL in a case study. This paper highlights some of the key findings from this project.

3 Technology Needs for Structural Uses of RPL

There are four major obstacles to be overcome for RPL to be accepted in load bearing applications. The first involves development of standards to test, evaluate and specify the various types of RPL based on its' performance. The second major obstacle is the need for design guidelines that will aid structural engineers to use these standardized properties to compute the stiffness, maximum load carrying capacity, and long term performance of structures. The third barrier is the lack of a database or handbook of mechanical properties and durability data for the various types of RPL. The fourth and final barrier is an accepted LCCA methodology for economic justification for the structural use of RPL.

The Plastic Lumber Trade Association (PLTA) consisting of the manufacturers of RPL together with the American Society of Testing and Materials (ASTM) has formed ASTM Committee D20.20.01 to address the first barrier. This group is charged with developing standard test methods as well as performance based specifications for RPL. Five standards [2-6] been -approved by ASTM and several more have been drafted and are under review.

Outside of this project, however, there has not been a concerted effort to overcome the remaining three barriers. Recently, McLaren [7] has discussed the need for a design methodology and proposed a procedure to develop load-duration-factors for designing with RPL similar to those that exist for traditional materials such as wood or steel.

4 Case study - RPL pallet evaluation

4.1 Laboratory experiments and analysis

In this pilot project for developing a design guideline and establishing a methodology for performance based specification, we chose shipping pallets fabricated from RPL as a candidate product. Since shipping pallets are used extensively by industry and government agencies, developing a performance based specification would be the first step in the creation of a procurement guideline. Such a guideline would significantly expand the available markets for RPL. The U.S. Department of Energy (DOE) needed to investigate the use of RPL pallets at some of their low-level radiation sites and determine whether these were acceptable alternatives to conventional wood and steel pallets. The pallets were essentially used to store and transport 55-gallon drums containing low-level radioactive waste.

The structural requirements of the RPL pallets by DOE at their site in Fernald, Ohio were quite severe. The technical report on this project [8] provides details of these specifications. Several modifications to an existing pallet design were made by Battelle and The Plastic Lumber Company based on past experience with heavy-duty pallets. The engineering drawing for the final design of the RPL pallet used in the field evaluation is shown in Figure 1. Based on past experience, this design was considered to be robust enough for the site requirements.

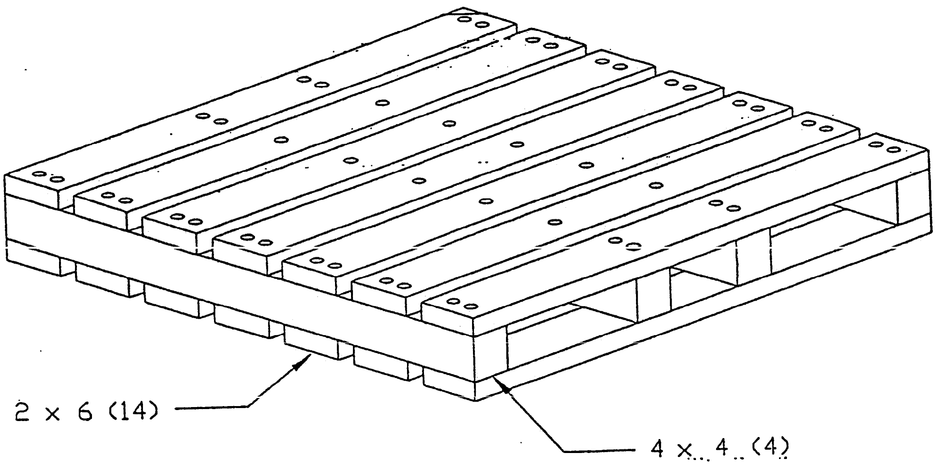

Figure 1. Schematic of the heavy-duty RPL pallet design

However, further full-scale testing of the pallet was conducted to ensure that the load carrying requirements were met. These results are discussed next.

Four RPL pallets were fabricated by PLC as per the above design and the following full-scale tests conducted according to ASTM standards: (1) Stiffness and Flexural Strength tests, (2) Vibration Testing of Pallet Loads, (3) Lateral Stability and Diagonal Rigidity tests due to drops, (4) Impact Test of Leading Edge, Blocks and Posts, and 5) Compression Test of Pallet with a simulated four, 55-gallon drum loading configuration. Details of these test procedures and results are provided [8]. Figure 2 shows the load-deflection curve for the pallet under compression load configuration using four 55-gallon drums. As seen, the maximum load carrying capacity in this test configuration is 20,355 pounds, which exceeded the requirement of 19,200 pounds by DOE-Fernald. The pallets also passed the vibration, drop and impact tests.

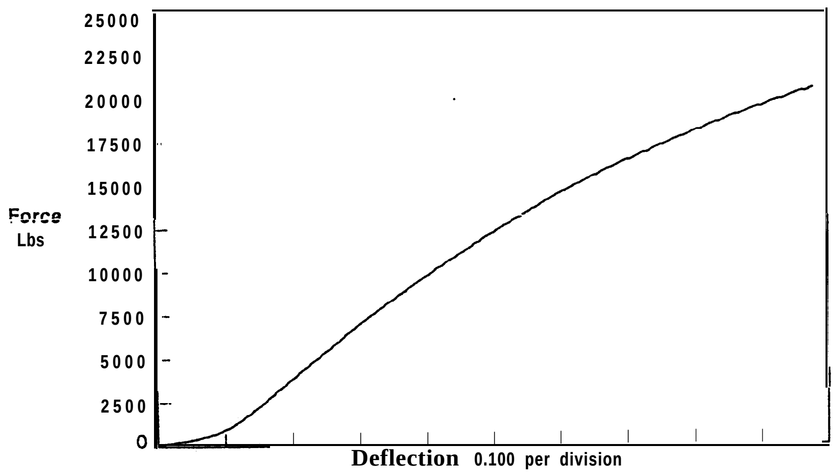

Figure 2. Load-deflection curve from full-scale test on RPL pallet under 4x55-gallon drum

An attempt was made to simulate the full-scale behavior of the pallets using the RPL material properties and Finite Element Analysis (FEA). The mechanical properties required of RPL for the computer simulation included flexural properties for the lumber (2"x6") and the compression properties of the stringers (4"x4"). A typical flexural stress-strain curve conducted using ASTM D 6109 is shown in Figures 3. These data were used in the finite element simulation.

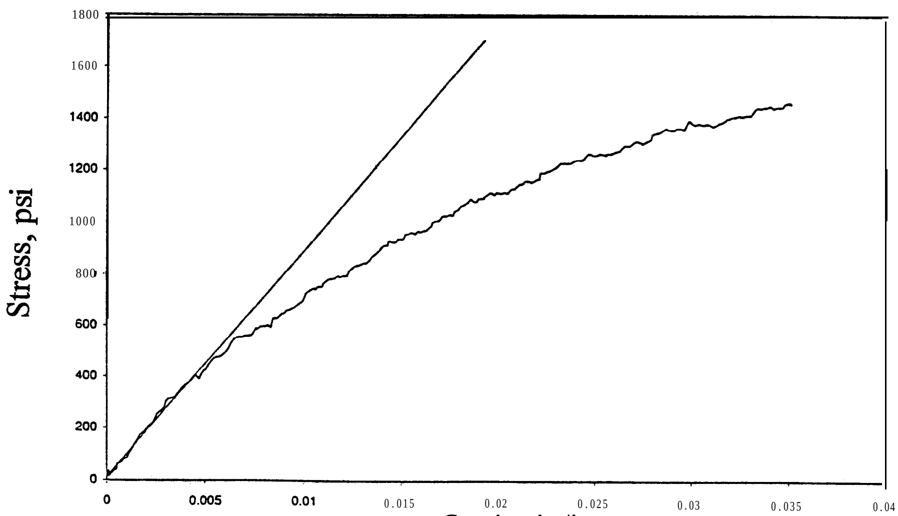

Figure 3. Stress-strain for RPL under flexural loading

A three-dimensional FEA model of one-quarter of the pallet was developed to simulate the full-scale test conducted. The results of the computer simulation indicate that the maximum loads were over-predicted by a significant margin. The level of discrepancy is not unexpected as the RPL is assumed to be homogenous and isotropic in the simulation while in reality it has a skin and foam core that is not homogenous and therefore anisotropic with regard to its stiffness and strength. Thus the original assumption is not valid and a better procedure to analytically evaluate RPL structures is currently being developed. Figure 4 shows that the deformed pallet shape qualitatively matches the experimental observations.

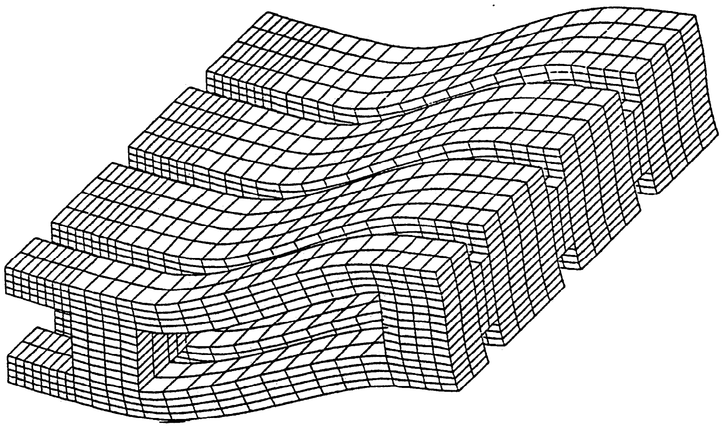

Figure 4. Finite element simulation of RPL pallet showing deformed shape

4.2 Field evaluation of RPL pallets

Six pallets fabricated to the design specifications were sent to DOE-Fernald for field evaluation. These were distributed among three locations within the site as follows: Location 1 – Production (5 pallets), Location 2 – Training (2 pallets), and Location 3 - Northstar (1 pallet). The evaluation conditions and findings are summarized below.

Location 1- Production: Three of the pallets were used at this production location where the pallets would be exposed to radiation. The three pallets were in a racked 'static load' configuration with four 55-gallon drums on each pallet. The material in the drums was Mag Flouride and the pallets were placed outdoors on a concrete floor. The total load on the bottom pallet was 9006 pounds (4094 kg.) and was sustained for five weeks.

Location 2 - Training: The training facility was supplied with two pallets and were subjected+ to 'dynamic loading', that is, they were used to move drums from one place on the location to another using fork trucks. The facility used to train operators of forklifts subjected the pallet to severe use with constant dragging and pushing of the pallets and the materials on it. Drums weighing about 4000 lbs were stacked and unstacked on these pallets routinely.

Location 3 - Northstar: The last pallet in the evaluation was used at this location for handling and moving 'dynamic' loads other than drums. The pallet was used to transport office equipment, desks chairs, etc. using fork trucks. The intent at this location was to study the pallet behavior under nonstandard loading configurations.

As indicated in the field performance reports [8], the pallets performed very satisfactorily at all three locations under a variety of loading configurations. There was no evidence of damage or cracks as a result of the sustained load. Apart from normal wear of the loading surface the pallet remained intact and no excessive deformation was noted at these usage levels. At the end of this period the top most pallet in Location 1 was removed from service and checked for radioactive contamination. No contamination was evident and the pallets were 'free-released'.

5 Life cycle cost analysis methodology

DOE-Fernald along with the Oak Ridge National Laboratories (ORNL) has developed a formal procedure for the life-cycle analysis of products and processes. This procedure provides a formal framework for evaluating the viability and economic feasibility of various options for a given process. This procedure detailed in [9 and 10] accounts for both tangible and intangible factors that affect various options for recycling and disposal at DOE sites. Embedded in these procedures is the LCCA of various product options for a given application. This procedure was followed in conducting the LCCA for RPL pallets versus other options.

The basic definition for 'life-cycle cost' in the DOE [9, 10] methodology is as follows: life cycle cost include the direct, indirect, recurring, nonrecurring and other related costs incurred or estimated to be incurred in the design, development production, operation, maintenance and support of an asset throughout its anticipated useful life span and through final disposal. Revenues such as user fees and salvage receipts should be included as an offset to the cost. The steps in the LCCA were as follows:

1. Identify the alternatives: In the case of pallets at DOE-Femald the alternatives available were: wooden pallets, galvanized steel pallets, and, RPL pallets.
2. Identify the life-cycle duration for each alternative: Since DOE-Femald is on a lo-year shutdown plan, the time duration for pallet needs for this study is 10 years. The estimated value of the design life for the alternatives were as follows [8]:

Pallet Type	Design Life, years
Wood	2
Steel .	10
RPL	5

3. Identify the cost categories for each pallet type: Various categories of costs for each alternative are as follows:
   - Acquisition (Initial) Cost: The cost of purchasing new pallets are:
     Wood - $20
     Steel - $160
     RPL - $275
   - Maintenance and Repair: Based on experience, some assumptions need to be made regarding frequency of repair and the cost of each repair for the various alternatives. It is assumed that the wooden pallets with a design life of 2 years are not repaired and are disposed off. The metal pallets being robust may not need any repairs during the lo-year life. Some of the boards on the RPL pallets may need to be replaced once during its design life of 5 years. The cost associated with this repair is accounted for in the LCC of the RPL pallet.
   - Disposal or Recycling Cost at end-of-life: At the end of their useful life since they are 'suspect-contaminated' the wooden and metal pallet, had to be disposed off through the appropriate procedure for contaminated materials. The cost of these options was included

in the analysis. Since the RPL pallets are not contaminated by radiation, they can be disassembled and recycled or sold as is for reuse under free-release conditions.

4. Identify costs in each year: Depending on the design life, maintenance required or disposal alternative involved the costs during each of the 10 years is identified.
5. Identify discount rate: For a 1 O-year project the real discount rate, R, is 3.5 percent as specified by the Office of Management and Budget [11].
6. Calculate present worth using discount rate: The total cost for each year is reduced to a net present value (NPV) using the formula

$$\mathbf{NPV = (Cost\ for\ Year\ Y)/(1+R)^{Y}}$$

where R is the discount rate and Y is the year under consideration. The total NPV for all 10 years then provides a life cycle cost for the given alternative.

The NPV value for the three options for the lo-year period were as follows:

Pallet Type	LCC at NPV
Wooden .	$815
Galvanized Steel	$517
RPL	**$587**

As seen, even though the initial cost of RPL pallets was considerably higher than the wooden pallets (Item 3 above), over the duration of lo-years the RPL pallets have a lower LCC. The RPL pallets are directly competitive with the Galvanized Steel pallets as the LCC for the two options are within 25 percent (the limits set by DOE methodology) of each other.

The DOE methodology [9,10] calls for evaluating the various alternatives using a Decision Matrix which account for both LCC as well as other intangible factors such as local public acceptance, impact on environment, institutional preference and worker safety impact. When all these intangible parameters were taken into account the RPL pallet did become a preferred option from the viewpoint of a life-cycle economic analysis.

6 Conclusions to date

The major conclusions regarding the development of design guidelines for structural uses of RPL include the following:

1. A combination of laboratory, full-scale and analytical predictions are needed to establish design guidelines for RPL in structures,
2. The ASTM standards provide necessary but not sufficient information for developing performance based specifications,
3. Design criteria must account for the unique type of material behavior exhibited by RPL in order to take advantage of all its other features and benefits.
4. A life-cycle cost analysis is usually needed to evaluate the economic feasibility of optional products to justify the use of RPL in structures.

8 Future work

Future efforts to expand the case study and pilot project described above involves a multi-client partnership between, state governments, federal agencies and the private sector. This partnership, is being coordinated by Battelle and the Plastic Lumber Trade Association and is addressing methods to overcome the barriers to RPL in the structural marketplace. This is a three-year, three-phase study that focuses on major potential applications for RPL, namely outdoor residential decks, marine boardwalks and other structures, and material handling items such as pallets. For each of these applications optimized design guidelines, durability information, and a database of appropriate material properties is being developed. The results of this study will be presented at future meetings.

9 Acknowledgements

This work was funded by the Ohio Department of Natural Resources (ODNR), the U.S. Department of Energy, Ohio Field Office, and by Battelle's internal research and development program. The author would like to acknowledge the support of Ms. Donna Stusek, and Ms.. Jenni Worster of ODNR, and Mr. Tom Baillieul and Mr. Pete Yerace of the U.S. DOE for their encouragement and support. The author is indebted to Dr. Kathy Yuracko for reviewing and commenting on the life-cycle cost methodology presented in the paper.

Information technologies and data formatting for the design life of buildings

L.S. Burn, I.S. Cole and S.N. Tucker
Division of Building, Construction and Engineering, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Melbourne, Australia

Abstract
The current information systems for data exchange and management, such as STEP and IAI, available in the international arena are currently unsuitable to allow the 'design life of buildings' process to be carried out. To allow this process to occur, an object-oriented approach needs to be taken for the manipulation of building component data. To each object or building component, specific attributes need to be attached that will allow the design life of the building to be calculated under a range of different environmental classifications. Additionally, possible maintenance techniques and frequencies also need to be attached to each construction-object to allow the design life to be achieved by selecting either the correct material or material/maintenance combination. If sufficient data is attached as detailed in the paper, optimisation of material selection and construction procedures can occur by utilising life cycle costing analysis.
Keywords: Design life, data exchange, information technologies, IAI, STEP, object orientation, CAD, life cycle costing.

1 Introduction

Information systems used in the architecture, engineering and construction (AEC) areas are developing rapidly, and the scenario has shifted from one where the data is used simply to plan buildings and reduce costs, to one where efforts are being made to utilise the vast amount of data and knowledge currently stored on the performance and degradation of construction materials. One area wishing to utilise this data and knowledge is an IS0 project on the design life of buildings (DLB) under the auspices of Committee TC59/SC3/WG9.

This committee is establishing the basic procedures necessary for the DLB process. However, for this to occur within the CAD environments currently available, an information management system is needed. An information system suitable for carrying out the DLB process, needs to meet a number of rigorous requirements.

- It needs to carry enough information and the correct algorithms to be able to calculate the effect of the environment on the building materials used. These algorithms must include the self-modifying effect that the materials can have on their own microclimate and the significant effect building orientation can have.
- It needs to be able to define maintenance schedules for different qualities of building materials installed under different environmental conditions, either by storing empirical data or by using degradation models for the materials.
- Life cycle costing methodologies must be able to be applied using the data to calculate the benefits of using either high performance materials with little maintenance or lower performance materials with better maintenance procedures.
- It needs to be flexible enough so that new knowledge and predictive systems for material performance and maintenance can be incorporated without destroying the structure that allows calculations based on current knowledge.
- The information must be fully portable between applications and be suitable for all users, such as designers and constructors, for use throughout the building lifecycle.

Information management and data exchange in AEC have not met these challenges and current developments in STEP [1] and IAI [2] are inadequate for this work because they address the data requirements necessary in AEC areas on an 'information model' approach rather than a 'functional model' approach, i.e. data for a material used in construction is static rather than being dependent upon the function for which it is used. To allow the DLB process to move forward rapidly, common specifications are necessary for the data requirements needed to calculate the design life of a building. In establishing these data requirements, IS0 TC59 must not adopt the dangerous position of being incompatible with the developments taking place worldwide in data interchange and interoperability. Conversely, current developments in world 'standardisation practice' need to design their architecture so that it will allow full integration of the necessary information needed in a DLB process.

2 Systems for data manipulation

2.1 STEP

In the Standard for the Exchange of Product Model Data (STEP), the term 'product data' is supposed to completely define a product for all applications over its expected life cycle. For a “design life' application this changes from design, through construction, operation, refurbishment and finally demolition. To be compatible with STEP, any methodology developed for DLB should use the descriptive methods group [3–5] which underpins the STEP standard. The next level in the STEP process is the 'integrated information resources' group (the actual STEP data models) which contain parts that are reusable by application protocols. The 'generic resource' in this group ('Part 45 – Materials [6]) should contain the information resources necessary for a DLB process – unfortunately at the moment it does not. At the top level of STEP, no application protocol (or data model) currently exists to describe the specific product data attributes necessary to undertake a DLB process, and no test methods have been defined to assess conformance. One application protocol that has been approved for development and may have an impact on the DLB process is Part 208 – Life Cycle Product Change Process. This application protocol may have implications in DLB calculations because 'life cycle costing' is an integral part of the overall DLB process.

In addition to shape representation, STEP can support a wide range of non-geometric data such as tolerance specifications, material properties and surface finish specifications [7]. It is expected that support for the DLB data would be detailed in Part 45 – Materials, which is at committee draft stage.

STEP possesses a rigid and mature architectural framework and consequently may not be able to easily meet the needs for applications such as DLB. This framework is currently more suited to a material property model used in relational databases and does not account for the functional relationships necessary in an object-oriented approach required for the DLB process. In this approach, an object used in the construction process needs to inherit some of its attributes or functions from the surrounding objects and the environment in which it is located. In this aspect, EXPRESS [4,5] may be suitable in that it supports inheritance and derived attributes functions.

2.2 IAI

The International Alliance for Interoperability (IAI) [2] is working in parallel to STEP to define industry foundation classes (IFCs) which will provide standard definitions for attributes associated with AEC entities, the structure and relationship between these identities, and standard formats for sharing attributes by static and dynamic exchange.

This will eventually enable interoperability between applications from different software vendors. Until October 1997, the domain required for the DLB process was not being addressed by IAI, who were looking at architectural design, HVAC engineering, design construction management and facilities management. Starting from October 1997, the IAI Australian chapter initiated an IFC project 'Performance attributes of materials for design' in the IFC Release 3 time frame (1997-2000). The project aims at identifying typical industry practice in materials selection, based on performance factors (e.g. environment, service life and life cycle cost), thus expanding the existing IFCs to include material properties that can be used across domains. The IAI Australian chapter will take up the concerns of the DLB process, which may involve an analysis of the current objects in both the IFC and STEP cores. For example, a column in the IFC model is a base unit and if it is made from concrete, it is composed of aggregate, sand, cement, water, processing aids and possibly fly ash. If this column is exposed externally, its durability is critically dependent upon the proportion and quality of these individual elements and the exposure environment.

2.3 Lexis

Both STEP and IAI define the data exchange protocols necessary in the AEC area. They do not fully define the suite of objects necessary for the DLB process nor the necessary attributes or functions that need to be attached to these objects to allow the process to be carried out. One development which may eventually provide a solution is Lexis [S], which proposes a language comprised of the range of objects neccessary for the total construction process. These objects can be distributed into views as necessary to reflect the management process required of the data, as shown in Figure 1.

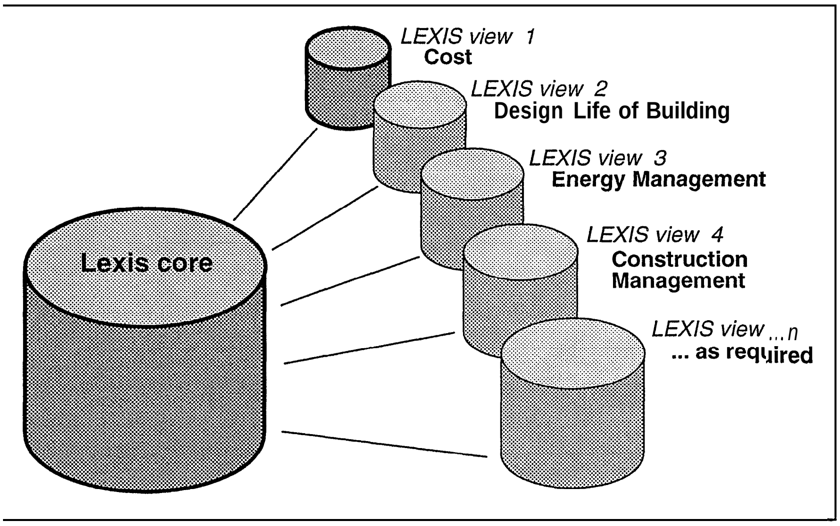

Figure 1. Lexis core and some possible views of this core

3 A system for the design life of buildings

The principle behind the DLB concept is to define the required design life for the building. Standard component lives are then allocated depending on their ease of accessibility. This process can be arbitrary as in the current IS0 TC59/SC3/WG9 document, established by legislation as in the New Zealand Building Code, or established in association with building product manufacturers. Once the standard component life is identified, the estimated component life can be calculated from:

$$ESLC = DLC \times A \times B \times C \times D \times E \times F$$

where ESLC = estimated service life of component, DLC = standard service life of component, A = quality of materials, B = design level, C = work execution level, D = environmental conditions, E = in-use conditions, and F = maintenance conditions, and the factors A-F vary from 0.8 to 1.2 depending upon the severity of the agent.

This approach is very simple and easily allows the expected service life of any individual component to be calculated. In a construction system, there are many thousands of individual components, with different expected lives, operating under different environmental, maintenance and operating conditions. Consequently, whilst the above simple approach may be suitable for individual components, for a computerised approach it would prove extremely cumbersome.

In utilising the concept used in the Lexis core language, the principle of an object-based scheme with attributes attached is the most workable scheme for the definition of the requirements to allow a DLB information storage and retrieval scheme to proceed, these objects being sorted into views depending upon the function or process being assessed. Hierarchical classification systems such as that proposed in Uniformat [9,10] may not be applicable, or if used would need significant modification, whilst the base documentation proposed in IS0 6241 [11], as shown in Figure 2, is applicable in that it divides the building up into the functional performance requirements (facade, electrical, services etc.). Subclassifications proposed in hierarchical systems such as these would need to be modified to meet an object-orientated approach – it may be easier to do away

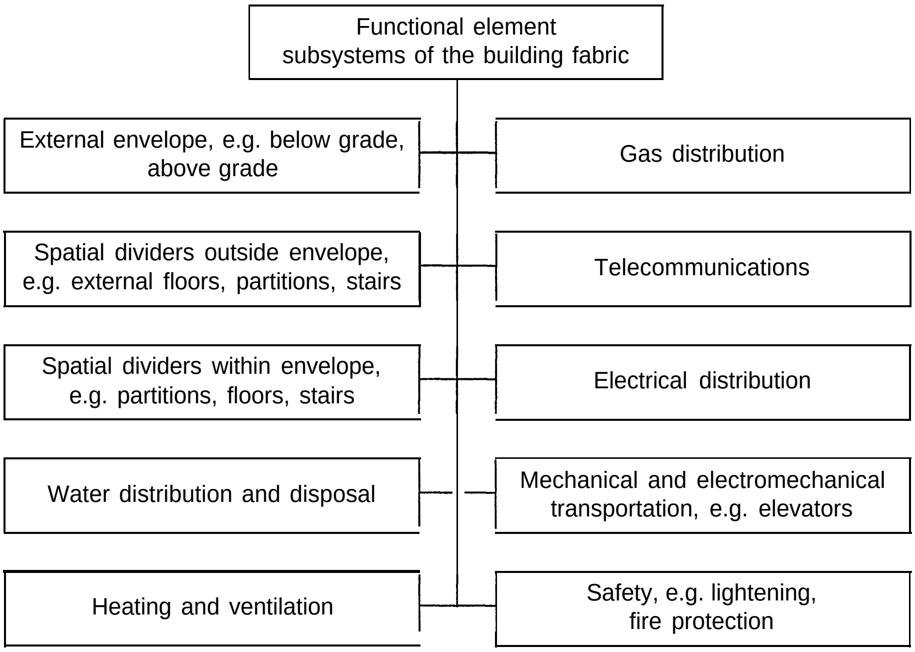

Figure 2. Building functional operations

with subclassification systems altogether and define the requirements of each object by a set of attributes, such as environment, maintenance, life cycle analysis and material performance, each being varied depending upon its functional application.

As well as allocating a range of attributes to construction-objectssuch as a door, the interaction of construction-objects is a critical factor for the DLB, e.g. dissimilar metals can corrode quickly and cause rapid degradation and shortened life. These relationships between objects have been discussed by Woestenenk [12] and some of these concepts, such as the interaction between spaces and boundary construction-objects, objects comprising part of larger objects, objects encountering each other and one object servicing another, are critical factors which have to be considered and included as necessary attributes to be attached to each construction-object.

3.1 The object approach

To develop a system to allow the DLB to be established, functional operations such as maintenance, refurbishment, demolition, thermal performance, acoustic performance and quantity estimation need to be considered.

Although these functional operations could be considered separately, they are considered together because each is controlled by material selection, degradation and the environment to which it is exposed. Additionally each may interact with another and modify each other's performance. Consequently a range of attributes needs to be attached to each construction-object as detailed in Appendix 1, with these attributes calculated from information stored in a range of libraries as detailed in Appendix 2.

Each of the attributes attached to the construction-object is required to allow the performance of the object in the building to be assessed, as well as to allow an adequate description of the object as its situation changes during the construction process. Once the object's environment is known, the performance of an object under the influence of this environment can be prescribed, either empirically or by means of degradation, life cycle or maintenance models. If the calculation is by a degradation model, then only the information specified in Appendix 2 is necessary. If the methodology is to utilise empirical data, supplied either by the object manufacturer or gathered from the field, then information for each environmental attribute is needed. Some of the essential attributes required for calculation of the DLB are expanded below.

4 Environmental attribute

In essence, there are three types of environments in a building, defined as:

- The external surface environment, which is the external macroclimate modified by the building surface to give a microclimate. This would include an envelope around the exterior of the building and would include below-ground and above-ground components and would take the building orientation into account.
- The inside building envelope environment, which includes the internal microclimate in the subfloor, wall cavities and roof spaces. This microclimate is heavily influenced by the external environment as well as the internal environment.
- The internal climate environment, which includes both internal living spaces and spaces between internal features such as internal wall cavities, internal first floor or above-floor spaces.

Definition of a construction-object's climate according to these three environments is currently difficult due to a lack of information. However, this may become possible as more information and more sophisticated prediction techniques are established to allow prediction of indoor and microclimate environments from external weather data.

In the meantime, it may be simplest to classify environments into broad categories with respect to the degradation factors affecting the major building components for both above-ground and below-ground applications. The principle is simple – an environment is classified in terms of its climatic factors such as temperature, rainfall, humidity, and the type and extent of pollution source. Additionally, UV needs to be defined for above-ground use to accommodate materials with different UV sensitivities. The importance of the various factors will vary for different types of construction-objects and where these objects are used in relation to the orientation of the building. There are also specific environmental factors that affect the degradation of particular objects but these are not considered in this discussion, although they will need to be discussed and included as the lifetime calculation models become more sophisticated.

5 Environmental Classification

A range of climate variables are necessary to define the aggressiveness of the environment. Some parameters relate directly to degradation, whilst others control the processes that promote degradation. The main factors affecting the environmental classification and thus the rate of degradation of construction-objects are time of wetness (on a metal plate), annual rainfall, surface equilibrium moisture content, extreme temperature, relative humidity, total global radiation and UV irradiance.

5.1 Climatic classification

It is proposed that climate be divided into four main classifications – dry, sub-humid, hurnid and very humid – and in turn these classifications may have a number of subsets as detailed in Table 1.

Class (abbreviation)	Subclass (abbreviation)	Examples
Dry (D)	Cold (C)	Icecaps, tundra, subartic
	Temperate (T)	Argentina desert
	Hot (H)	Australian desert
Sub-humid (S)	Cold (C)	Edmonton, central Canada
	Temperate (T)	European steppe
	Hot (H)	Central Queensland
Humid (H)	Cold (C)	Victoria, Canada
	Temperate (T)	Central east coast of Australia
	Hot (H)	Allahabad, India
Very humid (V)	Cold (C)	—
	Temperate (T)	Tokyo, Japan
	Hot (H)	Darwin, Australia

Table 1. Climate classifications

To establish the separate classes, a number of arbitrary decisions have been made and these may need slight modification to cope with the range of worldwide climatic conditions. The definitions are as follows:

- Dry – rainfall <400 mm per year or average 9 a.m. RH <50%.
- Sub-humid – rainfall 400–800 mm per year or average 9 a.m. RH >50% and <70%.
- Humid – rainfall 800–1300 mm or average 9 a.m. RH >70% and <80%.
- Very humid – rainfall >1300 mm or average 9 a.m. RH >80%.
- Cold – $AMM_{min}T$ <–5°C for more than two months of the year. Alternatively, $AMM_{max}T$ for the hottest month is <10°C.
- Temperate – $AMM_{min}T$ <–5°C for no more than one month and $AMM_{max}T$ >35°C for no more than one month.
- Hot – $AMM_{max}T$ >35°C for more than one month of the year.

$AMM_{min}T$/$AMM_{max}T$ are average monthly minimum/maximum temperatures.

In addition, the effects of total global radiation/UV radiation need to be considered separately as they do not easily fit into the above climate classification system.

5.2 Pollutant classification

Degradation of building materials due to pollution requires the determination of a number of factors such as airborne pollutant level (SO_x), airborne salinity, rain acidity, rain-ionic content, relative frequency of salt deposition/rain events, relative frequency of high pollutant/rain events, average wind speed and extreme wind speed. Incorporation of all these factors into a pollution classification scheme is complex. One such scheme where the pollutant classification depends upon the pollutant level and source is:

- Severe marine (SM) – airborne salinity exceeds a daily average of 300 mg/m^2.day.
- Marine (M) – average daily airborne salinity is between 60 and 300 mg/m^2.day.
- Severe industrial (SI) – airborne SO_x level exceeds 200 mg/m^2.day.
- Industrial (I) – airborne SO_x level is between 60 and 200 mg/m^2.day.
- Severe industrial and marine (SI+SM) – airborne salinity exceeds 300 mg/m^2.day and SO_x level exceeds 200 mg/m^2.day.
- Light marine or industrial (I) – either (a) airborne salinity is 15–60 mg/m^2.day, (b) airborne SO_x is 10–60 mg/m^2.day, or (c) rain water pH <5.5.

- Benign (B) – airborne salinity <15 mg/m^2.day ***and*** airborne SO, <10 mg/m^2.day ***and*** rain water pH >5.5.

Other specialised categories of pollutant may be included in given localities where geothermal, salt lake or soil contamination abnormalities exist.

5.3 Combined classification

A matrix of environments can be established by combining the climate with its subclass versus the pollutant source. The environment can be identified by a three-figure number where the first number defines the pollutant sources (severe marine and severe industrial (SM+SI = 1) to benign (B = 9)), the second defines the major climatic class (1 for dry to 4 for very humid), and the third defines the subclass (1 for cold to 3 for hot). For certain materials, it is essential to expand this matrix to take into account UV with a fourth number, varying from low (UV = 1) to high (UV = 3), where low is <14.4 MJ/m^2/day, medium is between 14.4 and 19.8 MJ/m^2/day and high is >19.8 MJ/m^2/day.

As shown in Table 2 (which only shows examples for a dry climate), a classification of 2-l-3-3 would signify an environment that is both severe marine and industrial, situated in a dry hot climate with high UV.

	SM+SI	SM+I	M+SI	M+I	SM	M	SI	I	B
DC-L	l-l-l-l	2-l-l-l	3-l-l-l	4-l-l-l	5-l-l-l	6-l-l-l	7-l-l-l	8-l-l-l	9-l-l-l
DC-M	l-l-l-2	2-l-l-2	3-l-l-2	4-l-l-2	5-l-l-2	6-l-l-2	7-l-l-2	8-l-l-2	9-l-l-2
DC-H	l-l-l-3	2-l-l-3	3-1-1-3	4-l-l-3	5-l-l-3	6-l-l-3	7-l-l-3	8-l-l-3	9-l-l-3
DT-L	1-1-2-1	2-1-2-1	3-1-2-1	4-1-2-1	5-1-2-1	6-1-2-1	7-1-2-1	8-1-2-1	9-1-2-1
DT-M	l-l-2-2	2-l-2-2	3-l-2-2	4-l-2-2	5-l-2-2	6-l-2-2	7-l-2-2	8-l-2-2	9-l-2-2

DH-H	l-l-3-3	2-l-3-3	3-l-3-3	4-l-3-3	5-l-3-3	6-l-3-3	7-l-3-3	8-l-3-3	9-l-3-3

Table 2. Matrix classification system for environmental data

5.4 Catastrophic events classification

The classification of a catastrophic/special hazard event or area is a difficult factor that has received significant attention in recent years and has resulted in significant changes to national building codes. Some of the factors that need to be considered include frequency of hailstorms, flood risk, cyclones, earthquakes and geothermal hazard.

5.5 Climatic parameters

The above parameters can be used to characterise some but not all of the degradation mechanisms affecting buildings. In general (except for the hazard parameters) they are applicable to external building components. In some areas, information on all of the degradation factors may not be available, in which case it may be possible to predict these factors from general climatic parameters.

The prediction of a hazard for a component within the building envelope is more complex and in general can only be estimated by some type of transfer function which considers the relevant external and internal environments, the building design and the relevant material characteristics. This paper will not define the transfer functions and development of these functions, but it should be emphasised that the development of these functions is a critical factor allowing the DLB process to occur for building components that are not exposed directly to the external environment.

6 Life Cycle Costing and Maintenance Attributes

Maintenance is defined as ‘all actions necessary for retaining an asset in, or restoring it to, its original condition’ [13]. Clearly the scope of the asset referred to in the definition identifies to some extent what should be included or excluded from maintenance in any specific case. Three types of activity, recognised as being distinct from maintenance, should be considered when calculating the life cycle costs of buildings. These are complete replacement of the item, rehabilitation to a new standard or new use, and cleaning.

For life cycle purposes, both complete replacement and cleaning carried out in conjunction with maintenance activities should be included, with only rehabilitation excluded. The timing and costs of maintenance, replacement and cleaning are needed for each item. Thus the life cycle details required are:

- Component items on whichdifferent maintenance, replacement and cleaning activities take place.
- Initial capital cost attributable to each item.
- Durability of each component item as a service life.
- Extent of maintenance, replacement or cleaning required.
- Cleaning and maintenance patterns or intervals.
- Cost of each maintenance, replacement or cleaning activity.

The component items are represented as instances of objects and must be separately identifiable at a level of detail which allows individual identification of the above details, i.e. object performance attributes 8-l 1 in Appendix 1. It could be argued that there should be a systematic elemental breakdown along the lines of the National Public Works Council elements and sub-elements [14], so that life cycle costs etc. can be categorised by recognised components of a building. If the Lexis [8] approach is taken, then objects can be classified into any group that is required.

The extent of maintenance, replacement or cleaning is determined by the rate of degradation and the minimum service life from a range of possible lives, e.g. given (predetermined), maintenance dependent and functional. The whole-of-life costs are reduced to a single life cycle cost of the object, possibly using standard discounted cash flow techniques. Whilst initial estimates of life cycle costs are deterministic, stochastic variations may be included to account for the possible variability in the future timing and costs by applying a distribution to each of the service lives and costs.

The library of information required to support the object performance attributes are more extensive (Appendix 2) and require additional details of the available cleaning and maintenance techniques, the labour, materials and plant necessary to carry out each maintenance, replacement or cleaning activity, and other information such as accessibility to the degraded item, and occupational health and safety precautions. There may even be a disposal cost of replaced parts or items. The library information on individual items needs to contain alternatives such as new construction, preventative maintenance and condition-based maintenance, but not all that data is required for all components, e.g. some components will require only one type of data and may have data in common with others.

The object-oriented database structure links particular components via a group type and available listings of data on relevant materials within each group to allow multiple access and minimal data, e.g. new construction will have a number of subgroups within it, such as metal cladding, concrete cladding, tile roof and metal roof, each of which has data on the five sub-items listed in the table.

Discounted cash flow calculations also require annual cost escalation rates (actual or differential real terms) to allow for changes in costs or improvements in maintenance, replacement or cleaning techniques so that the most cost-effective life cycle approach can be ascertained. The life cycle costs can be estimated at either the object or multiple object level. The discounted life cycle costs will be used to determine the best life cycle strategy including whether material will be totally replaced or just repaired.

7 Conclusions

At the time of writing, current protocols and data formatting techniques in STEP and IAI are not sufficient to allow the object-oriented procedures required in a 'design life of buildings' process. To enable this process, a range of attributes needs to be attached to construction-objects. These attributes covering the climatic and life cycle processes will allow calculation of the design life, and the maintenance schedules necessary to achieve this life.

Energy Related Environmental Impact of Buildings IEA Annex-31

P.A.G. Russell
Operating Agent for Annex-3 1
Research Division
Canada Mortgage and Housing Corporation.
Ottawa, Canada

Abstract
The paper describes the role of Annex 3 1, which is a shared task project supported by 14 of the countries that are members of the International Energy Agency's Implementing Agreement on Energy Conservation in Buildings and Community Systems. Its membership comprises government, academic and private sector researchers who have an expertise in how to evaluate the direct and indirect impact that buildings have over their full life cycle, on their interior, local, regional and global environments. Each participating country is to use an evaluation tool of its own choosing to assess the environmental impact of two simple reference building designs. The results will then be reviewed. Other evaluation cases that serve to illustrate particular merits of assessment methods will be included in the report. Additionally, it will have a section on the theory of Life Cycle Analysis, as it applies to buildings; a resources section comprising a classification and description of the numerous methods and data bases that have been developed, or are in the course of being developed and the last section will provide a reference and glossary. Additionally the potential to directly infuse results of the work into university curricula is being explored.

Keywords: buildings, energy, environmental impact, IEA

1 Introduction

Though it differs from country to country, buildings use about 30% of total energy directly, but when the indirect use is included closer to 50%(l). It is self evident then that their impact on the global environment is equally profound. The resolutions of the Kyoto conference are cause enough for concern in many countries as to how the goals can be met, but, as could well happen, that long before 2010 arrives the CO_2 reductions are deemed not to be sufficiently stringent, then all aspects of the economy will be stretched to find the most efficient ways to reduce energy demand, especially fossil fuels. It is vital that endeavours to reduce green house gas emissions do not become such an absorbing issue that others, such as water use efficiency, are not put into proper perspective. There is need for procedures that help decision makers answer the question, "all things considered what is the most efficient way to reduce the environmental impact of a particular building?"

This question is being addressed by many groups in several countries. As a result there is a growing inventory of approaches to the issue; from sophisticated multifactored methods of analysis to simple user-friendly check lists. Since the priority is to consider environmental repercussions in the long run, so, for the most part, the work of the annex is concentrating on Life Cycle Analysis (LCA) methods. The role of the annex is described below in this section.

The energy and mass flows associated with many materials are well studied, especially for example packaging products, and consumer products such as beer. Such studies are challenging enough, but at least they have the benefit that the complete life is highly predictable. Not so with buildings. The life expectancy of buildings is usually highly unpredictable; it is not known how occupants will use or misuse a building; changes in technology, society, economics and the environment and above all, land values, will influence a building's future. Any attempt to evaluate the impact that a building has on the environment must acknowledge that over its life-cycle the majority of the causes and effects of buildings on the environment are going to be intangible. Notwithstanding these factors, it is vital that all those who make decisions regarding the future of buildings have access to tools that can point them to more environmentally benign solutions.

Since such a large proportion of our future building needs will, for better or worse, have to be met by the existing stock, any comprehensive consideration of the topic must deal as much with existing buildings as with new ones.

For tools to be effective they must be devised so they can be relevant to a specific building and location, use sufficiently current data and be credible, comprehensible and affordable for the user, be they a building official, architect or developer. Apart from the need for tools at the specific building level is the need to understand what is required at a macro level to change the characteristics of the building stock as a whole. This is the realm of the building industry and government. In response, the annex addresses the challenge of how to agglomerate the impact of defined sets of buildings or even the building stock of a nation as a whole, as well as to identify what technical changes would be required to make buildings greener.

The myriad of audiences is far too broad to address in one report. For example, each country has some uniqueness with respect to the way in which its building industry operates creating different professional groups. There are circumstances when a highly detailed analysis is called for, a role for an experienced analyst. In contrast, a small-scale building contractor or do-it-yourselfer hopefully would also like to know how to go about construction in a most responsible fashion, clearly a very different audience.

The final annex report is being written therefore to meet the needs of those who themselves develop tools for specific audiences, in their own languages, idiom and requisite level of detail.

The role of the IEA annex on the Energy Related Environmental Impact of Buildings is therefore to see that the greening of buildings is accelerated by improving the availability and relevance of design tools. This it will do by providing those who are devising them with the best source of information on the subject. To do that there will be three outputs from the annex:

- a report comprising four sections: theory, application, resources and glossary;
- a short document that sells the importance and benefits of LCA analysis, and;
- prospectively, the foundations of a university level course that will pass into the hands of a consortium of universities to ensure excellence in teaching on the topic beyond the life of the annex.

The annex comprises academics and private sector and government researchers from 14 of the countries (see section 7 for list of participating countries) who are members of the International Energy Agency (IEA), Implementing Agreement (IA) on Energy Conservation in Buildings and Community Systems. Other IAs focus on different aspects of energy use. Their function is to initiate annexes, or international task sharing projects, that typically complete their goal within 4 years.

The work of this annex commenced with collecting one page summaries of methods already developed or being developed in the participating countries. There was no attempt to be exhaustive, nevertheless some 50 methods were identified providing the participants with a overview of methods that have been devised so far. It made clear the rage of different approaches that can be taken and the challenge for a neophyte to determine which method offers the best match for given needs. In reality the choices are usually quite restricted, through language and the pertinence of the data bases, to 'methods developed in the region in question.

Initially the work of the annex was divided into 8 sub-tasks but is now reduced to five, each corresponding with a section of the report. As mentioned above these sections are: introduction, theory, application, resources, and references and glossary. The following sections provide a brief review of what these sections will cover.

2 Outline of planned Annex report

2.1 Introduction

The introduction will prove an overview of what environmental impacts of buildings are, why is it important to be able to evaluate them and how it is currently being done. It will put the subject into a context of reality, namely that many of the elements that affect the environmental performance of a building are beyond the influence of anyone specifying a building architect for example. Though he cannot know what the life expectancy of a building may be, he or she may be able to specify elements of a design that will increase a building's ability to adapt to changing technology and use. But to link a feature of adaptability to energy use, whilst possible qualitatively, is rather beyond our ability to do it quantitatively at least yet.

Of course whether a building gets specified one way or another is governed in most jurisdictions by first cost, with operating costs often taking a back seat. But if we can strive to develop reliable and sufficiently accurate tools that concurrently estimate capital costs, operating costs as well as life cycle environmental impacts then one is empowering the decision maker to explore options that are presently just not economic . to explore.

2.2 Theory

To help describe the scope of the annex and to clarify its boundaries and interrelationships of factors important to the study, liberal use will be made of diagrams.

Much of the language of LCA has already been established by various bodies, for example, SETAC (Society for Environmental Toxicology and Chemistry) and SPOLD (Society for the Promotion of LCA Development). Their pertinence, and concepts such as inventory analysis and environmental loading, are introduced and made relevant to the building sector. The distinction between environmental loading and impacts is also explained.

2.2.1 Human factors

The pre-construction process follows different paths in each country. Nevertheless one can generalize the fundamental steps taken. With each step it is possible to put a human face on the process; who does what, when, and what information does each person need at each stage. For example, where there are options with respect to where a building will be located, it is important to be able to evaluate weigh up, the environmental transportation impacts, not just based on current modes of transport, but to the degree possible, the modes that are likely to evolve over the foreseeable life of the building. This is only pertinent at the concept stage and so there is little point in cluttering up the tools an architect may use with transportation factors if he has no influence over them. Thus the design of tools best follows the stream of typical decisions and decision makers.

2.2.2 Physical framework

What physical components are accounted for? Directly, are the immediate surroundings, envelope, structure, mechanical and electrical systems and fit out. Indirectly, are the externality elements: infrastructure, power stations, mining operations that feed the building materials sector; a long, but relevant, list.

2.2.3 Tools, rules and methods

To describe the features of the many analytical methods available, and thus facilitate comparison, it has been necessary to establish a framework within which to describe these methods. This has been the most challenging aspect of the work of the annex because a comprehensive review becomes an enormously complex to the extent that the wood cannot be seen for the trees. Hence we have had to rationalize on a much simplified framework so that it remains understandable.

Types of energy, energy chains and the environmental loading associated with them are described. Understanding the energy chains is fundamental to understanding the energy return on energy invested for alternative energy sources. How much more energy might have to be embodied in the design of a building to improve its passive solar performance? If the power demand of a building can be reduced by 1 kW, how much embodied energy is saved in the energy supply system? These are the energy questions that can be addressed by at least some of the methods.

The stages at which energy is use during a building life cycle is described, namely from the mining or harvesting of raw materials and recycling of other materials through to the eventual disassembly of a building. Questions such as what are all the stages, which ones are trivial and which are most relevant are answered; bearing in mind that what is most pertinent in one building, place and time may be quite different from another building.

Generally the operating energy demands of a conditioned building dominate other energy uses. However, as buildings become increasingly energy operationally efficient, other factors, such as maintenance and embodied energy become more relevant.

The theory section goes on to describe the use of benchmarks, sensitivity analysis, aggregation methods and data sources.

2.3 Application and Demonstration

The aim of this portion of work is to:

- demonstrate available tools for assessment of energy related environmental impact of buildings;
- show how the tools lead to improvements;
- (indirectly) convince building industry of the usefulness of these tools.

To emphasize the importance of LCA methods it is necessary to illustrate that some of the outputs are not intuitive. For example, in a study on the embodied energy of a new house in Canada it was calculated that the most energy intensive material was the carpets and underlay, assuming they were changed every 10 years(2).

The work is being carried out in three steps:

- assess similar buildings in different climates by using different tools;
- analyse and report existing designs or buildings for which assessment tools have been used, and;
- report on conclusions and recommendations.

The “similar buildings” are two simple designs: an office and a house. For each building each country is to carry out an environmental assessment using a tool that has been developed in the country concerned. In addition to this structured comparison there will be a section of precedents, or cases; i.e. examples of assessments of buildings that illustrate the value of a particular way of conducting an assessment.

In this regard there are direct linkages between the work of this annex and that of the Green Building Challenge ‘98, so some of the cases presented may also be those chosen for GBC’98.

2.4 Resources

This section will be a classified compendium of information on the design tools and data bases that are currently available or are being developed.

2.5 References and Glossary

This section of the report will provide the building fraternity with several useful lists and a glossary. Included will be a listings of

- agencies, universities and research centres. who are actively involved in the subject;
- an alphabetic listing of abbreviations and acronyms;
- a glossary of terms that are pertinent to the subject, and;
- a section on benchmark values and conversion factors.

3 Other Annex outputs

3.1 Summary document

In addition to the primary report, the annex will publish a concise brochure/booklet that illustrates and promotes the use of tools to improve the design of buildings. This will be written in a jargon free manner.

3.2 Web Site

The Annex operates a web site <http://annex3 1 .tce.rmit.edu.au/iea/home.html> which it is using to share the results of its work.

3.3 Educational support

Many universities faculties, typically schools of architecture, include in their curriculum some teaching on the subject of the linkage between buildings and the environment. The linkages of global concern are, in principle, common to them all. The members of the annex therefore support the idea of enriching these courses with the common component of their curriculum. It may foster a "we are all in this together". frame of mind amongst the students knowing that others are sharing the same knowledge. To this end, and at the time of writing, the annex is in the process of exploring the creation of a critical mass of university departments that would collaborate with the annex on the creation of curriculum content of common interest. Interest is being shown from Australatia, Asia, North America and Europe.

4 Schedule

Though the substantive part of the work of the annex will be complete within 1998. Time allowance for editing and printing will mean that the final report will not be available until sometime in 1999.

5 Conclusions

The work of annex 31 will make available an invaluable source information for those who already have a familiarity with the topic or who are serious students. Because it is a fast moving topic the shelf life for a substantial component of the final report will be limited. However the theory section should establish itself as long-term reference point. The prospect of establishing a consortium of universities to collaborate in order to ensure excellence and breadth in teaching offers the prospect of some continuity of expertise embodied in the participants of the annex. .

Weather-induced degradation of PVC profiles in Indian climate

B.Singh, M.Gupta and A.Verma
Central Building Research Institute, Roorkee, India

Abstract
Commercial PVC profiles were exposed to 7 years natural weathering and 3000 hours in accelerated weathering of UV exposure. The weathered profiles were evaluated in terms of emergence of surface topographic features, formation of degraded chemical species and loss in mechanical strength. SEM studies reveal that particle-induced blackening and white exudate deposits were the main weather-induced defects that appeared on the profile surface. The chemical species formed during outdoor and accelerated weathering exposure were very different as observed in diffuse reflectance spectra. Elongation data was used as an indicator for assessing the performance of PVC profiles under natural and accelerated exposure.
Keywords: PVC, weathering, UV exposure, degradation, elongation.

1 Introduction

Poly (vinyl chloride) is a low cost commodity polymer wed in rigid and semi-rigid formulations for various uses in buildings. It is reported that the consumption of PVC in buildings alone exceed 0.21 million tonnes (-80 % of total production) and is expected to continue to grow. PVC siding and profiles represent two of the more recent applications generating significant amount of commercial interest in buildings to replace conventional materials. However, the key concern is polymer stability under long term weathering with respect to property retention and aesthetics [1,2]. However, even small variations in the compounding formulations can lead to considerable changes in the ageing behaviour of PVC based materials. It has been estimated that roughly half of the annual tonnage of polymers are employed outdoors where performance can often be limited by weathering.

It is well known that PVC undergoes dehydrochlorination and photo-oxidative degradation upon exposure to outdoor environments. As a result of dehydrochlorination, PVC gradually becomes coloured, turning to reddish brown due to long chain conjugated polyene sequences, indicative of aesthetically objectionable performance fur sidings and profiles [3]. Subsequent rapid oxidation of polyene sequences leads to the formation of carbonyl and hydroperoxide groups that promote serious degradation and loss of physical properties via an autocatalytic free radical mechanism. In order to achieve long term weathering of PVC profiles, the present trend is to use an optimal level of recently developed new polymer additives alone and also in combinations to obtain synergistic effects in the formulation suitable to varying climates [4]. However, data on weathering performance of profiles based on these formulations is relatively unknown to users in tropical climates such as India. In the present paper, we report the performance of unplasticized PVC profiles in 7 years outdoor and 3000 hours in accelerated weathering exposures.

2 Experimental

Extruded UPVC profiles having thickness ranging from 2-2.5 mm were obtained from Indian manufacturers. The profile formulation contains PVC copolymer, organotin stabilizer, paraffin wax, calcium stearate, TiO_2 etc.

The UPVC samples were exposed to 7 years natural weathering mounted on fixed racks facing south at an angle of 45^0 to the horizon at Roorkee. Representative climatic data of Roorkee climate is given in Table 1. The samples were also artificially weathered for 3000 hours in a Xenotest-450 (Original Hanau-GmbH) in accordance with ASTM G-26 using a cycle of 102 minutes of *W* light at a black panel temperature of 35-40 °C and 18 minutes of *W* light and water spray at a black panel temperature of 25 °C. The specimens were drawn out periodically to measure various properties.

Table 1 Average climatic data of exposure site at Roorkee(India)

Climatic variables	Value
Max. mean annual tempera&	32 °C
Min. mean annual temperature	13.50 °C
Max. mean annual relative humidity	72%
Min. mean annual relative humidity	30%
Mean annual rainfall	1020 mm
Mean daily solar radiation	731 k cal / m^2 hr

The tensile properties of fresh and weathered profiles were determined according to ASTM D 638-74 at a cross head speed of 5 mm / minute. The reported results were the average of five tests. Surface topography of samples was carried out by scanning electron microscope (Phillips 501, Holland). Absorption spectra of fresh and exposed samples was also recorded by UV & Visible spectrophotometer (Perkin Elmer- 240) in diffuse reflectance mode.

3 Results and discussions

3.1 Micromorphology

The surface morphology of fresh and weathered samples in outdoor exposure is given in Figure 1 (a-d). Weathered surfaces showed discontinuity in surface in the form of particle-induced blackening, exposition and aggregation of particles and growth of microcracks. These defects appeared on the surface increase with the increase of exposure time. The phenomenon of blackening around sharp edge / aggregate particles could be explained on the basis of polyene formation by a zipper like elimination reaction of HCl. The exposition of particles near the surface indicates the erosion of surface due to weather-induced degradation. An interesting feature of white exudates due to migration of chemical constituents on the surface exposed to 3 years outdoor as reported earlier [5] can be seen in Figure lc. Thickening of these deposits was further noticed with extended periods of exposures (5-7 years) (Figure 1d). It is assumed that these exudates may sometimes act as a mechanical barrier protecting further degradation of the profile surface from solar radiation. Cracks / pits formed in the early stages of exposure are also filled with particles probably from the deteriorated and eroded surface itself.

Under accelerated weathering of W exposure (Figure 2 a,b), the deterioration of the surface is initiated with the formation of small blackish spots followed by its spreading and intensification. It is noticed that severe darkening is restricted only to aesthetics of profiles and little affecting the strength properties, as observed in the experiment. After 3000 hours exposure, surface roughness, white patches/ particle exposition and appearance of scattered, thread- like structure

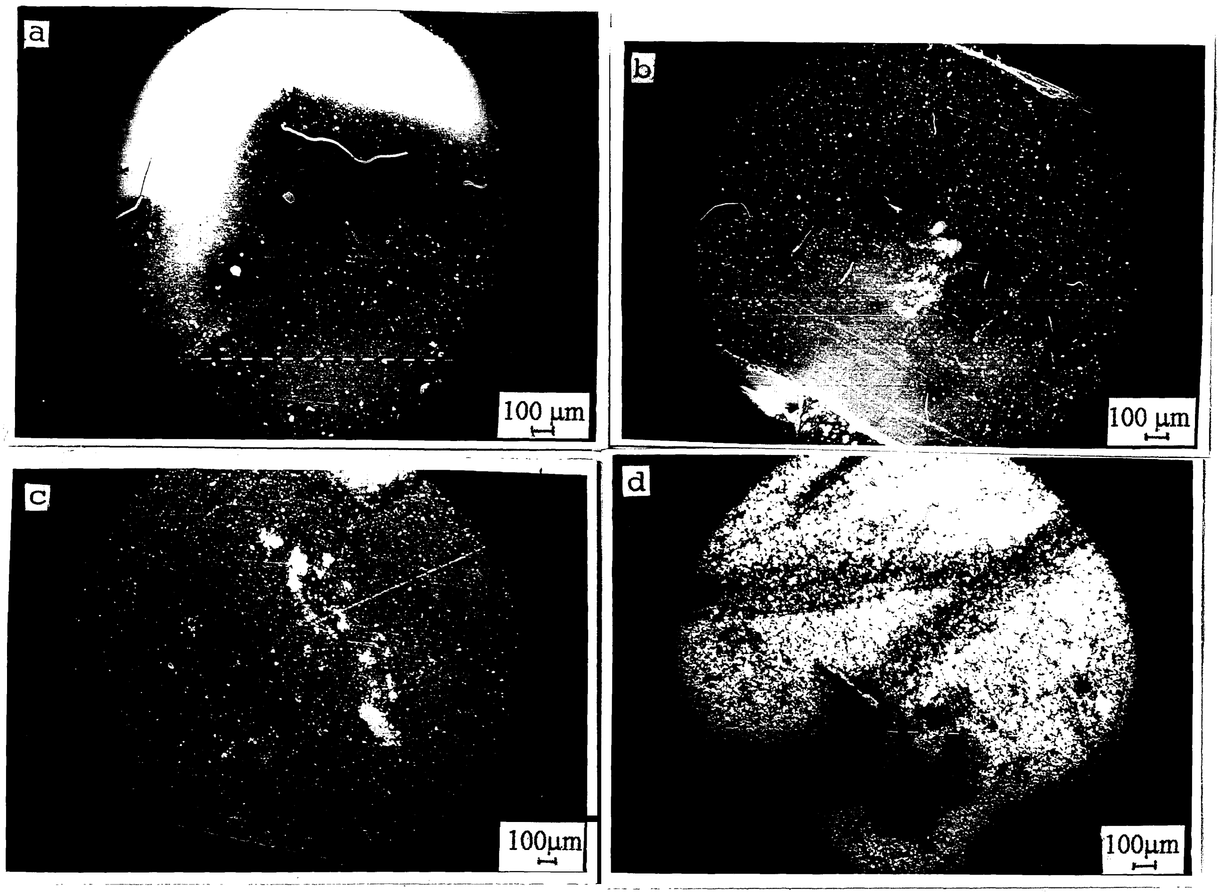

Figure 1 SEM of fresh and outdoor exposed PVC profiles (a) fresh (b) 1 year (c) 3 years (d) 7 years

surrounded by blackish area were observed. It can be seen that the extent of surface deterioration in 3000 hours exposure was microtopugraphically comparable to the 2-3 years outdoor exposure. However, the severity of the degradation was more pronounced in samples exposed to natural weathering.

3.2 Spectroscopic Studies

Figure 3 shows W & visible spectra of fresh and exposed PVC samples in diffuse reflectance mode. In accelerated weathering, there is an increase in the intensity of absorption bands at 300-330 nm whereas in natural weathering, the appearance of a new band at 220 nm and an increased peak intensity at 200 nm were observed. It is noticed that the formation of conjugated chromophoric groups increases with increasing exposure time. The shifting of absorption band towards the visible region in samples subjected to W exposure, results in darkening of the PVC. The peak at 300-330 nm is attributed to the formation of carbonyl /hydroxyl groups

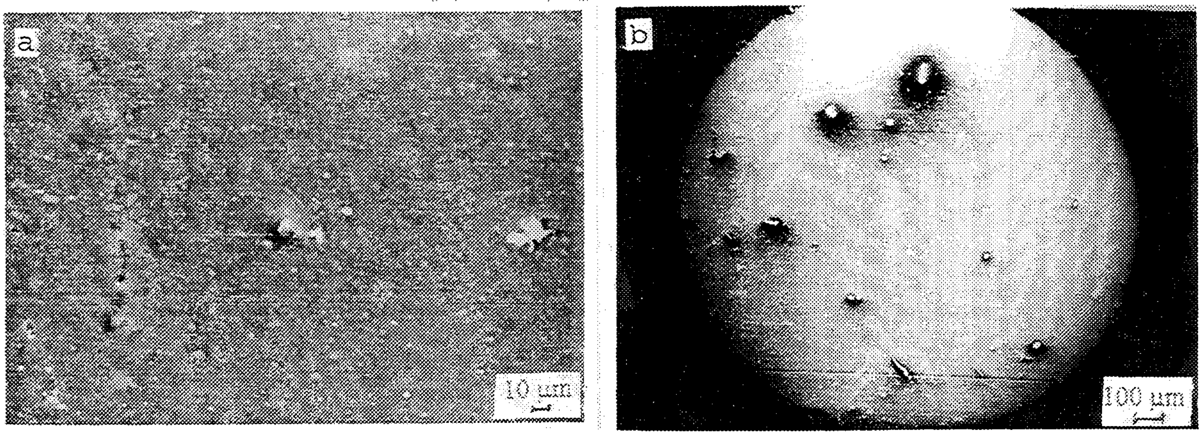

Figure 2 SEM of PVC exposed to accelerated weathering of UV exposure (a) 1000 hrs (b) 3000 hrs

(UV exposure) whereas the peaks at 220 and 200 nm are due to the conjugated carbonyl and carbon-carbon conjugated band sequence (natural exposure) respectively. Viewing the spectra, it appears that the PVC spectral sensitivity towards solar radiation and xenon arc UV are different. While recording IR spectra, the spectral changes in the intensity at 1730 cm^{-1}, 2925 cm^{-1} and broadening of 3600-3200 cm^{-1} region were noticed for both weatherings. The increase in peak intensity of different groups in exposed samples is the result of photo-oxidative degradation [6].

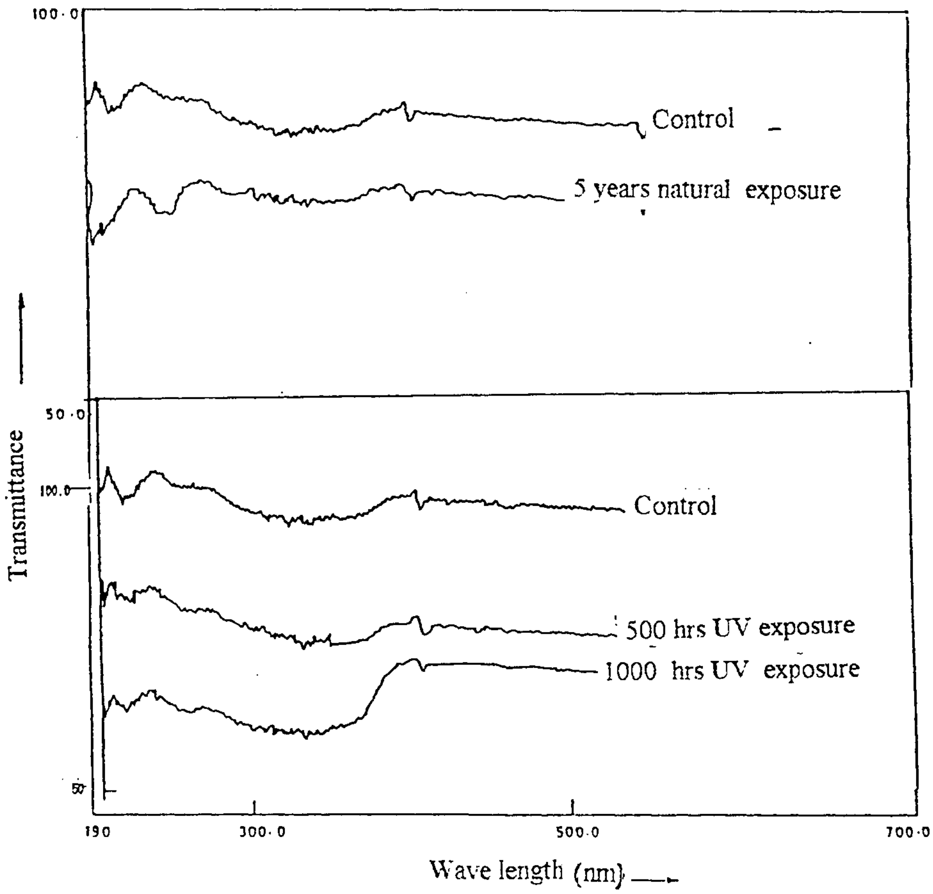

Figure 3 UV absorption spectra of fresh and exposed UPVC

3.3 Mechanical Properties

The tensile stress-strain diagrams of UPVC profiles under both weathering conditions are given in Figure 4. The samples exhibit a well defined yield drop followed by cold drawing showing shear yielding. The behaviour of curves of exposed samples was very similar to that of unexposed samples except that the elongation is reduced. The moderate decrease of tensile strength in outdoor exposure as well as in accelerated ***W*** exposure were observed. Elongation at break tended to be reduced drastically after exposure to both weathering conditions. Under outdoor exposure, there is a pronounced drop in elongation value up to lyear exposure and thereafter remains almost unchanged upon further exposure. On the contrary, a continuous decrease in the values of elongation was noticed in accelerated exposure. In the less steep portion of curve, the profile is already marked weathered and comparison is meaningless.

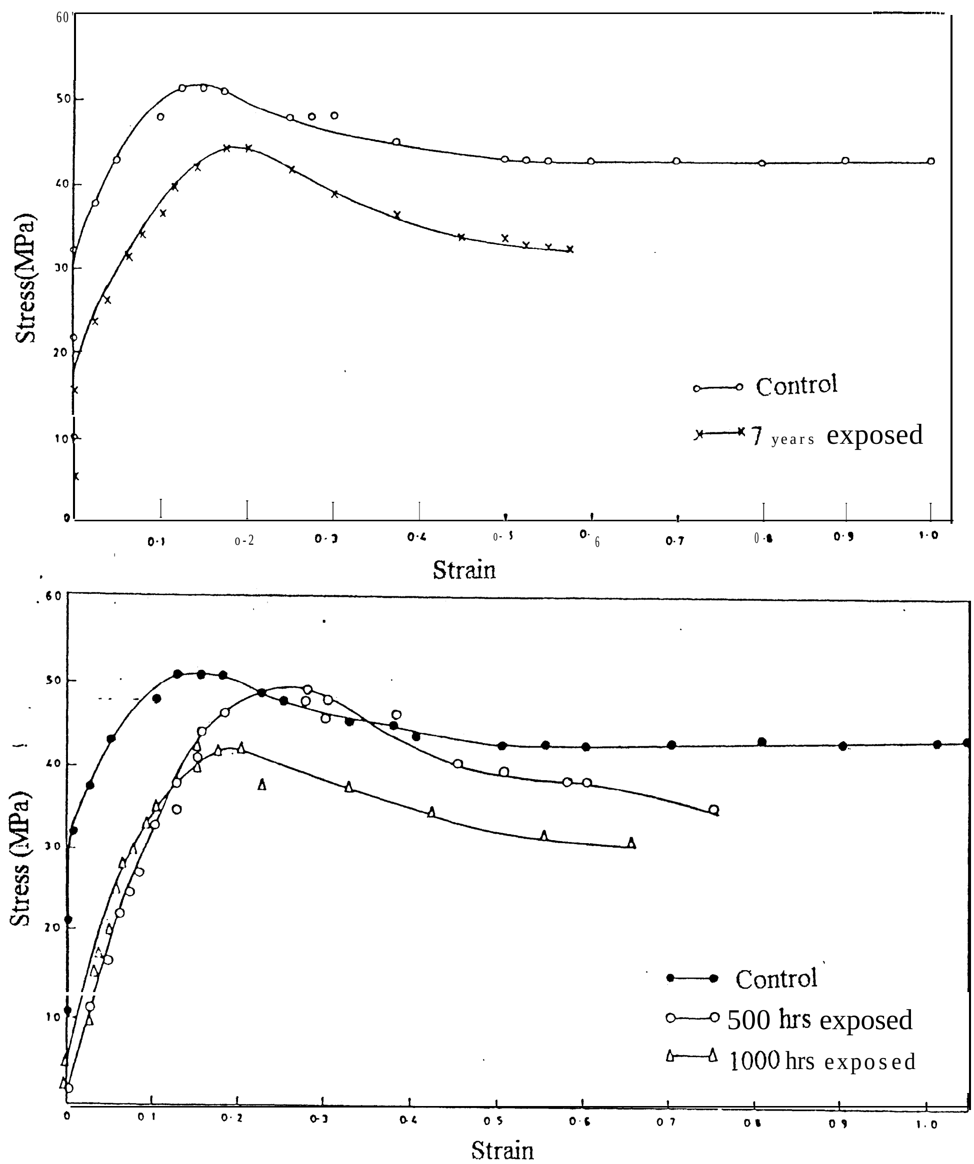

Figure 4 Stress-strain curves of fresh and exposed PVC sheet (a) outdoor exposure -7 years (b) accelerated W exposure -1000 hrs

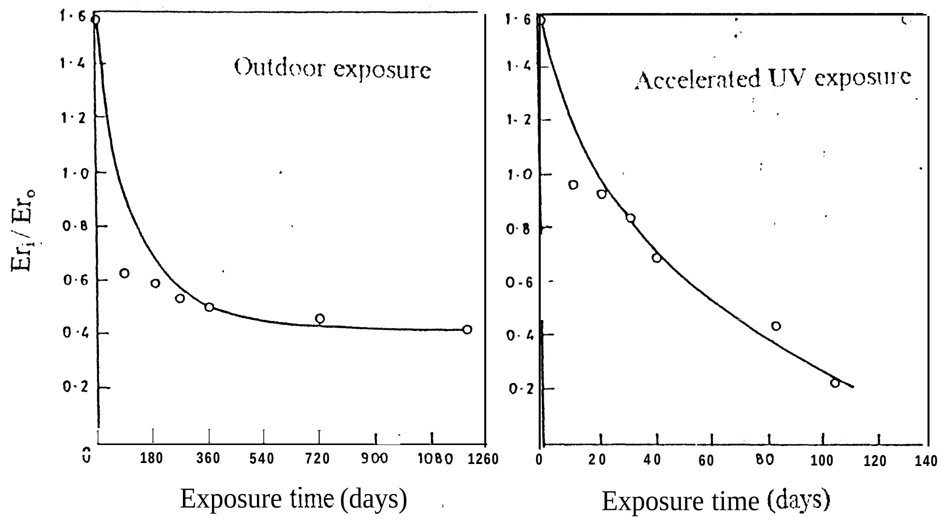

Figure 5 Ratio of Er_i / Er_o as a function of exposure time for UPVC sheet

As degradation process advances, surface flaws develop that serve as sites for stress concentration and hence centres from which mechanical failure can propagate [7].

A correlation between accelerated W and outdoor exposure is attempted on the basis of elongation data after various periods of exposure in particular because of its sensitivity towards exposure conditions. Figure 5 gives the values found for the ratio Er_i / Er_o where Er_i is the ultimate unit after time i of exposure to radiation and Er, is the same quantity for the material before exposure. It is roughly estimated that for these materials, 78 days in accelerated **W** is required to reach the Er_i/Er_o ratio of 0.40 (**1** year of natural exposure in Roorkee, India). More work is required to arrive at a definite conclusion.

4 Conclusions

The present studies have shown that weather-induced degradation causes extensive surface deterioration and impairment of mechanical properties under long term exposure conditions. Surface flaws induced by ***W*** radiation act as potential sites for the loss of mechanical properties especially elongation. For rapid introduction of these types of materials into the markets, the behaviour of new materials in actual use should be known to users for wider acceptance. Thus, more work is required to develop a technique for proper assessment of material performance in a very short period of time.

Information System for Maintenance of 2500 Buildings: A Case History

W.C. Greer, Jr,
Law Engineering and Environmental Services, Inc., Kennesaw, Georgia, USA.

W.C. Malek
Law Engineering and Environmental Services, Inc., Austin, Texas, USA.

Abstract
In 1994, the Texas Legislature passed a rule that required all state agencies to have no more than 153 square feet of office space per employee. Each agency was to survey its space and determine whether or not it complied. The Texas Department of Transportation (TXDOT) also chose to determine the physical condition of its facilities including the structural system and the estimated cost to maintain its facilities. The cost determination was to include immediate repairs and replacements which were defined as those required within two years and longer term costs over the following 28 years.

TXDOT has more than 2500 buildings of several types at more than 500 locations spread throughout the entire State of Texas. TXDOT chose to have the results of its survey compiled into a database system so that all of the physical condition information could be retrieved easily. This was also to provide the basis for a future facility management system which would aid maintenance decisions.

The methods use to inspect the buildings and catalog the conditions are presented. A condition rating system was developed to allow comparison of different systems, conditions, and building types. Service life aging curves were developed in order to predict when repairs, maintenance, or replacement would be necessary. cost estimates for the repair, maintenance, and replacement were also developed. Reports comprising 54 volumes and several feet of shelfspace were prepared from the database which was estimated to contain more than 1.5 million points of data. An Executive Summary report was also prepared from the database. All data are available in the database for future analysis.
Keywords: cost estimates, database, maintenance, management system, rehabilitation, repair, replacement, service life.

1. Introduction

In 1994, the Texas Legislature passed a rule that required all state agencies to have no more than 153 square feet of office space per employee. Each agency was to survey its space and determine whether or not it complied [1,2]. The Texas Department of Transportation (TXDOT) also chose to determine the physical condition of its facilities including the structural system and the estimated cost to maintain its facilities. The cost determination was to include immediate repairs and replacements which were defined as those required within two years and longer term costs over the following 28 years.

TXDOT has more than 2500 buildings of several types at more than 500 sites spread throughout the State of Texas. These buildings and sites are managed by 25 District Divisions under the overall supervision of the Headquarters Division. The types of space in these buildings include office, laboratory, warehouse for equipment and materials storage, vehicle maintenance, and rest area facilities along various highways. The total space in the buildings encompassed more than seven million square feet.

An outside consultant was retained by TXDOT to aid with the condition assessment survey and cost estimation. The scope of the project involved collecting quantitative data (system type, size, materials,, quantity, etc.), identifying deficiencies, establishing numerical condition rating systems, and estimating remaining service lives of systems, and establishing estimated repair, rehabilitation, and replacement costs. The assessment format and criteria, basis for evaluation and recommendations, and cost estimating methodology were documented. The data and information obtained were placed in a computer database which will become part of a planned future overall facilities maintenance management system for all of the facilities of TXDOT.

2. Conceptual maintenance management system

Maintenance management systems for any type of facility can be conceptually defined as shown in Figure 1. The first module is an Inventory Database which identifies all of the elements to be managed and contains the basic information for each element. Information concerning location, use, components, types of materials, and ages are stored in the database. The second module is the Condition Index System which allows the current condition to be quantified as a numerical rating based on the objective measurement of critical parameters. For items such as roofs, the critical parameters include defects such as blisters, splits, wrinkles, open flashing, etc. The Condition Index System must have the ability to also predict the future condition. This is necessary in order that plans for future repairs, rehabilitation, or replacement can be formulated. The module must also have the ability to store, retrieve, and analyze past condition information, if available, in order to improve predictions of future condition.

The third module is the Maintenance Policy System. This allows the owner to specify certain actions when specific sets of conditions occur or are predicted to occur. The fourth module is the Maintenance Priority System that ranks the various elements in terms of their importance relative to the fulfillment of the missions or needs of the owner, operator, or user of the facility. A warehouse in which paper products or an office building with computer operations on the top floor would likely require a higher priority than a warehouse in which unwrapped plastic pipe is stored. This allows the owner to allocate limited budgets in an optimum manner consistent with the importance of each element or component.

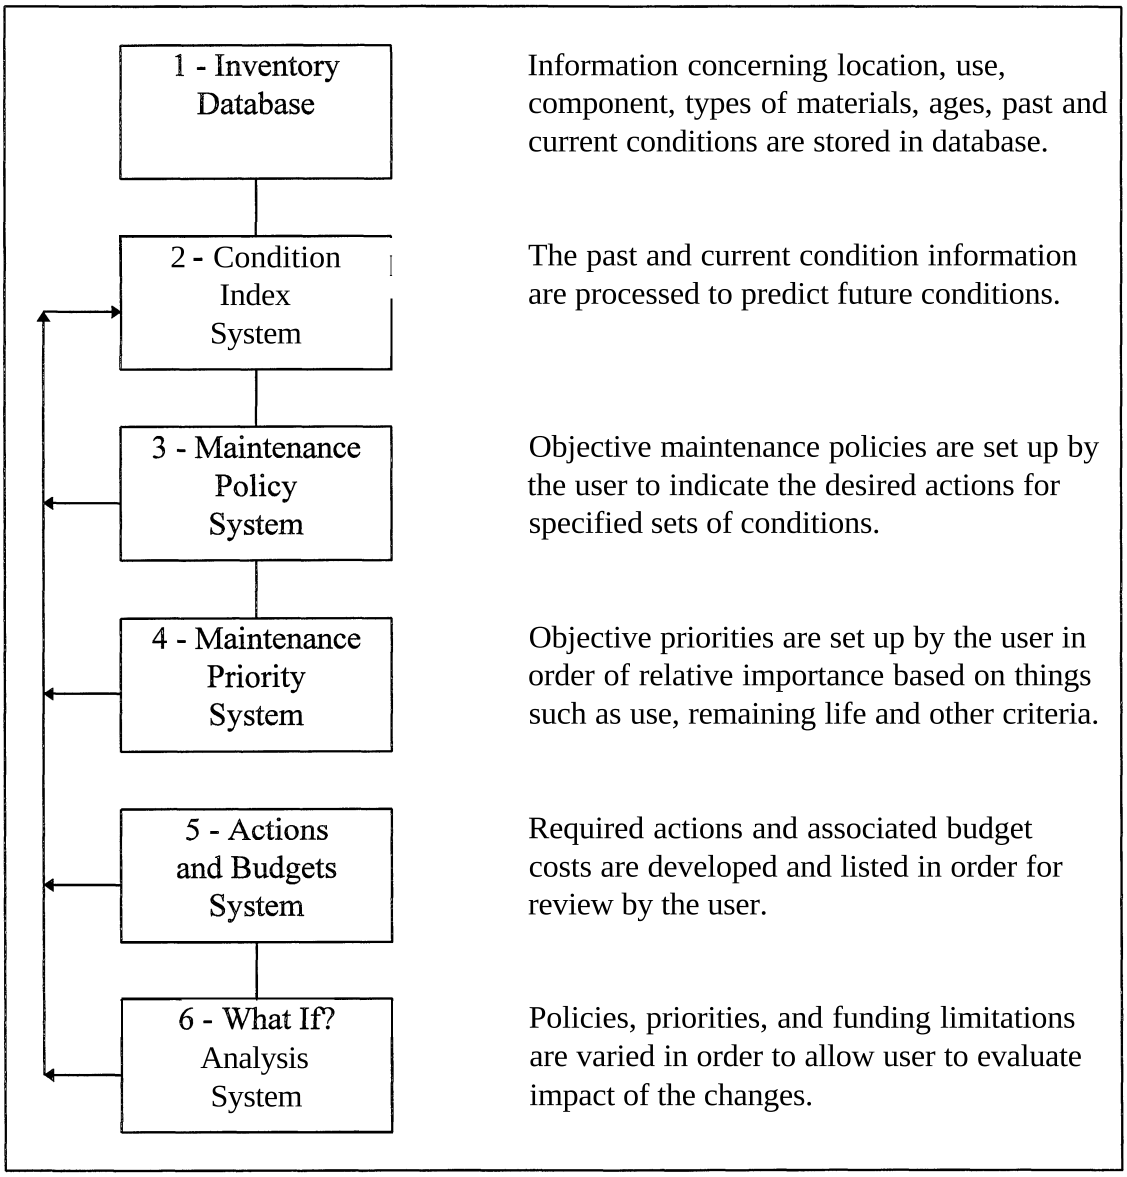

Figure 1. Schematic of conceptual maintenance management system.

The fifth module is the Actions and Budgets System. This module specifies actions and associated costs based on the Maintenance Policy System and the Maintenance Priority System. The sixth module is the What If Analysis System module that allows the owner to evaluate various options. With this tool the owner can change maintenance policies and maintenance priorities and see what impact these changes have on funding requirements. The owner can also evaluate the effect of funding limitations on the overall condition of the entire population or portions of the entire population of facilities. The amount of deferred maintenance can also be assessed in order to help substantiate maintenance budget requests. The project for TXDOT concentrated on modules 1, 2, and 5. This formed the basis for the development of an overall facilities maintenance management system at a future date.

3. TXDOT system

The various systems at each site or facility were divided into Site Related Systems and Building Related Systems. The site related systems included civil/site development and pavements. The building related systems were structure and foundations, exterior walls and windows, roofs, interiors (architecture), mechanical, electrical, plumbing, elevators, and safety.

The condition assessment process began with the definition of data to be obtained and documented during the site and building surveys. Specific information collected included existing construction information and defects for each system. The existing construction information included general system description, use, location, types of materials, components within the system, estimated quantities, and age, if identifiable. System defects for each system were identified and quantified. The information on defects was used to develop immediate repair work items and estimate remaining service lives for each site or building system or major components of each system.

Expected service lives for various site and building systems were established based on published information and the consultant’s experience with previous property condition surveys for several thousand buildings and facilities. Written descriptions of the types and level (severity) of defects typically found within each site or building system as the system ages through its normal service life were developed. These levels of defects were equated to a numerical Condition Index which varied from 10 for a new system with no defects to 0 for a system with defects so severe that the system no longer served its intended function Service life “Aging Curves” were developed to predict the effective remaining service life of a site or building system based on its Condition Index. Figure 2 presents a schematic of typical Aging Curves.

The type, extent, and severity of defects within a TXDOT site or building system allowed determination of a Condition Index for that particular system. The Condition Indices were then used to estimate the remaining service life. Repair costs were prepared from documented deficiencies and replacement times were established based on the effective remaining service life estimates.

4. TXDOT survey procedures

A pilot survey for site and building systems for approximately 100 buildings at IO sites was performed by several teams of trained professionals in December 1994 to test the basic concepts and evaluate reproducibility of the data and results.

Adjustments to the procedures were'made based on the information collected during the pilot survey. The remainder of the sites and buildings were surveyed during April to August 1995.

Each site and building system was divided into "Homogeneous Areas". An area was considered homogenous if it had similar components, materials, ages, and levels of defects. If a site had 500 linear feet of concrete sidewalk where 100 linear feet was new and 400 linear feet was 20 years old, two homogeneous areas were identified, surveyed, and assessed separately. If a building had two different mechanical systems which served different building areas, two homogeneous areas of mechanical systems were identified, surveyed, and assessed. This allowed different Condition Index values to be assigned to each area along with the associated different estimated effective remaining lives. The condition information collected for each building and site were input to a computer database. The number of pieces of data in the database is estimated to exceed 1.5 million.

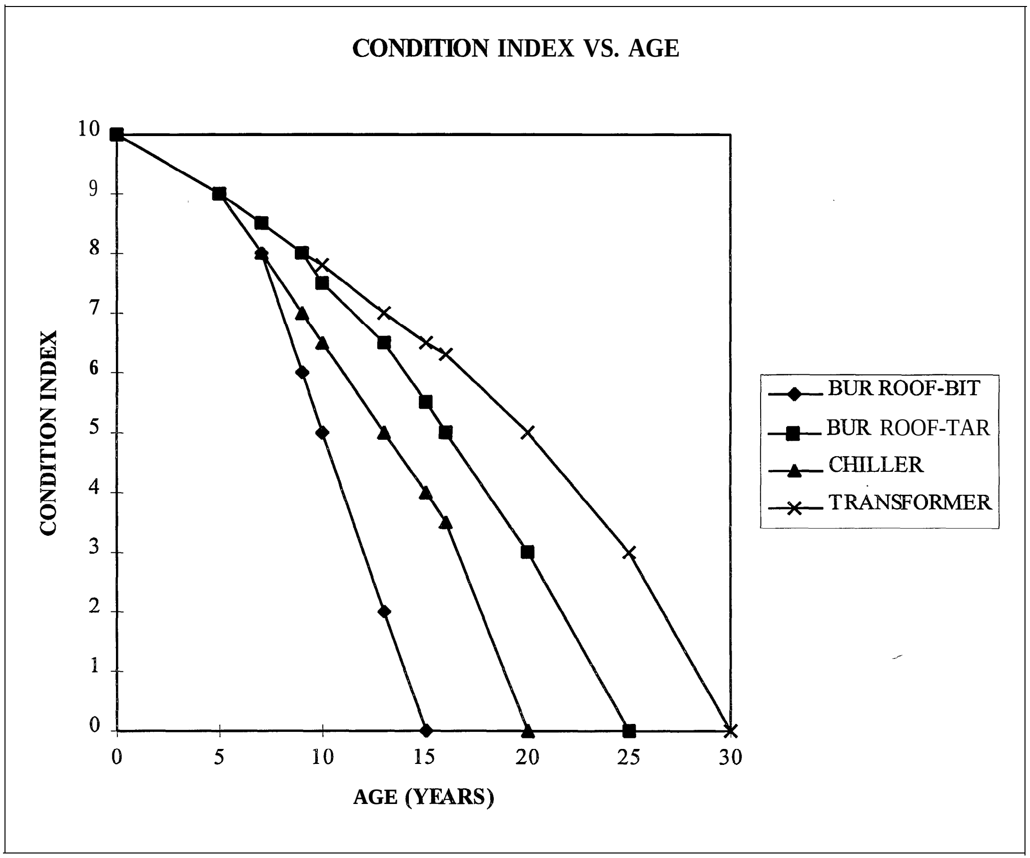

Figure 2. Schematic of Typical Aging Curves.

5. Building condition assessment score

The type of buildings for TXDOT were divided into 3 classes based on the type of occupancy, use, and presence or absence of various systems. The three classes were defined as follows:

Class A — The primary purpose of the building is to create a suitable environment for people to work. This type of building has mechanical, electrical, and plumbing systems, and interior finishes. Examples of Class A buildings include offices and laboratories.

Class B — The primary purpose of the building is to protect the building contents from the outside environment. The building is often enclosed on all sides and has an electrical system, but may not have mechanical or plumbing systems. Examples of Class B buildings include maintenance shops, warehouses, and large pole barns.

Class C — These buildings are termed ancillary buildings. The building may have been constructed by site personnel using available materials. The building may be a prefabricated temporary building or mobile unit without permanent foundations. The building may have minimal utility systems. Examples of Class C buildings include field offices/labs, metal sided storage sheds, and canopies.

A procedure was developed to assign a numerical rating of 0 to 100 for each building surveyed. The number 100 represented a new building with no defects while the number 0 represented an old building with no value. Based on a review of published information and estimated relative values of each system, possible "condition points" were assigned to each system for each class of building as presented in Table 1. Class C buildings were evaluated as a composite entity rather than a sunnnation of individual system conditions.

	Possible Condition Points		
System	Class A	Class B	Class C
Structure and foundations	27	49	Building = 100
Exterior walls	11	20	
Roofs	7	13	
Interiors (architecture)	15	0	
Mechanical	20	0	
Electrical	10	18	
Plumbing	5	0	
Elevators	2	0	
Safety	3	0	
Total points	100	100	100

Table 1. Possible total point distribution for various building systems.

The system condition index values assigned to each system during the field survey were used to develop the Building Condition Assessment Score. The condition points for each system were calculated based on the possible points times the system score or Condition Index as a decimal fraction of the maximum of 10. Thus, if the Condition Index for the roof of a Class A building was 8, the roof portion of the Building Condition Assessment Score was 5.6 (i.e. 0.8 x 7 = 5.6). If the building contained more than one roof, a weighted average based on square footage of each area and its associated Condition Index was calculated. The Building Condition Assessment Score was the summation of the condition points for each building system. The Building Condition Assessment Scores are generally comparable for buildings of the same class. A direct comparison of scores for different classes of buildings is less valid.

The statewide condition point averages for the building systems for the different classes of buildings along with the building condition assessment scores are presented in Table 2. The data indicate that the average system in the buildings has approximately 50 percent of its life still remaining.

	Condition Points					
Svstem	Class A		Class B		Class C	
	max	avg	max	avg	max	avg
Structure and foundations	27	18.5	49	33.3	100	61.2
Exterior walls	11	7.0	20	12.4		
Roofs	7	4.4	13	77 .		
Interiors (architecture)	15	8.8	0			
Mechanical	20	13.1	0			
Electrical	10	6.6	18	11.9		
Plumbing	5	3.3	0			
Elevators	2	1.8.	0			
Safety	3	2.1	0			
Total points	100	65.9	100	65.3	100	61.2

Table 2. Statewide averages for building systems and building condition assessment scores.

The repair and replacement costs were developed utilizing industry pricing methodologies and published information from R.S. Means. A detailed repair or replacement cost estimate was generated for all documented deficiencies. Unit costs for repair and replacement items considered demolition or removal, scaffolding, surface preparation, installation, and clean-up or repair of surrounding areas. Replacement costs also included the cost of associated items or systems affected by the specific item to be replaced. R.S. Means prices were United States average prices adjusted for major city corrections. The repair and replacement costs assumed institutional or government building quality of work. The costs did not include economy of scale effects such as letting a contract for roofing work on a large number of buildings in one contract. The total cost of immediate repairs and replacements was estimated at $62.3 million (US). A total additional cost of $1.391 billion (US) was estimated for the following 28 years.

Quality control measures utilized on the project included using specific survey forms and data documentation formats. Field survey personnel were trained in the use of these forms before they were allowed to go to the field. This consisted of a two day classroom training seminar so that they understood the data collection and condition ratings methods. They each spent a day in the field using the actual forms at the TXDOT District 14 Headquarters in Austin, Texas.

Information returned from the survey personnel during the execution of production inspections in the field was monitored to detect problems so they could be corrected in a timely manner. Senior personnel from the consultant also resurveyed a portion of the field work performed by each survey team to confirm that the data were accurate and consistent.

Summary

The TXDOT building condition survey program was very successful. It allowed the TXDOT to determine the level of compliance with the rule on office space limitations and the cost associated with bringing facilities in compliance. It also allowed TXDOT to estimate and plan for costs for the next three decades. All data was placed in a computer database that will provide the basis for an overall facilities maintenance management system which will allow the TXDOT to manage its facilities in a more economical and sustainable manner. The database was delivered to TXDOT and placed on the local area network at the Headquarters facility.

The Product's Milieu -
Towards an effective information domain to deliver sustainable building

S. Emmitt and D.P. Wyatt
Leeds Metropolitan University and Brighton University, UK.

Abstract
Designing to deliver an effective modus vivendi to secure a whole life provision for sustainable building may best be viewed through time sensitive product information demands. But research indicates that emphasis on the project is often at the expense of the finished product, with little practising of environmentally responsible ideals; at best there are a series of short lived links passing through a temporary circuit. Despite the large amount of information relating to sustainable issues, the problem appears to be one of relevance and encoding of disparate information, leading to an unwillingness (or inability) to access relevant information at the appropriate time. There is a need for an effective total information life system to underpin sustainable construction practice beyond the twenty first century.

This paper explores the need for a whole life approach to information to secure a sustainable, life designed, building. Such an approach may require a structural re-alignment for all those parties that build, supply, design, manage and work with buildings, including those who demolish and recover material for reuse and recycling through to reinstatement of a site. An information provision developed through service life planning and life managed buildings, centred upon the effective use of the supply chains of the materials used, within an embodied energy and carbon dioxide life tracking measurement. The sustainable dilemma is that key knowledge is missing from much of the whole life domain, an area in which developments in information technology and expert knowledge systems may go some way to resolving.

A change in the current design models, together with efforts to convince promoters, owners, maintainers and users that information for life should be their goal for sustainability, should now move centre stage. Expert knowledge systems and their electronic idiosyncrasies need careful consideration if, in a resource base sense, life information is to become a sustainable practice.

Keywords: Asset management; Disassembly; Information domain; Expert knowledge systems; Service life planning; Supply chain; Sustainability.

Introduction

The built environment makes an enormous impact on the planet's renewable and non-renewable resource base, contributing to CO2 emissions and other causes of global warming. In all respects, however, it is likely that the rules by which value and costs are shared, by including the externalities created by unsustainable development, will be changed. For example, the conflict between cost and value, combined with the likely phasing in of a built environment carbon tax.

That a more environmentally responsible approach is required is no longer doubted, but perhaps the means and the time frame to act are. Indeed, for some, the issues that need to be addressed are not seen as engineering or technical issues, but softer (and more challenging) factors, encompassing the management, organisation, evaluation and filtering of information. Soft factors require a full understanding of both communication channels and the information needs of a wide variety of potential users, combined with redefined terms of reference for those involved in the supply and value chains of a product, and its associated projects over its service life. Such an understanding may well be beyond the understanding of procurer, user and project participants because of the fragmented nature of the industry and the lack of consistency in the products use and function over time.

Research suggests that detailed evaluation of too many buildings' life fitness remain diffused and often poorly quantified: One felt that in pursuing a life cycle assessment approach (in order to verify the quality of a life design) meant that the information domain relied upon the user experience: a varied experience and one difficult to measure against technical or design parameters. A situation that might initially be made worse if sustainable building focused upon a life planning culture.

What then is the nature of the diffused information domain? Figure 1 illustrates an information system of interrelated components that collect (and retrieve), process, store and distribute information with the aim of supporting decision making, co-ordination and control in an organisation. But, is there such a centre? Is it possible to capture any meaningful life cycle assessment appropriate to a new sustainable model?

No attempt is made in Figure 1 to give it any shape because there is none that is universaly recognised beyond a drawing or documentation classification. It is suggested that only a loose grouping exists in the broad areas intimated. In effect, one might argue that there are two information circuits in train: one concerned largely with the project's modus operandi (process based) and the other concerned with the more permanent part of the project, the product (building) information circuit. In the dispersed model illustrated below there are contractual relationships, but with significantly different legal time frames, contractual risks and penalties: the significance and severity of which will depend upon the relational architecture of the procurement route chosen by the procurer and their advisers, in addition to ownership and legal duties of care.

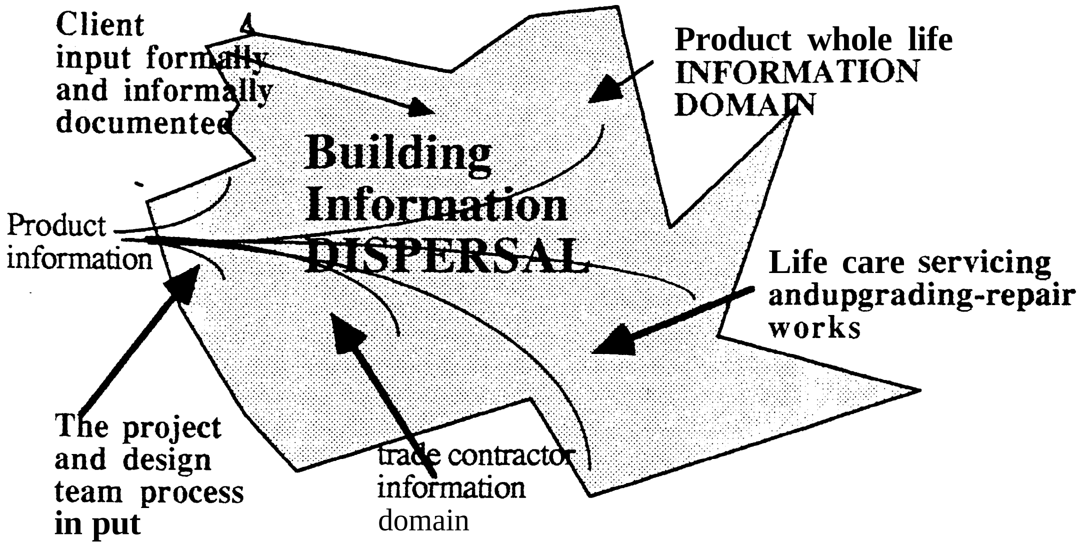

Figure 1
The dispersed information domain - the product's milieu.

Turning to the life care and the challenge facing the facilities manager. The dispersed nature of the building's information needs may in effect lead to a loss of design and technical expertise that created the building, despite everyones best intentions. For example, life cost information is difficult to find and also difficult to collate because of changing measurables, as such the data may have little credibility other than historical interest. It is all to common to find alterations and improvements to buildings carried out without Ml information, thus a Ml understanding of the new relationships that have come about through such action is often lacking. Whilst consultants may well be striving for product improvements and reliability in service life to limit down time, there is little evidence that the issue of information and its use to secure a sustainable future has been researched or responded to on any substantive basis (apart from the odd time capsule of certain project information coming to light through demolition - a theme that is not new). Yet the issue of project process and product information life mix continue to remain dispersed and largely inaccessible. This is an area of growing interest to the facilities management discipline, although to date it has been developing as an end in itself Perhaps the Scandinavian 'total build approach' to facilities management goes some way to addressing the fuller picture in calling for an integrated approach and a lifelong database (1), however there still remains a desperate need for overall vision and its strategic management.

In response to sustainable practise, buildings may have to be designed upon the basis of a life understanding and practice of durability, combined with the sustainable use of materials (2). The concept of designing for disassembly, whether in whole or in part, demands careful consideration, not just of the technical issues, but also of what and how relevant information it attached to the product - which raises the question, can the information be as durable as the product?

The new sustainable product domain

The product domain is made up of a range of products that have varying environmental implications, both in terms of abstraction and processing, and their disposal. Yet it is their green or environmental credentials that have to be questioned if the following product data is not forthcoming;

1. embodied energy rating, including the respective inbound CO2 associated with transportation being identified separately,
2. service life and weighting, or guidance on life reduction factors, to contribute to both service life planning and ultimately any future life gain,
3. environmental impact statements in terms of IS0 14000 I and guidance on recovery and final disposal,
4. life care guidance and options for reducing service loss for future re-use.

Some product manufacturers have started to promote products with (what might pass as) environmentally responsible labelling, but the response is patchy and the information provided is inconsistent and poorly quantified, thus it is impossible for the specifier to make realistic comparisons between competing products. In some respects, products have simply been marketed in a different way (the manufacturing processes tend to stay the same) and the opportunity for innovation spurned. In short, life data is neither readily discernible nor does life testing encourage sustainable development. Put simply, the product domain has yet to match the work of processed engineering capacity. In part this is due to fears over liability on behalf of the specifier and the specifier's office (3) and, because of the way in which the investment market works, it is not always in the procurer's best interest to bring sustainable issues to the fore.

Information lives

Both process and product information is dispersed throughout a building's life, from pre-conception through to its final removal (4). During any project there is usually a significant information base generated which becomes dispersed amongst diverse trade contractors (5). In fact one may introduce the construct of an information life, like the products themselves having lives. There have been calls for a product information system (6) that may help to address the European Directive on Building Products. Fair enough, but how does the designer validate or verify design decisions when the information domain does not embrace a core whole life quantification based upon user experience? When appraising the quality area what information should be retained from the commissioning corrective work area?, or the product's domain (7)?

Information in use

In a richer picture, each grouping may need key information which could contribute to a future whole life design or life track. A track intimated in Figure 2 merges the product and the process information domain to one for, and in, use. In particular, for that anticipated future such life track would be focused upon the practice in the centre.

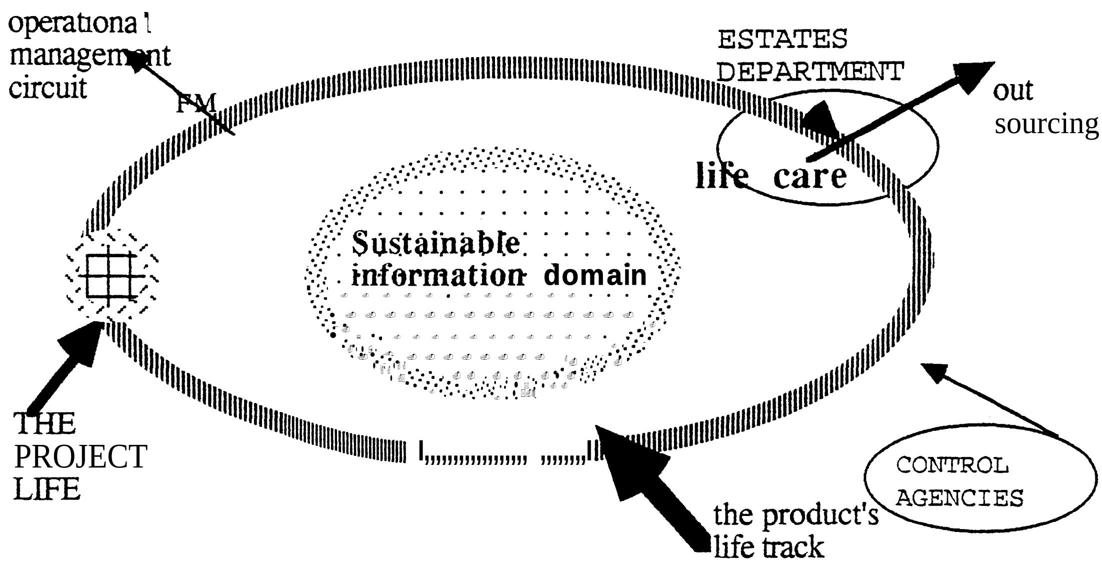

Figure 2
The product life information life track

Despite the extensive range of products, all with different cost in use profiles, the designer seldom has the quantified data required to make an informed decision. It is largely left to the clients estates team, facilities or asset managers to provide or establish reliable cost data. Until such a point is reached the dislocated and diffuse nature of information will act as a barrier to achieving a sustainable whole life briefing. Such information is dependent upon a feedback culture (largely lacking at present) based on accessible serviceability records, which themselves may be inappropriate in a future situation.

Contributors to the information domain may range from the statute makers, with legislation constantly changing both nationally and internationally, through changing users, to some future participants of alteration, upgrading, technical appraisal and/or forensic investigation work. Whatever the input, however, the product may not be proven, worse still the behaviour of a building's constituent parts may be remarkably diffused. Yet for product reliability, the need for verification over time in use requires feedback to secure environmentally responsible design. As such there appears to be an information network problem - we need the medical life records of a building- and its pathological field to become significant if building life quality and resource base management is to become more effective.

There is a common link; the supply chain that is drawn upon, held within the building and ultimately dispersed for reuse, recycling or landfill. To tie a sustainable approach to the supply chain would mean that the title of this paper could be met - provided that all relevant information can be framed in a life information mapping system; an expert knowledge system associated with individual buildings to an electronically standard (GIS?) national sustainable city system.

Design, product life and expert knowledge systems

The established procurement model may now have to include sustainable life quality by addressing the information needs and form of each element, component or system needs; ranging from embodied accounting, cleaning, servicing, repair, replacement and extending to deal with the failure of building services systems. Design has a pivotal role in service life planning (8), but there must also be a willingness from the client to extend their brief to include a use beyond their original intentions and consider disassembly and recycling potential. A wider brief may need the development of a suitable (and user friendly) expert system to allow for life tracking and inventory analysis, thus facilitating the management of the asset over time. Such systems may appear in the future to address service life **(9)** and service life planning (IS0 15686) to permit life auditing during the following stages;

1. pre-briefing,
2. in project process,
3. commissioning,
4. operational status,
5. decommissioning,
6. recommissioning,
7. removal.

Meanwhile, the life methodology needs to be honed so that it is appropriate to the level of assessment called for within its design life performance operating standards. Even so, it is likely that the life information of fitness is likely to remain diffused or unknown and may actually work against the securing of sustainable building due to unexpected maintenance or repair bills until life information is managed.

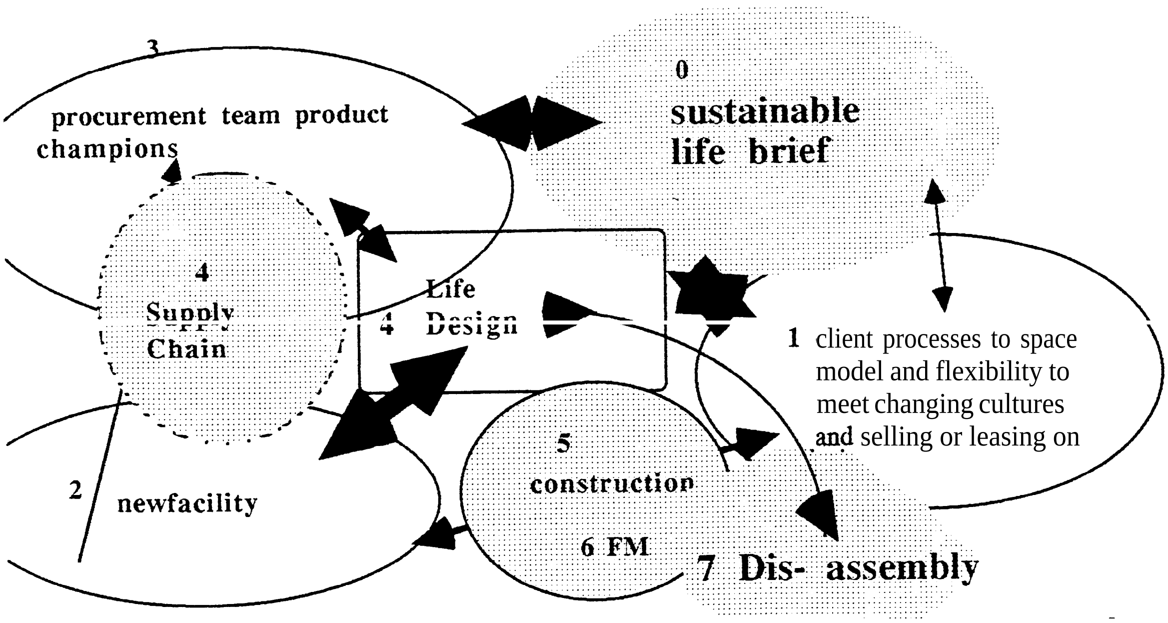

Figure 3
Addressing the discrete life information sub-domains

How can we define what information is needed?, for what stages in the life process?, and in what format? Perhaps a framework akin to the RIBA Plan of Work is needed, a framework extended to include a variety of potential scenarios within the sustainable agenda. Perhaps the model illustrated in Figure 3 might intimate something of what might happen, and why information should be viewed as one of the critical factors in securing future building design and life management of societies' built assets. Currently, the process may terminate at specific stages, but filter out both hard and soft information. But as the building becomes operational the information needs change to that of either monitoring the building or operating life procedures, (eg. inspection or cleaning according to the status set down by supplier, designer or client). Thus at each new briefing there remains an information domain which must be re-interpreted and the whole process reiterated. This could be seen as one of the structural weaknesses of the fragmented design processes which lacks a design information management system or life expert knowledge system.

Whatever future strategies are evolved to secure sustainable building, they must embrace all relevant parties in both the project and product domain. In such an embrace, it should be clear that the manufacturers, material suppliers and the disassembly management sector must be included. As a consequence, in this 'whole life appraisal' the respective parties' trading economics must be balanced within the defined delimiters of a particular development's environmental impact. So whilst one may need to understand the network problem, one must recognise that the role of the architect has changed. Whether an information manager will emerge to take control of the system remains to be seen. Meanwhile, adoption will onlv come about if architects, developers and clients have the desire to pursue common knvironmentally responsible ideals. Similarly, the pressures put upon them by the general public and building users, who will be affected by development, will influence the rate of change for those that do not lead, but choose to follow (10).

From the 'chunky' parts of Figure 3 then, in a future information domain a re-interrogation of the whole design process may be needed or reiterated in any future change of use or enhancement. In responding this may mean the building's service life profile becomes part of the condition based information life system. Next, life information management scope would have to be kept under regular review and updated as change occurs (including sustainable construction initiatives, client and user experience) in part leading to the evolution of more effective life cycle assessment studies, improved supply chain management and environmental initiatives. Finally, beyond the building's operational or decommissioning stage, both the form the information is in and the quality of any record found may have serious implications for those attempting to influence decisions decades ahead or even several centuries down a sustainable life track, through the supply chain inventory.

Conclusion

At present, neither the construction industry nor its many participants are geared up to hold and maintain life documentation. A life documentation that may range from a short term building facility (say 10-20 years) to building stock that might well be standing in 200 years time. A time scale which may be extended if CO_2 becomes a serious delimit on the way one designs and builds. Equally, it is clear that environmentally responsible ideals and practices form a challenge to the majority of participants, who may well continue to act in a familiar manner despite the fact that their knowledge domain has shifted towards sustainable issues. A significant change in attitude, information dissemination and capture is required if sustainable building is to come about - the information is already available, the challenge is to both find it and then use it effectively throughout a buildings service life.

The product team are, in effect, addressing a building made up of many materials, sub-systems, jointing systems and their associated protective coatings and finishes. The information domain may not be able to manage the range of sub-product changes over time, nor would a single firm necessarily have the appropriate data base. It should also be remembered that the technology used in today's data bases and expert knowledge systems may become inaccessible as technology advances (or systems cease to trade) and firms strive to stay up to date. The prospect of information loss is real.

A change in the current design models, together with efforts to convince promoters, owners, maintainers and users that information for life should be their goal for sustainability, should now move centre stage. Expert knowledge systems and their electronic idiosyncrasies need careful consideration if in a resource base sense, life information is to become a sustainable practice.

Abstract
Some attempt on recycling excavated soil at site was conducted in order to reduce total amount of soil carrying out of a site. It becomes more and more difficult to find reclamation sites for excavated soil to dump around large cities, typically Tokyo and Osaka in Japan. This trend is due mainly on shortage in reclamation sites around large cities and increase in excavated soil around there.
Under such a circumstance, the ministry of construction in Japan has set a campaign, called Recycle Plan 21 Century, in 1995 and promotes R & D on new recycling technologies in order to utilize more amounts of construction wastes. This paper relates to this campaign and copes with recycling excavated soil.

The developed recycling technique, called "Liquefied Stabilized Soil" is a method that excavated soil is thoroughly mixed with muddy water (or water) and cementing material and then placed in space where back filling is necessary at site. The method is simple to apply at site except a mixing design specification and a mixing machine. Excavated soil may be any kinds, including cohesive soil with high water contents that has conventionally been concidered unsuitable for earth works. Thus, it is thought acceptable widely over construction sites and promotive on recycling.

On the one hand, the method is possible to simplify construction sequence; one of examples is that LSS flows like concrete mortal and its placing requires no compaction effort. On the other hand, the soil after hardening shows good outcomes; at the level of strength where hand shovel excavation is available, the soil is substantially little in shrinkage, permeability, and corrosion under ground water level.

This paper presents a recent application example of this method; a large amount of excavated soil is recycled at site where excavation is done. The application is oriented to reduce soil to be carried out of the site.
The paper also presents a proportional mixing design of LSS and its producing system with outcome of quality control tests.

Recycling Excavated Soil, Clay with High Water Contents, Liquefied Stabilized Soil, Back-Filling., Narrow Space, No Compaction

1 Introduction

Some recycling technique for excavated soil to be a back fill material has been developed, namely 'Liquefied Stabilized Soil Method". The method consists of simple stabilizing processes except a mixing specification. It deals with any kinds of soils, including a cohesive soil with high water contents that has conventionally been considered unsuitable for earth works. Thus, the method is thought acceptable widely over construction sites and promotive on recycling.
A common recycling procedure is that excavated soil is carried to a remote plant for stabilizing and carried back to a site for back filling. When an amount of handling soil is large, thousands of trucks necessarily transport them Thus, a plant at a construction site is preferable from environmental and economical points of view. The paper presents a case history of this site plant application with introduction of Liquefied Stabilized Soil Method.

2 Excavated soil

In 1997, excavated soils resulted in 44 million cubic meters in Japan. This amount is 18 % increase from 1992. Except soil with high water contents, excavated soil is basically re-useable without any stabilizing process for an embankment fill material and/or a back filling material. Yet, in past only 15% of them are re-used at construction site while 85% is simply dumped at inland and/or offshore reclamation sites.

On the other hand, construction sites prefer purchasing new sand as a filling material. In 1997, sands used at construction sites are 20.6 millions cubic meters. Among them., a new sand is 68%, a recycled sand 29%, a stabilized soil 3%; these values were 64%, 34%, and 2% in 1992 respectively.
It would be concluded from these data that recycling is slowly progressing but a large amount of reusable excavated soil is still dumped at reclamation sites while a large amount of a new sand is excavated from a natural ground [1].

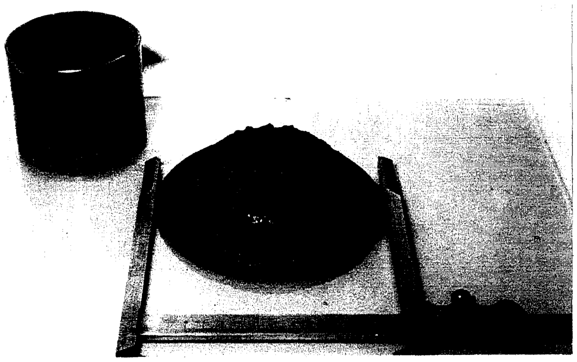
3 Liquefied stabilized soil

Liquefied Stabilized Soil (hereinafter called "LSS"), a new soil stabilization technique is made by mixing soils as principal materials with muddy water (or water) and cement [2]. LSS flows like concrete before hardening. It yields the necessary strength according to proportion of the mixture. It requires no compaction at the time of use and little volumetric shrinkage after hardening. Therefore, it is expected that this stabilized soil is highly applicable for back filling and filling at construction sites where compaction is difficult (Picture 1).

Picture 1 Back Filling of LSS

By adjusting the content of the principal materials, muddy water and a cementing material, it is possible to set the condition of LSS where wanted filling characteristics can be obtained. The filling characteristics are expressed in parameters such as strength, flow value, density, and bleeding ratio. They are decided according to the purpose of the site and produced through a proper mixing proportion after a certain combination of soil tests [3] . The strength of LSS is set at the level fitted for the purpose ranging from the strength of such degree so as to permit hand excavation to the strength equal to the lean mixture concrete.

The fluidity is evaluated by flow value; the spread diameter of LSS originally set in and released vertically from a cylinder measuring 8 cm high and 8cm in diameter (Picture 2). By changing mix proportion., it is possible to yield the required flow value. The flow value changes along with density and time passage. It is known that a low value of 11 cm is the limit to pump LSS out and 14 to 25 cm is a good range [4]. The density is related to all parameters and usually set at 1.4 or higher. The bleeding ratio is restricted to within 1% in most cases or 0.5 % in the case of strictly limited volumetric change like when filling a cavity [5] .



Picture 2 mow value 160 mm of LSS

Beside from above expertise, past series of experiments show that hardened LSS in ground revealed following characters.

1) easy to re-excavate
2) little shrinkage in the ground
3) little corrosion by the running water in the ground
4) almost in-permeable
5) liquefaction free in earthquake
6) no pH rise around the ground
7) slurry waste also useful

Picture 3 Back Filling Space

4 Application example

General condition

In the center of Tokyo, two buildings adjacent each other were constructed sequentially. First building was chosen for this application and was 19 stories building with 4 basements; its total floor area 112,700 square meters, height 90 meters, and ground area 7,500 square meters.

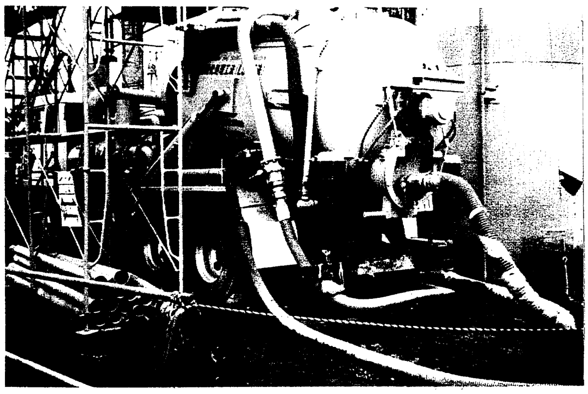
A depth of excavation was 33.5 meters at the deepest and an amount of excavated soil was nearly 261,000 cubic meters. Back filling between a retaining wall and basement structures, typically 4 meters wide, was initially planed by placing sand with compaction. Its space is about 36,000 cubic meters (Picture 3).
A retaining wall was made by a Soil Mixing Wall Method and bottom grounds were improved by deep soil stabilization before excavation so that excavated space was isolated from underground water.

LSS method became attractive comparing to back filling sand and compaction by following reasons.

1) An amount of excavated soil is massive and recycling is preferred.
2) A back filling period overlaps with an above structure work which prefers no men working below.
3) There are narrow spaces where back filling with sand and compaction is barely possible.
4) Excavated soil is a kind of clay with high water contents.

Application of LSS

It is common that LSS plant is set remote from a construction site. Its procedure is that first excavated soil is carried to the remote plant, secondly it is processed to LSS, and LSS sends back to a site for back filling. This system is available in adjusting time lag of excavation and back filling and/or supplying LSS to any sits when it is necessary.



Picture 4 Outlook of a Movable Plant

However, the systemneeds transportation carrying soils out and bringing LSS back, resulting not ignoring amount of cost.

This application uses a site plant experimentally. Since two buildings are constructed in some time differences, it is thought possible that excavated soil at one building is used for the other. For this application, a movable mixing plant was developed to reduce a plant area (Picture 4 and Figure 1). This plant is moved out of site easily when no needs. In addition, construction sequence is carefully re-scheduled so that amount of soil to excavate and LSS to back fill is balancing.

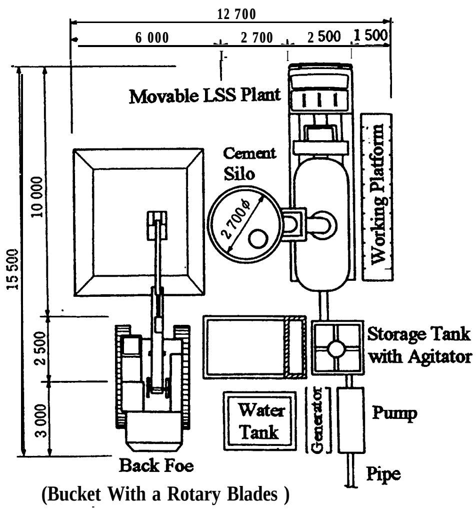


Figure 1 Occupancy of A Plant

Soil Property and Mix Proportion

Excavated soil is mainly Kanto-Loam whose characteristics are seen in Table 1. Since silt and clay proportion is 66%, bleeding can be controlled within 1% without any treatment. However, it is difficult to make dense LSS with this material alone.

Main properties wanted for LSS are strength and bleeding ratio. Table 2 shows target properties of LSS for this application.

Unconfined strengths were set at the level equal to that of surrounding grounds. At that levels hand excavation is still available and substructure was sustained firmly by lateral earth pressure. However, target strengths were modified somewhat higher by two considerations. A Soil Mixing Wall exhibits stiff behavior and soil between the wall and substructure is preferred similar to that of the wall. A target density is slightly lower than 1.4 and higher strength can be secure in durability.

A bleeding ratio is less than 1 % and expected no segregation with water and no substantial shrinkage in the ground.

A density prefers being high because of durability. To do so is to reduce a void in LSS; concretely lowering water contents. On the other hand, it becomes difficult to flow when water contents becomes low; placing prefers a high flow value. At a flow value of 300 mm, LSS flows by less than 1% gradient. In this proportion, a designed flow value is set low for gaining more density.

Table 3 is a designed mix proportion for the target properties. Since an original soil is rather uniform, one proportion is adopted.

Table 1 Excavated Soil Characteristics

Soil	Gravel	Sand	Silt	Clay	Water Contents	Unit Weight
Kant0 Loam	11.7%	22.2%	24.0 %	42.1 %	80.0 %	1.42 (t/m^3)

Table 2 Target Properties for LSS

Location	Initial UCS (kgf/cm^2)	Final UCS (kgf/cm^2)	Bleeding Ratio(%)	F. Value (mm)	LSS Unit Weight (t/m^3)
Above GL – 10 m	2.00	10.2	Less 1%	Over 160 mm	1.387
Below GL -10 m	3.75	10.2	Less 1%	Over 160 mm	1.387
Concave Space of Substructure	10.2	10.2	Less 1%	Over 160 mm	1.387

Note: UCS at 28 days and $1\,kg\,f/cm^2 = 100\,kN/m^2$

Table 3 Mixing Proportion

Excavated Soil	Water	Cement
664 kg	505 kg	218

Cement is for 1.25 time of target strength

LSS work at site

Figure 2 shows a system flow at this site. Excavated soil is moved to the plant in a site. Sequentially, it is mixed with water by a bucket rotary mixer. Density of slurry is monitored every minute so that it meets with the mix design. A movable plant draws in necessary amounts of slurry and cementing agent by a vacuum and a measure. After cementing agents are uniformly mixed among slurry, LSS has been made and sent to a storage in which an agitator runs preventing segregation. Finally, LSS goes to where back filling is necessary by a squeeze pump.

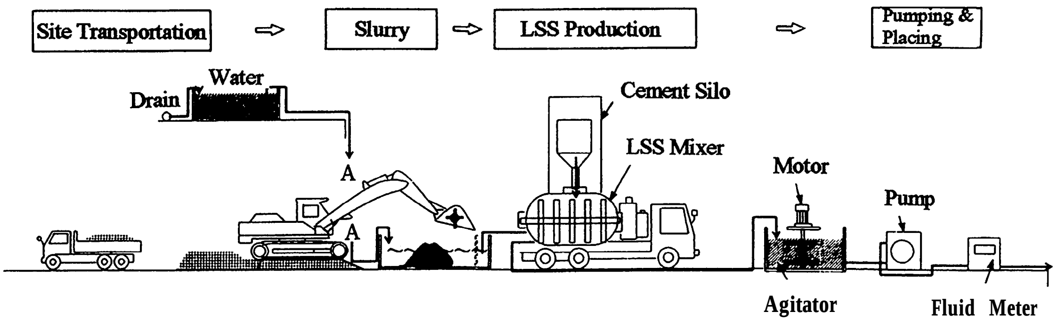

Figure 2 Site LSS System Flow

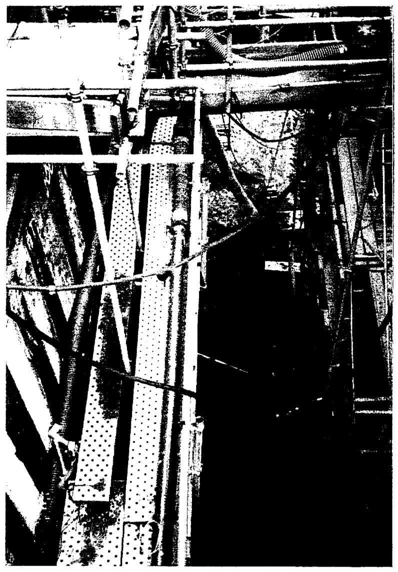
Pumping does placement of LSS. Pipes for placement are set when no structural works are active. They are easy to carry and joint together. Length of piles is long, say 250 meters at longest, their setting is arranged in a way that their length is shorter and bends are less. Picture 5 shows LSS placing. A previously set pipe discharges LSS where back filling is necessary. Note there is few men in back filling operation.

This placement of LSS consists of three phases. The first phase is for back filling until one third of total depth from the bottom Around the top, there are stress units of anchors and lateral bracing. A total length around the substructure is about 350 meter. A pipe is extended to the far end from the plant site and discharges LSS. During this far end placement, water, if any remained at the bottom, is pushed by LSS toward the location of the plant and drained. After LSS accumulates near the bracing, the pipe is located where LSS piles up low, typically 15 meter away for the previous discharge point. A placement continues till a surface of LSS coming equal to the other. When placed LSS gets hardened at the surface, stress units and lateral bracing are taken apart without scaffolding works. The second and third phases go up to next stress units of anchor and lateral bracing level with same procedure of the first phase. When LSS comes to near ground, its surface is covered by excavated soil. Figure 3 shows results of placement in a day. A total amount of placed LSS became 36,000 cubic meters.



Picture 5 Placing LSS

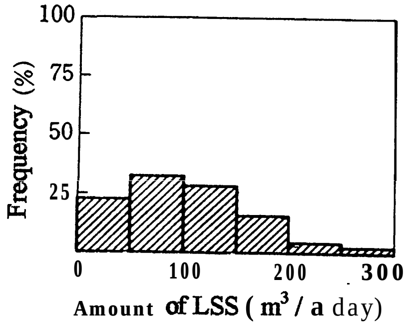


Figure 3 LSS produced in a day

Quality test

Quality control tests are conducted before and after hardening of LSS. The former is for confirming if LSS is adequately produced according to the mix proportion while the latter is for assuring quality of placed LSS. The former type of a quality control test is done every batch in terms of slurry density, LSS density, flow value and the latter type is two sampling a day in terms of bleeding ratio and unconfined strength. Test results are shown in Figure 4 to 6. Produced LSS are fallen over acceptable ranges of the target values and there are no defect products. The figures also indicate no significant deviation in distribution.

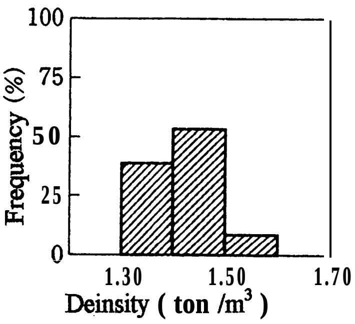

Figure 4 Density Distribution

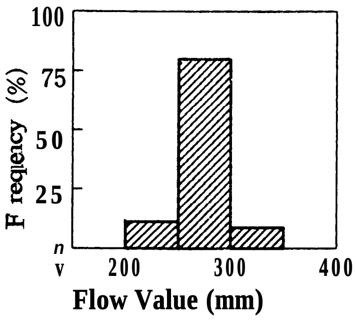

Figure 5 Flow Distribution

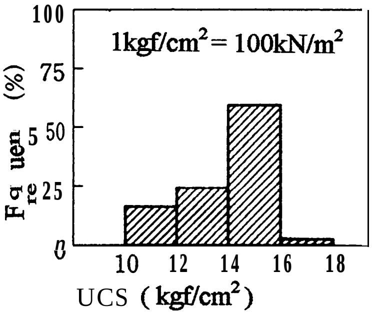

Figure 6 Strength Distribution

5 Summary

A newly developed recycling technique is applied for a soil with high water contents at the construction site, This application indicates following expertise;

1) Excavated soil with high water contents is easily reused at a site and considered as useful resources.
2) A small plant space is capable of producing a large amount of LSS, in this case 300 cubic meters a day at maximum.
3) Quality of LSS is steady if excavated soil is uniform; this implies a site plant is preferable to a remote plant, which collects any kinds of soils.
4) Placing LSS with pumping reduces labor resources significantly.
5) LSS little segregates into water if bleeding ratio less than 1%.

Acknowledgement

The Liquefied Stabilized Soil Method was developed by the collaboration study with Public Work Research Institute, Ministry of Construction and Japan Association of Representative General Contractors during 1992 to 1997. This case history was conducted after this research. During that time, many research engineers contributed significant efforts. Here at the end, authors give special thanks to those related the development, especially, Dr. Miki, H and Mori, N at the Public Work Research Institute.

Building Physics - No Way around It

G. Jóhannesson and P. Levin
Division of Building Technology, KTH - Royal Institute of Technology, Stockholm,
Sweden

Abstract
In recent years, growing interest in life cycle cost analysis regarding environmental and economic factors has focused on the choice of materials with regard to the chemical composition, embodied energy, emissions of gasses and other more or less quantifiable processes. In some cases, this concentration on material properties has lead to inferior solutions regarding thermal performance, moisture protection and durability in general. In this paper, an attempt is made to establish a relation between design that neglects common theories of building physics and the consequent environmental and economic cost. The study is based on a Swedish single-family house having a normal design where components are successively exchanged to materials and constructions that are today commonly known as being environmentally feasible.

For each solution, the method estimates the impact on the use of energy and emission of greenhouse gasses. With additional information the need for maintenance, repair and replacement at some intervals should also be included in such a study. The analysis will always be partly built on unreliable input data and subjective reasoning. The aim here is not to give exact results but to place emphasis on the importance of a proper perspective for the technical design when considering the life cycle.

For both analysed cases with the timber-framed wall and the different methods for airtightness it is evident that their role in the operation of the buildings dominates the differences in the environmental impacts of the construction itself. It can be concluded, from these examples that recommendations on environmentally feasible constructions based on unreliable information regarding the environmental impact of materials without considering the functionality of the material and the constructions as a whole over the lifetime of the building or building component, are to be considered as more or less organised desinformation to builders and buyers.

Finding alternative building materials and more effective means for the building process is in no way to be considered as unimportant in our efforts for a better environment. However, the examples above show that the functionality of alternative solutions and materials must be considered when designing from the perspective of the life cycle of a construction before these can be recommended as fulfilling the requirements of both sustainability and functionality.
Keywords: durability, embodied energy, emissions, energy use, performance, service life

1 Introduction

In recent years, growing interest in life cycle cost analysis regarding environmental and economical factors has focused on the choice of materials with regard to the chemical composition, embodied energy, emissions of gasses and other more or less quantifiable processes. In some cases, this emphasis on material properties has lead to inferior solutions regarding thermal performance, moisture protection and durability in general. In this paper, an attempt is made to establish a relation between design that neglects common theories of building physics and the consequent environmental and economic cost. The study is based on a Swedish single-family house having normal design where components are successively exchanged for materials and constructions that are today commonly known as being environmentally feasible.

2 Methodology

When assessing the environmental impact of different building materials, the chemical composition and emissions have to be weighed to a comparative quantity. This is difficult but has been done using different approaches [1]. The next difficulty is to choose between different materials based on an assessment of environmental impact. The difficulty here is that the environmental impact partly refers to the material and partly to the functionality of the material as a part of a complex building structure in the exterior envelope of a whole building. When making a choice between two materials with the same functionality the pure material properties can be considered. When choosing between materials with different functionalities the obvious risk is that the role of the material properties will dominate the functionality aspect and that this will lead to sub-optimisation that will not ultimately benefit the global environment. Also when a material with the same functionality but at a higher price is chosen, this has to be matched against the cost efficiency of other measures that could benefit the environment.

3 Case study of the vapour barrier in a timber-framed wall

3.1 Technical description of the timber-framed wall

The timber-framed wall built in Sweden today normally consist of materials that have been developed to fulfil one or two functions, i.e. separate material layers are used for vapour barriers, efficient insulation, surfaces etc. This permits the wall to meet high demands on performance but also it becomes vulnerable to damages and poor workmanship.

The layers of the timber-framed wall, starting from inside the interior cladding, consists of: gypsum board with paint, vapour barrier made of 0.2 mm polyethylene (PE) film, timber frame and light weight insulation where the timber part is assumed to be 15 %, wind barrier of low density tarred fibre board, a ventilated air gap and exterior cladding consisting of a wood panel.

The timber-framed wall does not have the same built-in natural airtightness as does, for instance, the masonry wall. The combination of studs and porous insulation demands both internal and external supplementary layers to secure the airtightness and to prevent air exchange between the insulation and the outdoor air.

3.2 Cost-benefit analysis for replacing the plastic film

One of the major aims of the enthusiasts for a better environment, has been to remove or replace the plastic film that over the years has traditionally been used as a vapour barrier on the inside of timber-framed constructions. The function of the plastic film is partly to provide a high vapour resistance on the inside of the construction and to provide adequate airtightness. There are two different dominating strategies for replacing the plastic film. The first is to eliminate it and use insulation materials that are supposed to absorb and release moisture over an annual cycle. The second is to replace the film with some other technology, such as an interior surface cladding with surface treatment and carefully made joints to provide good airtightness. A cost-benefit analysis for plastic film and mineral wool batts replaced by cellulose insulation can serve as an example of the actual complexity of such problems:

Eventual cost
- Extra work and materials for interior cladding surface treatments and joints
- Higher material cost for cellulose based insulation materials
- Increased energy use due to reduced airtightness
- Increased wall thickness due to higher thermal conductivity
- Increased energy use due to higher humidity level in the insulation layer
- Increased environmental cost due to reduced service life
- Higher risk for emissions from the interior of the construction to the inside.

Eventual benefits
- Materials from renewable sources
- The environmental cost of the plastic film is saved
- Material and installation cost for the plastic film is saved
- Has a market value since it is easy to convince ignorant buyers about the health hazard connected to the use of plastic film.

Environmental data on construction materials, components and elements can vary within wide limits depending on where the products are produced and applied. We have chosen data provided by other researchers [1, 2] and have studied two alternative constructions, one with plastic film vapour barrier and mineral wool insulation batts (thermal conductivity 0.036 W/mK) and one without a vapour barrier and with cellulose insulation (thermal conductivity 0.039 W/mK). For the construction we summed the energy used and the greenhouse gasses emitted to the atmosphere in relation to the production of materials and construction. We referred to the references for the basic values. To relate these values to possible emissions owing to the energy used during the operation of the building over 70 years we used oil burned in a rather effective plant as a reference. These values represent a possible scenario but are by no means valid in all cases. The choice of oil as a reference source for heating is of course disputable. Together with hydro power and nuclear fission the burning of oil is still a major source of heat in Sweden and one can assume that a great part of a marginal increase in energy consumption will be met with oil burners.

Table 1 shows the total energy used and the most important greenhouse gas emissions for the two construction alternatives.

Table 1. Used energy and air emissions for two wall construction alternatives including effects of energy use for heating during 70 years of operation.

Timber framed walls	**Energy MJ/m²**	**CO_2 g/m²**	**SO_x g/m²**	**NO_x g/m²**

Constr. and operation	6849.4	488032.3	2456.1	1080.8
Total difference	**150.6**	**14001.6**	94.3	29.6

Replacing the mineral wool and plastic film with cellulose insulation reduces the embodied energy by 20 %, the CO_2 and NOx emissions by 40% and 5 % respectively, whereas the SOx emissions are increased by 4 %. When the operation of the wall with 130 degree-days per year over a period of 70 years is included, CO_2 emissions increased by 140 %, SOx emissions by over 200% and NOx emissions increased by 20 %.

The above examples shows that choosing a material with lower thermal performance very rarely will be environmentally feasible even though the material itself may have less embedded energy and fewer greenhouse gas emissions. The difficulty with such a comparison is the choice of cases for comparison. Replacing the cellulose fibre insulation with mineral wool with higher thermal conductivity would also have given increased environmental impact. There is also an economic angle. If the two construction alternatives had been given different insulation thickness to reach the same price per m^2 for the construction a more expensive product like the cellulose fibre insulation alternative would have shown much higher environmental impact. The above analysis also assumes the same airtightness for both constructions.

3.3 Life cycle cost assessment of the timber-framed wall

The building design process is a series of choices. In earlier times it was sufficient to make the monetary cost - benefit analysis. That is to regard the economy of the project from a present value perspective for a given specification based on technical and construction related aspects and as well on estethic performance. Now we should also consider the environmental impact of our choices. The economic and environmental impact can also be closely related.

In a timber-framed construction the thickness of the timber frame for structural purposes is approximately 100 mm. To maintain a low U-value the thickness of the frame has to be increased beyond this just for insulation purposes. A wall with 200 mm mineral wool and a crossing-stud timber frame gives a U-value of approximately 0.20 W/m^2K. If the wall is instead insulated with cellulose fibre insulation the U-value can be increased to 0.22 W/m^2K. To compensate for the higher thermal conductivity the thickness has to be increased to 220 mm. The additional cost for the cellulose fibre insulation is about 40 SEK/m^2 for the original thickness and about 25 SEK/m^2 for the extra construction thickness. The additional cost for the same insulation performance is therefore 65 SEK/m^2 or about 10000 SEK for a 150 m^2 house. This amount could instead be invested in an air-to-air heat exchanger or an exhaust air heat pump saving 3000 kWh per year or 2.5 m^3 of oil over a 70 year lifetime. The other choice would be to insulate with the same thickness resulting in an increase in energy use by 400 kWh per year or about 0.4 m^3 of oil which is still large compared to the 30 1 of oil saved by not using the plastic film.

The airtightness of a timber framed construction has normally been provided with a plastic film behind the interior cladding. The oil consumption for heating infiltrated air is for a 150 m^2 house with 0.5 air exchanges per hour approximately 50 m^3 over a lifetime of 70 years. An inferior construction in term of airtightness can easily give an increase in infiltration of 0.05 - 0.1 air exchanges per hour resulting in an extra consumption of 5-10 m^3 of oil over the lifetime of the building which can be compared with the oil saved by not installing a plastic film being less than 100 kg.

Owing to the relatively small impact of the construction compared with the operation, the impact of functionality of the construction dominates the total picture. This also means that the question of service life is suppressed looking at the construction for itself. If however the construction can be seen as the weakest link in the service life estimation for the whole building with its infrastructure and also including the possible negative effects of the decay on the construction on the indoor environment the picture becomes different.

4 Case study of caulking joints between walls and windows/doors

This example is illustrated by a rectangular one story house of 10 by 12 meters. The window area is assumed to be 18 % of the floor area and the joint length is 4 m per window with two doors giving a total crack length of about 100 m. For simplicity we assume 25 m on each face of the building and no other air leakage paths present. The house is equipped with a mechanical exhaust and supply ventilation system that takes care of the desired airchange rate. Additional air leakage is undesired. The house is placed in Stockholm with an average heating season temperature of +2°C and 4 m/s wind speed. Indoor temperature is 20°C.

Results from laboratory measurements of air leakage of different joints between windows/doors and wall frame, and the corresponding air leakage curves were found in literature [3, 4]. The relations between air leakage flow and pressure difference from these measurements were expressed as:
$q = 0.0440 \cdot \Delta p^{0.86}$ m^3/hm for a joint sealed with mineral wool packing but without elastic compound and $q = 0.0012 \cdot \Delta p^{0.79}$ m^3/hm for a joint with elastic compound. For a well performed joint using polyurethane foam sealing the value was practically zero.

To find a relevant seasonal average pressure difference for these air leakage paths, standard pressure coefficients for wind perpendicular to the long face of the building were assumed. Thus, the air infiltrates through the windward wall of the building and exfiltrates through the other walls. The building, including pressure coefficients, wind speed and temperatures were inserted in the IDA-MAE computer program to find the resulting pressure differences and air flows [5].

The calculated reduced air flow from using elastic compound in addition to mineral wool packing amounted to 8.6 m^3/h for this house, which could be estimated to reduce heating need with about 300 kWh/year in the Stockholm climate. Using the polyurethane foam, which normally is installed without mineral wool packing, the reduction will be slightly larger.

In Table 2, the environmental impact of three types of joints is estimated by total energy use and emissions to air. Also the saved emissions originating from energy saving (reduced oil burning) over a 20 year service life owing to the reduced air infiltration is also provided. In this example, a 20 year service life was chosen as reasonable for the three types of joints considering functionality and seasonal moisture and temperature movements. Environmental impact data is taken from previously mentioned sources and [6, 7].

Table 2. Environmental impact for three types of joints for a single-storey house (100 m joint length) compared to the saved emissions over 20 years from reduced energy losses.

	Type of joint	Mass kg/m joint	Total energy use MJ	CO_2 g	SO_x g	NO_x g
1	Polyurethane foam	0.030	313.1	12.19	0.0573	0.0533
2	Butyl (PP base exc. filler)	0.180	1 440.5	19.8	0.198	0.18
	Backing rod (LDPE)	0.010	83.0	0.61	0.0027	0.0079
	Glassfibre wool packing	0.090	186.5	6 882.5	4.91	29.45
	Sum of materials		1 710.0	6 902.9	5.1	29.6
3	Glassfibre wool packing	0.090	186.5	6 882.5	4.91	29.45
	Saved emissions over 20 years (joint 2 compared to joint 3)		21600	1637280	8208	3240

As can be seen from Table 2, the impact of the saved emissions totally dominates over the impact from the materials for all of the investigated parameters. This example shows the importance to create building detail solutions that gives as low energy use as possible.

A new trend that can be seen is to recommend packing with cellulose fibre insulation and omitting the caulking. Measurements are not available but assuming that the cellulose fibre insulation will give similar results as packing with only mineral wool, it is obvious that small environmental benefits looking only at the construction itself will quickly be eaten up during the first years of operation.

5 Conclusions

From the above examples it can be concluded that recommendations on environmentally feasible constructions based on unreliable information concerning the environmental impact of materials, without first considering the functionality of materials and constructions as a whole over the lifetime of the building, must be considered as more or less organised desinformation to builders and buyers. Whether these are commercially or otherwise motivated, these kinds of recommendations could be harmful to the environment because they could lead to wrong decisions and also because they undermine the more serious long-time work for a better environment based on science and technology.

Finding alternative building materials and more effective means for the building process is in no way to be considered as unimportant in our efforts for a better environment. However, the examples above show that the functionality of alternative solutions and materials must be considered when designing from the perspective of the life cycle of a construction before these can be recommended as fulfilling the requirements of both sustainability and functionality.

Evaluation of the Factor Method to estimate the service life of building components

P. J. Hovde
Department of Building and Construction Engineering, The Norwegian University of Science and Technology, Trondheim, Norway

Abstract
In this paper is presented an evaluation of a method to estimate the service life of building materials or components. The method is called the Factor Method, and it is based on a reference service life (RSL) and a set of factors to be multiplied with each other and with the RSL. The Factor Method is proposed in an IS0 Draft Standard which is under development.

Intitally, a brief presentation is given of the background and needs for service life prediction which has appeared during the last 10-l 5 years. International as well as national research and standardization activities are mentioned.

After a presentation of the Factor Method itself, a survey is given of important publications which contains general descriptions or criteria which should be applied to methods for prediction or estimation of service life. Finally, a discussion of the Factor Method is given, including suggestions for further studies to improve the method.

In the conclusions it is stated that the Factor Method has gained specific interest over the last years, but little experience has been gained by use of the method so far. The discussion has shown that there are several aspects of the method which need to be further evaluated, in order to achieve a method which is sufficiently reliable and user-friendly. There is also a great need for input data for various materials and components in order to use the method. More studies are going on in order to develop the Factor Method further, or to get more experience with the method, e.g. within the joint CIB W80/RILEM-SLM group "Service life methodologies".
Keywords: service life, estimation, Factor Method, building materials, building components.

1 Introduction

Over the last decades, there has been an ever increasing focus on the needs to determine durability and service life of materials, components, installations, structures and buildings. This has been based on two important aspects:

- environmental issues: lack of material and energy resources and pollution stress on the environment
- economical issues: the total value of the built environment on a national level and the value of each part of it (buildings, structures, roads, quays, etc.) for the specific owner (authorities, private companies or individuals). The conditions of the built environment and the annual costs of management and maintenance are of major importance for the economy and the competition.

The importance of these aspects has been reflected in several intiatives and activities at both an international as well as a national level. Some of those are briefly mentioned here:

- the UN Conference on Environment and Development (UNCED) which was held in Rio de Janeiro, Brazil, in 1992. This conference resulted in two international agreements, two principal statements and an Agenda for a global sustainable development (Agenda **21)** [1]
- adoption of the Construction Products Directive (CPD)[2] within the European Union (EU) in 1988. In the Directive six essential requirements are given, and a statement that one or more of these requirements have to be fulfilled during the economical working life of the actual material or component
- publication of a RILEM Recommendation for service life prediction [3] in 1989
- publication of a Principal Guide for service life planning of buildings in Japan [4] in 1989 (English edition in 1993)
- international research and development activities within CIB (W60, W70, W80, W94) and RILEM
- international standardization work within IS0 (TC 59, TC 207)
- publication of national standards and building regulations regarding durability and service life of building materials and components. As examples the following countries can be mentioned: Canada, New Zealand, Norway, United Kingdom.

2 The Factor Method

The concept of the factorial evaluation of the service life as described in the Japanese Principal Guide [4] has been introduced in a proposal for an International Standard for service life planning of buildings [5]. The proposed Factor Method is said to *"allow an estimate of the service life to be made for a particular component or assembly in specific conditions"*. The method is based on a reference service life (RSL) and a series of modifying factors that relate to the specific conditions of the case. The RSL is said to be *"in essence the expected service life in the conditions that generally apply to that* *type of component or assembly..... ".* The RSL is similar to the standard service life as defined in the Japanese Principal Guide.

In the present version of the IS0 Factor Method (Draft of May 1996), the following factors are used:

A material and components
B design
C sitework/execution
D indoor environment
F outdoor environment
G operating characteristics
H maintenance level

The Factor Method is then expressed as the following equation where the estimated service life of a component (ESLC) can be calculated by a combination of the reference service life of the component (RSLC) and the factors mentioned:

$$ESLC = RSLC \times \text{factor } A \times \text{factor } B \times \text{factor } C \times \text{factor } D \times \text{factor } F \times \text{factor } G \times \text{factor } H \quad (1)$$

In an informative appendix of the Draft Standard, three worked examples for use of the Factor Method are given. These examples are dealing with prestressed steel lintel, softwood window and fibre-based cement slates.

3 General requirements for service life prediction

Service life prediction of materials, components, building elements or buildings is rather difficult. It can be based on two different principal approaches:

- deterministic approach
- probabilistic approach

In the deterministic approach, exact figures are used and no evaluation of uncertainty or statistical variation of the factors is considered. In the probabilistic approach, considerations are shown to the fact that the reference service life (RSL) as well as the factors vary with a statistical distribution within certain limits.

Since the first half of the 1980s, much work has been done within international research and standardization organizations (CIB, RILEM, ISO) and on a national level in some countries to develop methods, tools and standards for description of service life. In many of these studies, efforts have been put into the description of general requirements which should be posed to service life prediction or estimation methods. Some important examples of such requirements are mentioned below.

As mentioned in clause 2, a RILEM Recommendation based on work within a joint CIB/RILEM Committee was published in 1989 [3]. The document outlines a systematic approach or methodology for service life prediction of building materials and components. The methodology is said to include the identification of needed information, the selection or development of tests, the interpretation of data and the reporting of results. It uses an iterative research approach, thereby permitting improved predictions to be made as the base of knowledge grows. Mathematical analyses needed for prediction of service life are not described in detail, but either deterministic or probabilistic analyses may be used.

The RILEM Recommendation is intended to be generic, and therefore applicable to all types of building materials and components. Specific test methods and test equipment will vary with the materials or components to be evaluated and with the user requirements, and therefore are not included in the document. The Recommendation has been used as a basis for the development of the IS0 Draft Standard [5].

In the Japanese Principal Guide [4] it is mentioned that various principles for the prediction of physical service life has been proposed. Some national development and standards are mentioned (US, France, Australia, Japan), along with the work of joint CIB/RILEM Committees. It is stated that the system for service life prediction used in the RILEM Recommendation is based upon the same principle as used in the Guide.

In 1992, a national standard for determination of durability was published in the United Kingdom [6]. In the standard it is stated that a designer needs to have information on durability to meet the building owner's requirements and to develop a rational policy for the durability of the whole construction. Further, some statements are made saying that prediction of durability is subject to many variables and can not be an exact science. Prediction of service life will normally apply to components and small scale assemblies. Whole buildings and large assemblies are more often one-off designs which make previous experiences of durability less relevant and because of their size it is less easy to test their performance under controlled conditions. In cases where the prediction of service life can not be very accurate, it may nevertheless serve as a useful purpose when items are being ranked in order of durability.

A comprehensive study on methodologies for predicting the service lives of coating systems has been published by Martin et.al. [7]. They present a set of criteria for judging the adequacy of any proposed service life prediction methodology. These criteria include the abilitv to

1. handle large variability in the times-to-failure for nominally identical specimens
2. analyze multivariate data
3. discriminate among these variables
4. fit both empirical and mechanistic failure models to short-term laboratory-based exposure results
5. establish a connection between short-term laboratory-based and long-term in-service results
6. provide mathematical techniques to predict the service life of a coating system exposed in its intended in-service environment

A RILEM Report on durability design of concrete structures has been edited by Sarja and Vesikari [8]. They present a discussion of what they call durability models. These models may be called degradation models, performance models or service life models. The authors have identified the following needs for durability models:

1. technical material development
2. ecological evaluation of materials
3. network level management systems for the maintenance, repair and rehabilitation of structures
4. planning of project level repairs
5. risk analysis of important structures
6. design of a material mix and quality assurance at the construction site
7. structural durability design

In relation to the development of an IS0 Standard for service life prediction, Bourke and Davies have published, a discussion paper on service life prediction [9]. They present a list of essential and/or desirable characteristics of a service life prediction system. No definitive list exists, and the characteristics will be more or less important. In a discussion of advantages and disadvantages of alternative approaches, the authors give the following evaluation of coefficient factorial systems:

Advantages

- recognise the effect of combined deteriorating factors
- permit flexibility as the model can be. developed along simple or complex lines

Disadvantages

- value judgements will still need to be made relating to the relative importance of each deteriorating or protective factor, and guidance on this may not be available
- precise mathematical impact of the adjustments may imply a greater level of conficence in the judgement than the data available would warrant
- unless fairly definite limitations on the number of factors are adopted the process could become very long and complex, reducing its appeal

4 Evaluation of the Factor Method

4.1 General

Up to now there is very little experience from use of the Factor Method as proposed in the IS0 Draft Standard [5]. This is also easily explained for two reasons: the method itself is not much known, and there is a lack of input data for the reference service life (RSL) and for the various factors. If the Factor Method is published as a part of the IS0 Standard for service life prediction, there is a strong need for further evaluation of the method. In the short range, there is need for input data both for the quantification of RSL for various materials and building components, as well as for figures for the various factors in equation **(1).** In the long range, it will be necessary to carry out a more comprehensive evaluation of the Factor Method and the possible quantification of the RSL and the different factors used. The method should be evaluated in relation to the general requirements to service life prediction models as explained in clause **3.** Here are only briefly mentioned some items which ought to be further evaluated.

4.2 Estimation of the reference service life (RSL)

Different methods exist to estimate RSL. The simplest way is to make a guess based on experience and knowledge of actual circumstances including choice of materials and components, climate exposure conditions and maintenance. Alternatively, more specific procedures can be used including various types of testing or statistical data. The most precise procedure for determination of RSL today is the use of the RILEM Recommendation [3]. However, this is also a rather laborious procedure.

Irrespective of the procedure used to determine RSL, it is most important to know what amount of information which has been put into the actual figure. It is important to establish a most general value, and not to incorporate more specific, local experience related to e.g. workmanship, climate conditions and maintenance procedures, since this will be handled by use of the various factors of equation (1).

4.3 Important factors

In equation (1), 7 factors are used to describe various conditions which need to be taken into consideration. These are meant to cover all relevant aspects in a service life estimation. However, in each specific case it will be necessary to ask what are the important factors which can influence the service life of a specific material or component in a specific application. This gives the opportunity to include conditions and factors which have a concrete influence on the service life.

4.4 Necessary number and type of factors

In equation (1), each factor is given by one single number. In the Japan Principal Guide [4] however, in many of the examples the various factors are explained in more detail by splitting into a more specific description of each factor. This gives the opportunity to include specific conditions which are regarded to be of importance for the value of each factor.

4.5 Use of the factors in an equation

In equation (1), the factors are simply multiplied to give one total figure to be multiplied by RSL. However, based on experience or a physical description or interpretation of each factor or the relations between the factors, it may be more correct to combine the factors in alternative ways. Such examples are shown in the Japanese Principal Guide [4], where factors or groups of factors may be multiplied, added or divided. As mentioned in clause 4.4, a more varying use of the factors will contribute to a more correct description of the influence of each factor. On the other hand, it will be necessary to have a defined combination of the various factors and subfactors in order to treat the materials and components in a harmonized way.

4.6 Reasonable span of the values of the different factors

In some examples using the Factor Method in the IS0 Draft Standard, the figures for each factor are varied within the interval 1.0 ± 0.2. In fact, the values 0.8, 1.0 or 1.2 are used. In practical situations, it may be necessary to use other values. The value to be used for each factor has to be based on an evaluation of the statistical variation of the parameter expressed by each factor. The value of some of the factors can vary several hundred percent, and the extreme values can be strongly asymmetric compared to the "neutral" value 1 .O. E.g. this is found for wood materials, based on data from practical use (effect of paint or impregnation, panel profiles, wall construction, etc) [10], [11].

4.7 Relative importance of the factors

As mentioned in clause 4.5, the factors may be combined by multiplication, addition or division. Further, in clause 4.6 it is shown that the value of a factor can vary within hundreds of percent. Altogether, this may give the necessary freedom for variation of the factor values. However, an other way of varying the factors may be to weigh them relative to each other. This can be an alternative way of combining the factors and to express their interrelations. Exponents can be used for the simple factors shown in equation (1), or in more sophisticated expressions as explained in clause 4.5. Use of weighing factors may be of interest in a future refinement of the Factor Method, when more input data and experience with the method has been achieved.

4.8 Uncertainty of the factors

The values chosen for the factors of equation (1) are not exact figures. They are based on experience or probabilistic data, and will in fact have some statistical distribution. It will therefore be necessary to develop some statistical distribution for each of the factors, and a calculation has to be carried out to see how the single distributions altogether can influence on the total outcome of the estimated service life. Due to the multiplication of the factors, the total result is quite sensitive to variations of each factor. As an example, it can be shown that an increase of each factor by 10 % will increase the estimated service life by approximately 100 %, whereas a decrease of each factor by 10 % will decrease the estimated service life to approximately 50 %. However, consideration has to be made on the probability distribution of the final value of the estimated service life. This example also illustrates the necessity of deter-mining the value of each factor as good as possible. Some preliminary studies are being carried out to see how statistical methods can be used to estimate the most reliable mean value and variation of the different factors of equation (1).

4.9 Factor dependency on material or component to be evaluated

When choosing values for each of the factors in equation (1), it is necessary to regard the actual material to be evaluated. E.g. for choosing a value of the factor describing an external coastal climate including sea spray (factor F), it will be important to difference between reinforced concrete and wood. For the first material, the climate mentioned will cause a reduced factor, whereas for wood material the salt exposure probably will cause an increased factor. Similar relations between materials or components and factors may be caused by a specific design of a component or a building, or by a specific indoor climate.

4.10 Important considerations for practical use

As briefly shown in the clauses above, there are several aspects to be taken into consideration when using the Factor Method. The final description of the method and the expression of the equation(s) to be used, have to be a compromise between many requirements and wishes. The method to be published in a standard should be regarded in relation to the aspects shown in figure 1. If the potential users are not convinced that the method covers these aspects to a sufficient extent, it will not be used

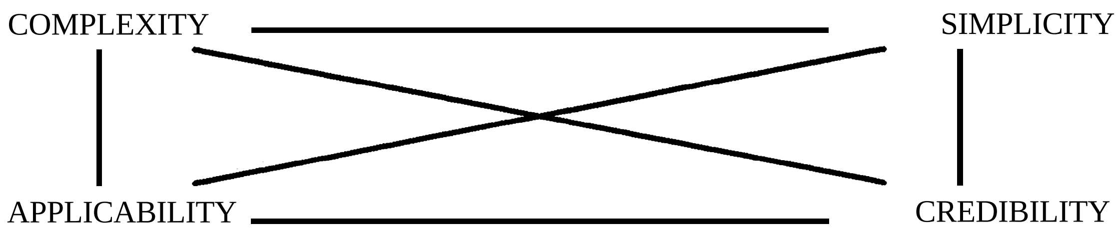

Figure 1. Relations to take into consideration in evaluation of the Factor Method.

5 Conclusions

Over the last decade, there has been an increasing interest of and need for tools to determine service life for materials, components, constructions and buildings. Some comprehensive studies have been carried out regarding service life of specific materials or products, e.g. concrete, metals and paint. An outcome of this work has also been general requirements of methods for prediction or estimation of service life.

The Factor Method has been introduced in an IS0 Draft Standard as a tool for estimation of service life. The method has gained specific interest over the last years, but little experience has been gained by use of the method so far. The discussion in this paper has shown that there are several aspects of the method which need to be further evaluated, in order to achieve a method which is sufficiently reliable and user-friendly. There is also a great need for input data for various materials and components in order to use the method.

More studies are going on in order to develop the Factor Method further, or to get more experience with the method. Such work will be carried out within the joint CIB W80/RILEM-SLM group “Service life methodologies” until the year 2000, or in national projects related to specific materials (concrete, wood) or buildings.

Acknowledgements

The work has been sponsored by the Norwegian Research Council. The author wants to express thanks to members of the CIB W80/RILEM-SLM group “Service life methodologies”, ISO/TC 59/SC 3/WG 9 “Design life of buildings” and to colleagues for important information and interesting discussions in the evaluation of the Factor Method.

Necessary measures to reduce construction waste in Egypt: A model for developing countries

0. E. K. Daoud
Management of Construction and Contracts Department, Dar Al-Handasah Consultants (Shair & Partners), Cairo, Egypt

Abstract
In order to attract foreign investments and increase industrial production, the Egyptian government initiated the construction of some 20 new cities around the old urban centers. Numerous tourist villages were constructed along the coasts of the Mediterranean and the Red Sea to attract European tourists and Egyptian holiday makers. Most of the construction activities that took place in these areas, used traditional methods of construction and traditional materials. As a result of poor construction practices, thousands of tons of construction waste is now polluting these areas which were once virgin environment. Reducing this waste is now a necessity in order to maintain these areas for the coming generations. A national policy should be established so that all concerned parties are aware of the consequences of construction waste and its impact on the environment. This policy should require modifications at the design stage, by adopting new materials that produce less waste during construction, as well as changing the construction methods in order to reduce the waste. Such a plan should not blindly adopt environmental measures taken in the developed world. Third World countries have different priorities in dealing with waste management. A successful policy will recognize this fact and deal with it realistically. Waste reduction in Egypt can be achieved through proper application of quality control measures, accurate estimation of ordered materials, and changes in the traditional design and construction procedures. Applying basic engineering practice, such as thorough geotechnical and geological investigations, will help to avoid constructing new developments on unstable soil, and hence avoid waste.

Training of professionals and technicians and generating a common interest in environmental protection and preservation is essential. It must be recognized and accepted that successful construction projects are those which are not only cost effective, but also less damaging to the environment. This paper looks at the sources of construction waste in Egypt, proposes methods of reducing waste and examines the role of the construction team and authorities in adhering to this policy in all forthcoming projects.

Keywords: Construction waste, concrete, design, building materials, environment protection, training, recycling, developing countries.

1 Introduction

In countries undergoing ambitious development plans, decision makers, are often more concerned with the immediate results than with the long-term outcome. Many of the environmental problems facing the world now could have been avoided had decision makers 50 or 60 years ago been well informed of the consequences of the huge industrial and construction boom that followed the end of the Second World War. Developing countries are going through the same fate now. It is necessary at this stage to sound the alarm to avoid repeating these mistakes.

The developed world has realized the serious drawbacks of having millions of tons of construction waste accumulated over the years. Hence, serious steps were taken towards reducing this waste. These are normally classified under one of the following:

- Increase the use of recycled materials in the construction industry.
- Order more accurate quantities of construction materials to avoid waste.
- Issue environmental legislation banning haphazard methods of waste treatment.
- Observe the strict application of the environmental protection laws by both governmental and public bodies.

In the Third World, the above steps are difficult to implement due to high cost and the more imminent problems that overshadow the environmental protection issue. This paper presents the experience of Egypt as an example to a Third World country suffering from this environmental problem.

In the past decade Egypt has promoted the creation of new urban and suburban communities in undeveloped areas around Greater Cairo, the north coast of the Mediterranean Sea, Sinai Peninsula and the Red Sea shore line. These communities serve as industrial, residential and recreational facilities to replace or supplement the over crowded facilities in Cairo and Alexandria and to open new opportunities for the Egyptian tourist industry. As a result, an unprecedented construction boom has occurred in these areas to meet the current and future demands.

Initially, these projects, especially those in the new cities, were constructed by contractors from the public sector under the supervision of the Ministry of Reconstruction and New Communities (MRNC). Consequently, a certain degree of control was imposed on the construction waste. A recent trend is to encourage the private sector to participate more positively in the construction works in these communities in order to foster competition to benefit the market and the end consumer. Since the private sector is inherently motivated by profit, the damage to the environment caused by the construction waste may be escalated. Many of the projects built in the new cities were developed using traditional design and construction techniques. As a result, many suffered from the traditional problems of poor quality of concrete works and finishes and leaking drainage systems and roofs encountered in the urban areas of Egypt. Construction waste and its effects are problems that require immediate attention, not only to reduce unnecessary cost, but also to preserve and protect the environment in these new communities.

Construction waste increases the cost of a project through the additional cost of transporting the surplus material to and from the construction site, and the cost of repairing the damage caused to the environment by the waste. The later could be quite expensive and should be accurately evaluated. This paper proposes an approach to reduce the construction waste and the damage it causes to the environment.

2. Sources of construction waste

The construction industry is based on team effort. Unless this team is well led, control will be lost,, leading to poor performance. Also, the construction process is a chain of related activities, and a defect in one may adversely affect successive activities and could result in redundant or defective work. This might require the demolition and reconstruction of the defective elements thus resulting in construction waste, delays and additional cost.

Some of the traditionally used materials produce excessive waste during construction. Bricks, for example, produce a large amount of waste due to broken units resulting from transportation, left-over materials and spoiled components during plaster application. Also, traditional formwork with wooden strips cut to fit the required dimensions for cast-in-situ concrete, may soon be spoiled and could not be easily adapted for other uses.

Chemicals newly introduced to the construction industry require special storage methods and have strict expiration dates. These materials, if not handled properly, can produce dangerous waste detrimental to the environment. For example, concrete admixtures, epoxy adhesives, paints, solvents and waterproofing compounds are now commonly used. Due to the remote nature of the sites of new cities, the contractor may be tempted to store larger quantities of materials to avoid shortages in supply. Surplus chemicals and chemicals that have exceeded the expiration date may be dumped on or near the site to save transportation costs. Oils and lubricants resulting from the maintenance of equipment used in road construction and land moving are normally dumped on the surrounding land. It is also common to bum rubber tires to melt bitumen for waterproofing work. Waste is also generated due to over estimation of the quantities of a required material. This is quite common when working with cast-in-situ materials. All this will create waste and hence pollute the environment.

3. Current methods adopted to deal with construction waste

Currently, the methods adopted to deal with the construction waste in the new cities and holiday resorts in Egypt are both primitive and damaging. In most of the cases, waste is dealt with through a waste remover, who is assigned by the contractor to remove the waste from the site. The contractor, the engineer and the project owner normally do not monitor the method of waste disposal. This allows the waste remover to use a variety of dumping methods regardless of their long-term impact on the environment. Often, this waste is used as a landfill material to level depressions in the natural grade profile. This can have costly or problematic consequences, if the backfilled land is used for construction works or some other uses in the future. It can also pollute the environment if the dumped materials are not inert. The effects of such practices on underground water and on the wildlife are detrimental.

4. Methods to reduce waste during the design stage

Waste reduction should be considered during the training of engineers and technicians involved in the construction industry. University education and short courses should offer a focused study of this topic for both students and professionals. Manv countries in the developed world have recognized the link between engineering system demands and environmental protection. This topic is introduced here at a project level, to be used as a model for Third World countries.

4.1. Documentation

The project contract should include specific provisions requiring the contractor to plan his site activities in such a manner to reduce waste. These requirements will form part of the quality assurance program to be implemented by the contractor under the supervision of the engineer This can be achieved through the following:

4.1.1 Contractual obligations

It is advisable to insert clauses in the Contract Conditions which obligate the contractors to preserve and protect the environment under threat of significant legal and financial penalties. It should be required that debris and construction waste be *properly* disposed of in licensed dumps. The contractor should be required to submit with his bid, his plans to minimize waste during the construction period and the method used to transport and dispose of any waste. The owner should review the tenderers' plans before awarding the contract. A tenderer, with the lowest cost and in full compliance with the technical and contractual requirements should not necessarily be awarded the contract if his proposals for environmental protection are not adequate. This is a major change in the traditional evaluation of tenders which requires strong support from the government. The authorities should be the first to apply this concept to establish a standard for by the private sector as well.

4.1.2 Site layout plan

One of the important submissions by the contractor during the mobilization period is the Site Layout Plan. This plan shows the location of temporary works and the land-use intended during the construction period, so that these facilities will not conflict with the permanent works. The temporary facilities shown on the plan should include the site storage areas, waste collection points and dumping yard. The engineer's review of this plan ensures that the contractor has planned efficiently to deal with the construction waste resulting from his work. If the engineer is not convinced of the efficiency of these plans he should reject them and insist on their modification to ensure proper environmental protection .

4.2 Materials selection

The utilization of prefabricated materials rather than in-situ fabrication will reduce the construction waste. This pertains to many aspects of architectural and structural works. The following examples illustrate this concept.

4.2.1 Waterproofing system

Waterproofing used in roofing systems was traditionally applied using an in-situ, built-up, multi-layer system of hot bitumen with reinforcing layers in between. Poor installation of such a system was found by Daoud and Abbas to be the reason for roof leakage in 600 houses in one project in Kuwait [1]. This was the only method available in Egypt until a few years ago. Gradually, prefabricated, modified-bitumen membranes, reinforced with non-woven layers of polyester or PVC, have been gaining acceptance in the market. Four years ago, one or two suppliers were providing this system for a limited number of projects. Now, more than ten suppliers dealing with imported materials from neighboring countries or Europe. Prefabricated membranes have many advantages over the built-up membranes since they have even thickness, require less skilled labor to lay, produce less debris, have consistent quality and can be applied faster. Also, the material is delivered in rolls of known length and width, hence fairly accurate estimation of the needed quantity can be made with minimum surplus or waste.

In-situ built-up membranes are easier to install around openings and are less expensive. However, considering the harsh environmental conditions such as high temperatures and sand storms in Egypt which may prevent adequate supervision during material application, prefabricated membranes will reduce the likelihood of defects in the waterproofing layer. This will reduce waste through minimizing the possibility of defected application or damage to underneath works due to leaking water.

4.2.2 Internal partitions

Traditionally, fired-clay brick walls were used for internal/external partitions in Egypt. Until fifteen or twenty years ago, this was the most commonly used material for this purpose. Concrete blocks, sand-lime bricks, lightweight-foamed concrete and other types of blocks became available due to the prohibition of using clay cut from cultivated land for the purpose of producing bricks. Almost all residential dwellings are built using reinforced concrete skeletons with unit blocks used only as infill. Damage to five percent or more of the blocks is normal during transportation and handling. This can increase to ten percent for extended transportation to new cities or to 25percent for certain types of blocks, such as concrete blocks, or due to double handling. The waste in brick work was found to range from 11 to 23 percent in Brazil, which is typical of developing countries, while waste in the Netherlands was only six percent [2]. Construction of block walls can be quite messy during mortar mixing and application, producing large amounts of waste. Furthermore, these block walls impose additional loads on the concrete structure which results in heavier elements at higher cost.

The use of lightweight partitions made of gypsum boards has gained acceptance in the USA and Europe. A few hotels and office buildings in Egypt have been built using this system. The system is less popular in residential units due to sound transmission. However, board partitions are lighter in weight which reduces the total load on the foundations, easier to control during construction, require no plastering work due to accurate alignment, produce less debris, do not require highly skilled labor for installation and require less labor during construction. Furthermore, the leftovers can be recycled, however, this is not feasible yet in Egypt since recycling will be quite expensive. Like all prefabricated elements, the quantity required for use can be accurately estimated to reduce the cost of transportation and waste resulting from surplus materials.

Due to their poor resistance to forced entry and, relatively higher sound transmission, lightweight partitions should be limited to internal partitions in the dwelling. A sound insulation layer of mineral wool can be inserted in the cavity of the dry partition to reduce sound transmission. The poor resistance to moisture was another disadvantage of the system which rendered it unsuitable for bathrooms and kitchens. However, moisture-resistant boards are now available in the market and are gaining acceptance for use in wet areas.

4.23 Load-carrying system

As mentioned above, most of the structures built in the new cities and tourist villages are made of reinforced, cast-in-situ concrete skeletons. The use of such a system in these remote areas is bound to result in more defective elements than normally experienced in other construction sites. Due to the remoteness of the site, the engineer's supervision of contractor's work is reduced, as well as contractor's supervision of his laborers. As a result, defects in concrete skeletons are more likely to occur. The concrete will deteriorate at a fast pace due to its exposure to humidity and salts and will be costly to repair or replace. Beside the resulting debris, waste materials in large quantities are common with cast-in-situ concrete. In a study by Soibelman et al. [3], 12 percent of the concrete purchased in Brazil was wasted. The waste for cement alone was 46 percent while for sand it was 3 1 percent. These materials are normally dumped on the project site or on neighboring sites. The pollution of the Mediterranean Coast by discarded concrete is only one example of the possible damage caused during the construction of tourist villages.

The use of precast/prefabricated units produced in precasting yards ensure higher quality, less waste and less pollution. Using load bearing walls instead of reinforced concrete skeletons with in-fill walls will ensure more durable construction with greater resistance to the aggressive environment to which sea front structures are subjected. This may also be more cost effective and requires less time for construction. It is ironic that in many of the summer houses built on the northern shore line, limestone veneer from neighboring quarries is used to clad the external facades. It would be more practical to use this stone as a carrying element especially for one and two story buildings. Furthermore, load-bearing wall systems will produce less waste during construction since the surplus materials (blocks) are reusable elsewhere.

4.2.4 Recycled materials

It is advisable to consider the waste problem from an economic as well as environmental viewpoint. Economic benefits can be achieved if the construction waste can be recycled to produce fresh usable materials. This concept should be implemented by designers and enforced through the bylaws issued by the MRNC for the new cities. Until recycling is carried out on a large scale, the cost of recycled materials in Egypt may be uneconomical.

5. Methods to reduce waste during the construction stage

A wise contractor will do his best to reduce waste in order to maximize his profits. However, contractors who are accustomed to a certain way of conducting their work cannot reduce waste unless they modify or change these traditional ways of construction. Following are some examples of the sources of waste arising from the traditional construction methods, and the suggestions to reduce the resulting waste.

5.1 Concrete formwork

The traditional method of concrete formwork is used throughout construction sites for dwellings and residential apartments The sheathing is made by strips of wood, 10 to 15 cm wide, nailed together and jointed by clamps and nails. The shores are made of wood poles clamped together or tied with ropes. The wood not only wears quickly, due to its physical vulnerability, but it also results in considerable waste during fabrication [4]. The resultant pieces of damaged wood are normally piled on the site or burned. This formwork could be reused four to five times with good results, but often it is used more times to save on cost, which reduces the quality of the concrete surface requiring thicker plaster work and resulting in more waste.

Prefabricated formwork is made of plywood, metal, metal-framed plywood faced or other materials. Steel rods are used for scaffolding and props. This type of formwork is expensive, but is easier to use and adapts to different shapes. Furthermore, it can be reused up to eight times with continuous good quality. It is also faster to erect and dismantle, easier to store, and above all, produces much less waste. In projects with repeated units, prefab formwork can expedite the concrete production with consistent surface quality and savings in the cost of finishes.

5.2 Tight quality control

Construction waste can be reduced by adopting a quality control (QC) program to ensure the quality of the final product in accordance with the specifications. This will require implementing tight control procedures ensuring the quality of the end product and hence to minimize removing or replacing defective elements, wasted time, cost and unwanted materials. Unfortunately, this approach is not yet well recognized by many owners, consultants and contractors.

In the Third World, in general, project owners do not appreciate QC if it results in higher cost. Consulting engineers will not recruit specialist QC personnel because they are expensive; instead they often assign this responsibility to the least experienced staff member on site. For projects in new cities, contractors depend upon the fact that the site is remote and often assume that substandard materials and workmanship will go unnoticed. Hence, they lower their cost, at the expense of quality, to increase their chances of winning the contract. As long as these principles dominate the construction industry, and in the absence of government regulations to impose proper QC, poor quality will prevail, resulting in significant waste, surplus and unwanted materials.

6. General requirements for the Egyptian market

6.1 Training

Though McDonald claimed that site staff in Australia required little training to minimize waste [5], this may not be applicable in Egypt. Training programs for professionals and laborers involved in the construction industry are required to improve the standard of their work and reduce site defects and hence waste. This calls for a national scheme to be adopted by professional syndicates and labor unions. Training should concentrate on QC procedures, quality assurance measures, new trends in the construction business, modern management procedures and performance of building materials. Specialized training centers equipped and staffed adequately are needed to provide this service under the supervision of professional bodies and a national committee for advanced training. On-the-job training should concentrate on methods to separate waste for reuse, correct orders of materials to ensure accuracy, and in the future, separate waste for recycling. This could be achieved through regular site meetings.

6.2 Quality control of manufactured materials

Since many of the materials used in the construction industry are now manufactured locally, it is important to provide quality control during the manufacturing process. Consistent quality and adherence to acceptable standards should be maintained. Often local products do not satisfy these requirements and lead to abortive work in replacing defective elements and a waste of money and material. The development of appropriate local standards and well equipped laboratories should be encouraged. Translating foreign standards to be adopted as Egyptian standards is not practical and could be misleading: often these are poorly translated and out of date by the time they appear on the market. However, their is no harm in adopting valid foreign standards if appropriate to the local environment. The lack of well equipped laboratories to test these products would invalidate any attempt to apply QC procedures in Egypt. Several tests cannot be performed locally and samples must be sent to Europe for evaluation. This is not practical and is time and cost consuming.

6.3 Reduce tenants modifications

Many of the apartments constructed by the government are modified when their tenants move in. These modifications are due to poor quality of materials installed, unrealistic design that does not satisfy the tenants' backgrounds and, in a few cases, the need to distinguish one's self from the neighbors. Major reconstruction work would result in huge waste. It would be more economic to study these modifications and adopt them in new designs from the beginning or consult the tenants before finalizing the design.

6.4 Conduct comprehensive field survey

Since the new cities are built in remote areas, comprehensive geotechnical and geological studies are needed before the site is allocated for construction. This will reduce any possible waste due to removal of constructed facilities built on unsuitable soil. Several cases have been reported of construction of new cities taking place on questionable soils that suffer from serious defects. A whole city in upper Egypt (The New Minia) [6] and several neighborhoods around Cairo [7] could be removed due to cavities in the soil underneath or other soil defects.

7 Conclusions

The subject of reducing construction waste must be addressed in all construction projects and, in particular, those to develop new cities and seaside resorts. In order to avoid long-term damage to the environment, the current haphazard procedures of waste disposal used in inner cities should be avoided in new locations. It is the duty of all those concerned, including the government offices, local authorities, consultants and contractors to prepare a national plan addressing this issue. The environmental considerations are important criteria, not only during the construction stage, but also during the early planning and design stages. It should be understood that nothing is free. The owners, including the concerned governmental departments, should expect a higher initial cost as a result of these environmental measures. However, this cost should be weighed against the hazards to the future generations of these new communities if such measures are ignored or deferred.

8 Acknowledgment

The author is thankful to Dar Al-Handasah Consultants *(Shair and Partners)* for the facilities granted during the preparation of this work.

Abstract

A detailed study of the application of waste management to a single multi-million dollar residential project in Queensland is described. The study incorporates the assessment of a current on-site waste management operations plan and a questionnaire survey of the construction workers involved to ascertain their involvement and attitude towards the processes.

Keywords: Landfill, recycle, reuse, waste disposal, waste management.

1 Introduction

It is estimated that 13-30% of all solid waste deposited in landfills worldwide comprises construction and demolition waste[l] with a 1:2 ratio of construction to demolition waste[2]. In Holland, for example, this amounts to around 4.25 thousand million tonnes of construction waste each year. Insights into the causes of the generation of waste in construction projects are growing however[1][3] and waste management policies have been developed in Europe for example [4]. In response to increasing awareness of the environment, the Australian Government has established several strategies to implement ecologically sustainable development (ESD). One major arm of ESD is the National Waste Minimisation Strategy, which has set a target of a 50% reduction in waste, 15 % of which is from building and demolition work, going to landfill by the year 2000 based on 1991 standards.

This shift in social attitudes towards 'environmentally friendly' values together with the possibility of future state and local government legislation or taxation on the lines of the UK Landfill Tax[5] suggests that strict guidelines for commercial ventures will soon be introduced. In October 1997, the Queensland Government produced Proposed Waste Management Legislation Public Consultation Documents. As a result, it is becoming necessary for organisations to establish some form of environmental management system.

Previous studies in this field suggest that high rates of success may be obtained by implementing waste management strategies in the construction industry. Other defined benefits include financial gains, through the sale of salvaged products or reduced disposal costs, and environmental benefits[5][6][7][8].

This paper reports an investigation of the current Waste Management Strategy implemented by a major Australian contractor (1) to determine the efficacy of the strategies in use, and (2) to evaluate the practicality and desirability of further developments.

2 Casestudy

2.1 The project

The researchers studied the waste management methods employed by a major Australian construction company and their operation on one construction project in the Brisbane area of Queensland. The project was a Brisbane inner city apartment project, completed in October 1996. Access to the site did not present any problems for coordinating through traffic, as the site was located at the end of the local traffic area. The construction works consisted of two (2) residential towers of five (5) stories each featuring high quality apartments, underground car parking and landscaped surrounds. A permanent crane established centrally serviced both towers. Throughout the site were designated lay-down areas for the storage of goods, site accommodation and waste bins as required.

The project served the purpose of being a pilot project for the contractor in regards to waste management. It was intended to provide a comprehensive trial of waste management procedures and did so successfully. There were several features of note: no previous data or information was available to draw on; personnel were unaccustomed to waste management procedures; there were restrictions on labour availability and time; and there was no material hoist on-site which limited the capacity of handling segregated waste containers. In addition, the contractor had already commissioned and received a consultant report for a Waste Management Strategy for a recent brewery project and the principles noted in this report were also implemented on the case study project. These issues concerned: bin positioning, use and identification; the workers induction program; the provision of a list of local recyclers; and the collection of statistical information.

The contractor drafted a Waste Management Plan (WMP) clearly defining its policy, staff responsibilities and procedures to be adopted and designed to meet and exceed the company's current obligations under the Environmental Protection Act 1994. Although some guidance was provided to develop ways in which to avoid or minimise waste, no specific guidelines were established in work process optimisation, material planning, on-site training and methods of effective and efficient reporting of waste quantities.

The Project Manager correlated the trades represented on the program with the major waste streams, to establish which products presented an opportunity to recycle. Anticipated wastes suitable for recycling included concrete, masonry, timber, metals, and plasterboard. Other waste not suitable for recycling and disposed of as general waste incurred normal disposal charges. In the event that any unacceptable contamination of waste occurred, and disposal at the Brisbane City Council transfer station was required, an additional charge of $55 per tonne was incurred. Hence, handling methods were considered crucial to the effective disposal of waste with the aim of maximising recycling to benefit the environment and reducing disposal costs.

2.2 The waste contractor

A specialist waste transportation firm was commissioned for this project. On this project the specialist's primary responsibilities included the provision of waste collection bins and labelling of the bins to suit the waste streams identified in the contractor's WMP.

Early negotiations with the specialist enabled the planning of suitable methods of disposal of various waste streams and allowed the setting of a fee scale depending on the items removed. The contractor's WMP stipulated that waste material could become the property of the waste removal contractor on collection from site, and that any rebates paid on recyclable products should be made to the account of the waste removal contractor.

The task of monitoring was delegated to the specialist waste handler and included data collection and the subsequent collation and analysis. The driver of the waste bin service truck was responsible for determining where the waste was to be delivered to and whether it was contaminated or not. If the waste was considered to be contaminated the site supervisor was informed and asked to co-sign the delivery docket to indicate agreement that it was contaminated and would be unsuitable for recycling.

At the point of pick up the driver recorded the date, bin size, waste product type and the place of disposal. This method of data collection produced only approximate results. There was concern about the accuracy of data available for this study because of the lack of awareness by drivers of the type of product to be collected and where it was to be disposed.

The waste analysis undertaken by the waste specialist for the contractor provided a month by month breakdown of wastes removed from site and information regarding the specific waste streams targeted for separation and recycling. Calculations were based on weights and provided monthly and cumulative totals and percentage ratios of the respective wastes.

2.3 Site observations

During the course of the project several site visits were conducted during which observations and general conversations with site management were noted. Some of the more important discussions covered waste types, waste handling methods, programming, project types, cost implications, education and human influence on waste management. Observations made in relation to waste management during site visits noted signs and notices, bin contents and waste handling procedures, control issues and site layout.

The waste handling method on-site began at the work area, where wastes were stockpiled and then removed by labourers daily into a small collection bin suspended by the site crane at the edge of the working deck. The crane was used for approximately one hour per day to carry out this clean-up operation. Discussions indicated that this method of waste collection must be analysed closely prior to implementation, to ensure that a particular type of project was compatible with waste handling methods proposed.

Disposal of the four key material types were analysed in detail:

Timber. The majority of timber waste was generated during the formwork process. Primarily, waste occurred from work undertaken on the materials to make them suit the required shape and size of the formed concrete, and due to rough stripping methods. Good planning by the subcontractor to m&e formwork 'fit' with minimal modification and better care during the stripping of formwork would have contributed to reducing waste. Waste timber products generated by formwork were deposited into bins at the work area since there was easy crane access to place bins onto the working platform. So a high proportion of material could be separated for recycling. Problems included the careless contamination of timber with foreign substances such as masonry or other waste at the ground floor level. The whole load of timber then became non-recyclable and forced the waste contractor to dispose of large quantities of timber waste as general waste.

Masonry and plasterboard. These were used for partitioning works. During construction, a majority of the masonry blocks ordered and used were standard sizes available from the manufacturer, consequently waste was avoided to a large extent. Waste during construction occurred when blocks remaining from various work areas were left over and no effort was made to collect and use them elsewhere. Often these were simply disposed of during clean up. Other minimal waste occurred through broken blocks or due to unusable off-cuts. Plasterboard was susceptible to damage both during handling and also once in place. Planning of sheet sizes required at various stages during the project minimised waste and was carried out by the Project Manager in conjunction with the plasterboard subcontractor and plasterboard manufacturer. Although a bin was provided to receive concrete and masonry waste, no materials of this type were successfully separated. All concrete and masonry waste on this site was disposed of as general waste. Plasterboard waste was collected in stockpiles near the work areas. During the clean up process, the waste was deposited into suspended crane bins as described for metal products. Due to the large volumes of this material segregation was relatively simple. Therefore a substantial amount of plasterboard waste was successfully separated. No recycling opportunities existed for plasterboard on this project, as the manufacturer did not have the facilities to reprocess this product. However, as plasterboard was classified a potentially hazardous waste by the Brisbane City Council and required disposal at special landfill sites, the isolation of this material reduced disposal costs.

Paper Products. A large amount of paper packaging of goods on-site had to be appropriately disposed of. Packaging itself was not significant during the product use phase as it was generally intended for disposal and acted as a protection to goods during handling. Paper products derived from packaging were to be deposited into a bin provided by ***Visy Board*** at the ground floor. Again, sorting difficulties on each floor meant that very little paper products went into the designated bin and were mainly disposed of as general waste.

Metal. Metal waste was mainly derived from reinforcement, steel partition framing and roofmg off-cuts. Reinforcement waste was minimal and primarily resulted from miscellaneous spare items left after the completion of the works. Metal roofing waste was due to off-cuts and modifications made to sheet materials and flashings to suit roof penetrations and geometry. Metal stud waste was attributed to the requirement of size modifications to suit the application. The metal scrap bin was centrally located at the ground floor level between the two apartment buildings. At rubbish collection time, all refuse was collected into one suspended container at each floor level by the crane. Consequently loading work was hurried in order to minimise crane time, and various waste streams could not be sorted prior to placing in bins. Therefore, only large and easily separable metal waste was placed in the scrap metal waste bin. Valuable waste such as copper and aluminium was retrieved and taken off-site by the subcontractors and did not contribute significantly to metal waste. The remainder was disposed of in the general refuse bin.

Waste types contributing to a majority of the bulk refuse were plasterboard and formwork scrap. When building products were inexpensive, as was the case with plasterboard, little consideration was given to waste minimisation. In the case of formwork, which was not a cheap product and yet still produced high quantities of waste, the reduction of waste required closer supervision.

Human influence on the success of a waste management plan was apparent as it was the work-groups, which had the final control over the waste handling process. The introduction of Waste Management has been viewed in a light similar to Quality Assurance and Workplace He&h and Safety, which are now generally accepted but each required time before becoming completely effective. Generally, people were willing to contribute positively to the environment but it has been difficult to change habits and culture. During discussions with site management, it was mentioned that the younger generation seemed to accept waste minimisation readily whereas the older generation was a little more difficult to convince. Perseverance and continually updated training will, some would hope, influence construction workers positively in due time. Also of influence may be stricter contractual obligations with possible penalty charges for non-compliance. Alternatively, a system promoting a spirit of competition and enthusiasm using incentives may provide the appropriate motivation.

Colour coded notices were placed at various strategic locations on the site including lunchroom walls and the notice boards. However, the effect of waste management notices and signs was lost amongst other general information. Possibly, brighter displays isolated from general news and advertising bulletins may have attracted more attention. The notice itself was clear and easy to understand and should have served as a good reminder of the waste separation requirements established on site. The main waste bins had easily identifiable signs clearly displayed on the appropriate bins at most times. Occasional problems occurred with the correct labelling of the bins as the signs were removable and were shifted around when the bins were picked up by the trucks. All people involved should have taken greater care in handling the bins or depositing waste, to make sure the correct sign was clearly displayed.

Upon examination of the bin contents it became apparent that there was a general disregard for placing the rubbish in the proper bin. General rubbish contained materials that could have been separated with minimal effort. The difficulties of controlling waste segregation at all times became apparent during the distribution of the questionnaires around the site. Work was carried out throughout various areas of the project and workers were difficult to locate. Therefore, it was difficult for one person to oversee the compliance of waste separation and workers' attitudes were such that they could not be relied upon to monitor themselves.

3 Questionnaire survey

The key element in the success of a Waste Management program is the involvement, commitment and perception of construction workers on the project. To determine the influence of the key elements amongst workers, a questionnaire was prepared to obtain their general views regarding the principles of waste management and to obtain background information regarding their knowledge of the process. Seventy seven forms were distributed over the site during two survey periods, and a total of thirty nine were returned, representing a response rate of 51% .

In the staff group analysis, the belief that waste from construction works could affect the environment was generally high across all staff levels. Distinct differences, in the understanding of the waste management processes implemented on this site however, occurred between employees and senior site personnel such as leading hands / foremen and managers. Even though both groups had equal quality training, results showed a higher degree of comprehension among subcontract employees than site management. A conclusion which may be drawn from this is that the lack of interest by leading hands and foremen reflected in their disregard the WMP, as they do not consider it a vital component in producing their work cost effectively.

Analysis of various trade groups showed that a majority of subcontract employees considered that they were supervised for less than 25% of the time. Awareness of environmental issues by major waste producing trades was high indicated by the 85.7% understanding that building waste affects the environment, and a 61.9% belief that waste products from their particular trades could be recycled.

For the major waste producing trade of plasterboard, the education and knowledge segment of the questionnaire indicated only an intermediate level of understanding of the waste management process. This result indicated that the subcontractor’s personnel accepted little personal responsibility for waste disposal. Furthermore, a large portion of the plasterboard trade indicated that they had not received any training in waste management. In contrast, a high percentage of the masonry trade indicated that they had an understanding of the waste management process and that it was explained to them. Even though waste generation within the masonry trade was minimised through efficient ordering and material use, the nil success rate indicates that improvements could be made. Perhaps accountability and clean up supervision needs to be upgraded for this trade. Other trades indicated a higher level of understanding of the waste management process. However, the survey showed that part of the plumbing trade group felt that the explanation of the process was not comprehensive enough. Possible explanations for the apparent poor comprehension of the waste management process on this site could be attributed to lack of interest during the site induction, poor recall and low understanding by the workers or because the waste management segment was not presented clearly during the induction process.

Overall, the correlation between the proportion of waste produced by the various trades and the levels of supervision, awareness, knowledge and perception was inconclusive. However, there is some indication that poor results in the plasterboard trade were due to a lack of understanding of the WMP.

The open parts of the questionnaire sought to attract suggestions and comments regarding waste reduction and separation. The results indicate that waste segregation procedures were followed early in the project but that methods became lax as the project proceeded. The comments suggested that to sort rubbish at the point of creation would require more bins which must be clearly labelled and available on each level. It was suggested that additional time should be allowed for clean up and that clean up supervision should be provided at set times in various areas.

A problem that was envisaged with the method of segregating waste at the point of creation concerned the space needed for the various bins required on the working platform. This suggestion however is debatable as waste stockpiles around the work areas consume space and space requirements for a bin are less than for a stockpile of rubbish of the same volume. Also, mobile bins enable better handling of the waste at clean up time and can be moved if they get in the way of works whereas a stockpile of rubbish requires a somewhat greater effort to be moved.

The facilities indicated as being required included more accessible bins and clearer marking on those receptacles. Also mentioned was the requirement for more effort and common sense by the workers on-site and that this be promoted by additional training.

The question of reducing waste was interpreted in two ways, the waste creation process and the waste disposal process. The waste creation processes highlighted the need for an increase in workmanship skills, tighter ordering procedures and reduced packaging. These were previously mentioned as key factors in reducing waste by prevention. It is obviously an area that subcontractors and manufacturers should address and, if done properly, could have financial benefits.

The waste disposal process indicated the requirement for more accessible bins to assure better waste separation to allow recycling. Also noted was the fact that the subcontractors often took financially viable scrap waste home, which resulted in a reduction in the amount of waste on site but with little value remaining in the segregated products. For example, the contents of the metal scrap bin mainly consisted of scrap steel of minimal value.

4 Conclusions

The results of this case study suggest two key criteria, training and process optimisation, for the success of a Waste Management Strategy on a construction site.

Training. Site training of the workers is considered as the key issue to ensure the operation of a successful waste management program on site. The survey of workers indicated that on site training was carried out and a high percentage of the workers understood the procedures. Some indications were given that training in the procedures of waste management were not comprehensive enough and that there may have been a lack of interest during the induction process and that poor comprehension and recall may also have attributed to a lack of commitment to the process. It is suggested, therefore, that training includes a more detailed explanation of the processes during the induction with an emphasis on getting the worker involved in the process and encouraging self monitoring by highlighting the benefits of the program and the way in which the worker can contribute. Finally, to conclude the induction, a worker could be asked to complete a brief questionnaire and sign a declaration of understanding.

Process optimisation. The process of waste handling is seen as a critical issue in that it affects the overall costs of the system and has a large bearing on the success of the program. Costs can be minimised by reducing handling time and labour, and the best way in which to achieve this has been determined to be waste separation at the point of creation. Although training can encourage participation by the workers in the program, site facilities must be provided to ensure success and the site itself must be suitable for the program. To facilitate the best results bins should be placed near the work areas and should be suitably tagged. Workers then have the opportunity to place waste directly into bins thereby eliminating the need for a labourer to carry out this work. The resulting reduction in waste handling, time and effort as well as encouraging workers to keep a cleaner and safer work environment should lower costs. To facilitate this outcome the waste coordinator should conduct an analysis of the site conditions and the wastes derived to determine the most appropriate methods.

A program forecasting waste streams should be developed by the waste coordinator. This forecast will enable the arrangement of a suitable waste handler and the appropriate main waste bins. Where no waste recycling facilities exist, waste should be deposited into general waste bins.

To monitor the progress of waste management on-site data should be collected regarding the waste types and quantities removed from the site. Thus, the early detection of any problem areas can be identified and the dependence upon data from the waste contractor reduced. This data can then be analysed by site administrative personnel as shown in previous sections of this report.

Waste avoidance and reduction were identified as the most beneficial methods of waste management on a construction site. Waste management requires the cooperation of the builder and the subcontractor to plan material requirements and allow adequate and safe material handling and storage on-site.

INIES - A framework to compile information on building products' environmental quality

JF Le Téno, JL Chevalier, M Rubaud
Centre Scientifique et Technique du Bâtiment, Materials Department,
St Martin d'Hères, France

Abstract

INIES is a set of grids intended to document building products' environmental quality (EQ). It is based on a merging of life cycle analysis (LCA) and risk analysis (RA) into a semiquantitative approach. INIES provides general information on EQ as it is available and gives status indications according to the RA steps (hazard identification, risk assessment and risk management).

INIES has been developed and successfully applied within the context of a large scale public funded project involving many types of actors in the construction domain and it is now being experimented as a basis for the introduction of products' EQ information in French construction standards and technical assessment procedures.

Keywords: Life cycle analysis, risk analysis, qualitative, environmental quality, INIES.

1 A view on LCA from theory and practice

From our experience of the theoretical and practical aspects of environmental quality (EQ) evaluation on all types of building products with various partners like manufacturers, general contractors, architects, public bodies, professional associations, etc. we have learned that products' (and buildings') EQ are viewed as a risk of non conformance to legal standards and societal demands.
The true question asked is to get insights on the environmental and sanitary risks associated with building products and how to manage them.

1.1 LCA as a tool for risk assessment

Life Cycle Analysis (LCA) has now become a classical tool for product environmental quality (EQ). According to the new IS0 framework for LCA [1], LCA is defined as an iterative improvement process undergoing the following steps (called "elements" in IS0 language) :

1. Goal and scope definition
2. Inventory analysis (LCI)
3. Impact Assessment (LCIA)
4. Interpretation

In practice, claims for a simple list of "green products", "preferred products", etc. are commonplace. We interpret them as an expression of EQ conscious actors' anxiety and willingness to get quick answers to their question, because they feel like they lack a conceptual framework encompassing also their usual points of concerns like products' technical capabilities and costs and also their legal, social and cultural context.
This is a particularly prominent point when dealing with building products which are intended to be included into a building, i.e. a living and lived-in complex context.
Also, practices like restriction of inventory boundaries to a minimum, not performing impact assessment, and devising "translation" schemes to get simple synthetic results out of multiple-pages ecoprofiles – like [2] for example, may be interpreted as a tentative reorientation of the current LCA model towards actual and practical points of concern.
On the theoretical side, as discussed in [3], subjectivity takes an increasing importance as an LCA progresses through its elements.
In our opinion, the root cause is that, in the meantime, the LCA is moving closer to the complex outer reality of interwined natural and industrial ecosystems and actors – which is what incidentally triggers the intrusion of subjectivity. This should not be a problem providing that all claims for absolute, definitive and numerical values of a product's EQ are abandoned [4], but this point is only beginning to make its way into the LCA theorists' community. This is illustrated in a recent paper from [5], for instance.
Hence the biggest problem with using LCA to answer building products EQ questions is the widening gap between its outputs – and time requirements, and the complex and broad context of the reality in which some kind of decision-making is taking place and is calling for insights on products' EQ.
Hopefully will the IS0 14000 framework gain increased recognition in the future and will provide this lacking framework. But it must be recognised that it is not a fact yet.
Also the IS0 14040's interpretation element should help putting all results back in perspective and integrating them into a global context for decision. But this element is

still in its early infancy and probably requires new concepts and tools, of which few have been proposed so far [6].

In our opinion, there are several reasons why the gap is currently widening.

The first one is that LCA is capitalising on old elements to move to new ones – from LCI definition to LCIA for example, thus constraining more and more its outputs' format and scope to a point where their usefulness for professionals can be questioned. Put simply, in some respects LCA is evolving as a independent science and seems to forget its initial targets in the process.

The second reason is that the claimed scope of LCA is comparatively wide with its actual capabilities. We do use LCA a lot, but we restrict this use to situations where detailed information are required to answer very precise questions; testing the pros and cons of a product manufacturing process change is a typical situation perfectly suited for LCA.

The third reason stems from the fact mentioned earlier that actors want a risk analysis of building products. As will be discussed below, this procedure is not exactly in the same line of thoughts as LCA.

1.2 Risk analysis

Risk analysis (RA) is a three steps procedure [7,8]:

- The first step is to perform a large review of the hazards implied. This is the *identification* step.
- The second step of RA is the *assessment* of the risk related to a given hazard, i.e. the production of a measure of its probability of occurrence and of the severity of its consequences.
- The third step is the *management* of the risks assessed at step 2.

One clear advantage of this approach is to make a separate task out of risk management issues. Indeed, some risks can be judged acceptable by some actors but not by others.

Although simplified numerical models exist for RA [7], their applicability to EQ problems seem inappropriate to us because EQ is not a technical issue only, but rather an ethical topic that will be openly discussed in not technically oriented communities and institutions as well as by engineers.

As discussed in [8], to successfully assess the risks of a problem with numerous stake holders and global implications like building products' EQ problems, the "minimal scope" is already wide enough and is outlined in Tableau 1.

[8] also gives recommendations for the presentation of the results in order for an RA to be successful – i.e. to actually provide usable answers to the questions asked. These constraints have mostly to deal with transparency on assumptions made, indications of possible bias, uncertainties and their consequences and of limitations on the review depth and results significance, etc. Also to be included is a written summary statement.

1.3 LCA vs. RA ?

Although it might be argued that RA is the purpose of the impact assessment element, there are significant differences of scope and approach between RA and LCA. These differences partly explain that the later is not fully functional today.

Firstly, it should be obvious from Tableau 1 that LCA *alone* is not able today to provide the data required to perform RA correctly.

Indeed, considering "all feasible options" requires a technical survey of existing and planned alternatives; considering "all major consequences" calls for a highly complex prospective study of the global effects of what can be considered as negligible differences between alternatives; considering "all sources of uncertainty" goes far beyond all numerical enrichments discussed today to implement sensitivity analysis in LCA [9] and finally, considering "all reasonable values" is new to an important part of the LCA research community.

Consider all feasible options	Consider all sources of uncertainty
Modify wants	In scientific knowledge
Modify technology	In society's values
Prevent initiating events	In decision-making methods
Prevent release	In implementation
Prevent exposure	
Prevent consequences	**Consider all reasonable values**
Mitigate consequences	
Consider all major consequences	
Economics	
Environment	
Societal resilience	
Equity	

Tableau 1 - Minimal scope for a risk analysis, from [8]

Secondly, LCA alone is not able to comply with the transparency and clarity of conclusion requirements, partly because some issues have not been sorted out yet and still retain researchers' attention – data quality for example, but also because LCA is always trying to quantify things, which is an incredibly severe constraint when trying to follow such requirements.

An enlightening consequence of this situation is the comparatively poor conclusion chapters found in most intensive and time consuming building products' LCAs publicly available today.

We do not advocate a solution where LCA would be further developed to finally encompass RA - except possibly as the basis the newly born interpretation element, but we would rather favour a solution where the existing LCA and RA frameworks are merged together in a practical way.

2 Merging LCA and RA at an acceptable level

So now, how can LCA be useful within a risk assessment procedure ? This question can be divided into a concept matching problem and a data matching one, both of which are addressed below.

At that point our first objective is to develop a simple framework, i.e. one that can be easily and cheaply deployed. We also aim at preserving as much of the rigour of LCA as possible, i.e. to avoid unacceptable criteria (sometimes called "top-down" criteria) like "recycled", "recyclable", "natural", "without CFC", etc.

2.1 Matching concepts

There are obvious similarities between the first two steps of RA and the LCI and LCIA steps respectively.
In order to get to the risk management step, RA has indeed to perform a broad review of possible hazards where the life cycle concept has an important role to play as a support to ensure the breadth of the review.
Hence, hazards identification can usefully capitalise on a life cycle inventory.
The situation is less clear as to the degree of compatibility between LCIA and risk assessment. In particular, the former is far less explicit than the later in terms of actual &pacts. On a qualitative level however, knowing that a given substance is a potential source of impact on the ozone layer for example, is the first step of risk assessment in RA
Hence, risk assessment can usefully capitalise on a qualitative life cycle impact assessment.
In conclusion, we do not suggest that LCA concepts can match those of RA, but rather that LCA elements can prove useful as tools to partially implement RA's three steps (see Figure 1)

Risk Analysis as a Framework	Corresponding LCA elements as a tools
Identification	Inventory
Assessment	Impact assessment (qualitative)
Management	(void)

Figure 1 - Matching RA concepts and LCA elements as tools

2.2 Matching data

It would not be realistic to try and merge LCA and RA just by "plugging" matching concepts one into the other at a numerical level and still hope to meet our simplicity and cost effectiveness requirements.
We suggest however, that it can be done if data are exchanged at a qualitative level. Indeed, ***words*** are often the most effective medium to convey complex and subtle, possibly fuzzy pieces of information. This "wordy" approach was already taken, in slightly different ways though, by [10] and [11].
The framework developed on the basis of this merging of RA and LCA as previously defined is called INIES. It is presented in the following paragraph.

3 The INIES framework

INIES stands for "INformation on Impacts Environmental and Sanitary". It is a simple approach merging the LCA concept and elements with the RA framework. INIES makes use of any numerical and qualitative data available on products' EQ and sets them in a grids structure (step 1) designed to be readable and not to make assumptions that would impede on the management step of the RA framework. Then, a written summary of the grids content can be produced, to answer specific questions (step 2). Both steps are introduced below.

3.1 INIES step 1 – Fill in grids

INIES is a series of four or five grids – one for each life cycle step of a building product: raw material extraction (optional); manufacturing (production); setting up (construction site); service life (including maintenance); end of life (demolition site and disposal/recovery/reuse). The grid framework has been designed taking in account the building sector particularities. Grids are laid out as shown on Figure 2.

LC Step :							
Flows (1)		Environmental themes (2)					Recommendations (4)
		Resources preservation	Ecosystems preservation	Waste management	Health	Quality of life	
Energy			↑				
Materials	→	→	(3)				
Waste							

Figure 2 - INIES grids general layout

Lines of column (1) contain input and output flows nature and quantity, as provided by an inventory. A specific line is dedicated to waste (which in fact is a material flow) because it is a major concern for building products.

The five environmental themes result from a building products-oriented choice for putting together all the classical impact headings.

Potential effect of each flow on each environmental theme (2) is then mentioned in the corresponding cell (3), based on a qualitative impact assessment and any other source of information, including experts reports.

Column (4) is intended for recommendations on how to suppress, prevent, mitigate, etc. the risks mentioned on one or more themes. This column is particularly useful when existing regulations are either not satisfactorily addressing the issue or not applied in practice - wood burning on the construction site, for example.

Since almost any piece of information available on EQ can be reported in the cells and also because users of this information are mainly interested in the knowing the risk induced by a given hazard and how to manage it, INIES provides clear status indications for every piece of information. Possible status are :

Hazard identification : - Data not available – in that case no assessment will be reported
- Quantitative data
- Qualitative data

Risk assessment :
- Data not available, i.e. risk not assessed
- Not relevant as to present knowledge; i.e. no risk induced.
- Assessment without experts consensus
- Assessment with experts consensus

Management :
- No information on management
- Management according to existing regulations
- Advice on management in lack of relevant regulation

Reference regulatory texts pertaining to building products are few. There are however some general references which are applicable in that specific context. Among these, one can mention the European Waste Catalogue [12] and the European directive on products labelling [13].
INIES has been developed as part of a large project financed by the French ministries of Industry and Housing and the Ademe (French governmental agency of environment), in partnership with industrial associations, some general contractors and architects. This project was aimed at reviewing technical, economical and environmental aspects of a broad range of products issued from the steel, concrete, clay and wood industries. Within that project, which also served as a test bed for the INIES approach, participants agreed that INIES made possible a compilation and a clear presentation of EQ aspects and helped avoid misinformed or biased statements.
Since the target of this project was to produce EQ information on the largest spectrum possible, filling the grids was enough. But filled-in grids are not the final word of the INIES framework.

3.2 INIES step 2 – Synthesize information

To follow the recommendations for successful RA discussed previously, providing data is not sufficient. Information must be synthesised to provide a documented answer to the questions asked by a given actor.
Again, our experience is that words are an effective medium to communicate EQ information to various types of actors, and succeed where numbers failed.
This second step is currently tested in two ongoing projects.
Firstly, INIES is used as a basis for the introduction of EQ recommendations into an experimental revision of the French standards for wooden-framed houses construction – known as the DTU 3 1.2 [14]. This project is co-financed by Irabois and Ademe. The basic philosophy of a DTU (« Document technique Unifié ») is to act as a code of good design and setting practice for a given construction element. Hence in this context, a specific use for the data compiled into INIES grids is defined. We decided to fill the grids and then produce a short text summarising all risk management information and recommendations relative to the setting, service life and disposal steps of the product's life cycle. This resulting text will be inserted within the new experimental version of DTU 31.2.
The second ongoing project involving INIES is aiming at developing a procedure to include EQ criteria into the French product technical agreement delivered by CSTB. Again, grids are filled in for the product to assess and a short summarising text will be produced.

4 Conclusions and Future work

INIES is a building products' EQ documentation framework merging RA and LCA at a qualitative level. In a first step grids are filled with existing EQ information. Attention is paid to giving risk management recommendations or applicable regulations when available. In a second step a summarising text can be produced to address a specific question.
INIES can be used to :

- Inform and communicate on a building product EQ,
- Get informed on building products' EQ,

- Point to aspects not covered enough. As an example, most products lack guidance on maintenance and refurbishment. The absence of data will appear in the service life INIES grid and can push actors into asking manufacturers for more details,
- Suggest improvement tracks to manufacturers and possibly other actors,
- Push actors into defining and communicating on their environmental policies, because decisions taken on the basis of the information presented in an INIES grid set must explicitly indicate preferences and trade-offs between risks.

Details needing to be further elaborated include a closed list of statements denoting the grid cells' content in an unambiguous way. This list will be particularly useful in regulatory texts and technical agreement procedures.

The INIES framework is now close to being fully operational and its application to a broad range of generic building products is planned.

"Durability and Reliability, Alternative Approaches to Assessment of Component Performance Over Time"

E. V. Bartlett
Building Performance Group, London, England, UK.
S. Simpson
Faculty of the Built Environment, University of the West of England, Bristol, England, UK.

Abstract
This paper will describe some of the findings of the current UK Teaching Company Directorate funded collaborative research between consultants, Building Performance Group and the University of the West of England. The objective of the research is to provide a practical database on the durability of components and materials used in the construction industry. The current second stage of the research is focused on mechanical and electrical services systems and components in commercial buildings. The paper will compare the type of service life data available for commercial building services systems and components with building fabric components. The different types of data and failure pattern curves indicate that a different approach to maintenance management may introduce higher levels of reliability and sustainability in buildings.

The use of reliability engineering in the assessment of component service life is contrasted with the construction industry's current approach using durability. Techniques including reliability-centred maintenance and condition monitoring will be discussed in relation to the assessment of environmental, economic and life cycle performance. There will also be an analysis of one statistical method of modelling performance that can be used to optimise maintenance and renewal of building services systems and components.
Keywords : Building fabric, building services, durability, function, life-cycle, maintenance, sustainability, reliability, service life, statistical analysis, Weibull.

1 Introduction

In response to the increased need for data on the service life of building components, Building Performance Group (BPG) and the University of the West of England have been carrying out a four year research project sponsored by the UK Teaching Company initiative. The current research relates to mechanical and electrical (M&E) building services components in commercial and industrial buildings. The main objective of the research is to produce a unique database of building component service life data. The research has already contributed to the Housing Association Property Mutual (HAPM) "Component Life Manual" [1], and it is hoped that a similar component manual will be produced for M&E services components.

This paper examines the differences in the types of data, and failure distributions between fabric components and M&E services components in buildings. It is desirable to integrate the two types of data sets into a common format in order to facilitate the development of a single "cost in use" model for buildings. It seems that the construction industry has a definite need for the data in this format. The principle of reliability will be discussed in comparison to durability together with a review of the relevance of historical data. The findings indicate that a different approach to maintenance management based on reliability studies may promote more cost-effective and sustainable use of resources. Techniques including reliability-centred maintenance and condition monitoring will be discussed in relation to the life cycle, environmental, and economic performance over time. There will also be an analysis of the statistical models for service life prediction that can be used to optimise renewal of building services systems and components.

2 Different Approaches to Data Collection

The first phase of the research developed a broad methodology for the service life assessment of building components and has been adapted to building services :

- Identify potential existing sources of data on the durability of building services plant and equipment by reference to relevant organisations and published sources.
- Assemble a knowledge base of information on the durability and failure modes of selected building services plant and equipment.
- Extend the scope of the existing building component lifespan database to include data on a range of building services components and equipment for commercial buildings.

The assessment of building services life and failure compared with building fabric has highlighted some key differences. Due to the dynamic nature of M&E services components, failure may cause much greater disruption to the operation of business than fabric materials. For example, the failure of a boiler is far more of a problem than a cracked floor tile or peeling paint. On the other hand, concrete gets stronger over time, while bearings wear out. Failure and service life of M&E components are thus examined in terms of reliability rather than durability. Reliability engineering is a science in itself with component life generally measured more accurately in hours rather than years.

M&E services components can fail due to a wide range of failure modes. The commissioning process and warranty period should resolve many of the early stages of potential failure with M&E components. This represents the "burn-in" or "'infant mortality" stage of a failure distribution (see Figure 1). Failures occurring in the stages after this period are perhaps the most important from a service life point of view, especially when failures are often beyond warranty periods provided by manufacturers, and can lead to full-scale replacement rather than repair. The following describes what data and methodologies are available for failure management, and how this data can be used to ensure selection of reliable building services components. The technical failure history issue has attracted much discussion in the field of reliability engineering. Numerous paradoxes and shortcomings occur in relation to maintenance policy and historical life data :

(1) It has been suggested that if we are collecting failure data then it is because the failures are not being prevented ("The Resnikoff Conundrum") [2].
(2) Planned preventative maintenance (PPM) prevents the failures occurring for which we need data to optimise PPM.
(3) PPM often leads to failures occurring either due to human error or simply de-stabilizing and disruption of a sophisticated system.

"Burn-in" failures are in effect re-introduced each time "preventive" maintenance is carried out. Studies on the reliability of boiler plant [3] illustrated this fact in the concluding thoughts on the research : *"A disturbing outcome of the study has been the effects of servicing on plant reliability. The probability of plant failure increases considerably in the monthsfollowing a service visit?* In addition some of the worst industrial catastrophes in recent history have been caused by unnecessary maintenance intervention, eg. Piper Alpha and Bhopal [2]. Further discussion on the effects of maintenance policy on component lives is further discussed in section 6.

It is often thought that the ultimate aim in service life data collection is to gain real data from installations where the history is well known or has been modelled over a certain period of time. It is true that this may be the most useful situation but the discussed failure process issues must first be taken into consideration. Historical records do, however, have a major part to play and should be used to reduce routine maintenance to the minimum, and determine less disruptive maintenance programs.

The problem of deciding on the level of data collection required to manage maintenance and performance has been identified in other industries, and has led to a "paradigm flip" [4]. The old paradigm was to gather information in hope of improving performance, in terms of service life which may be equated to the study of durability. The new paradigm is to ask what information is needed to determine the possible performance, reduce the gap between current and possible performance, and maintain that new performance level. The research aims to provide an indication of what performance is possible with components through the study of their reliability. Where there are large numbers of identical components in a system and there is a cost consideration to failure, then the collection of real life data is practical. For components that follow an age related failure distribution and where costs of failure are high, then collection of real data is also feasible.

Various organisations are now introducing programmes of asset life cycle management which include an element of verification of performance and life data. In the petrochemical industry companies are combining smart sensor technology, neural networks, expert systems and computer technology to predict plant failure. These "systems" are based on those developed for aircraft maintenance and include computer software that provides data collection, intelligence to diagnose a problem, assess risk, and recommend action [5].

3 Reliability v. Durability : "In building and construction, reliability is often called durability" [6]

For the purpose or tne research, we have adopted the followmg definitions given in BS5760 :

- Durability is "the ability of an item to perform its required function under stated conditions of preventative or corrective maintenance until a limiting state is achieved".
- Reliability is defined as "the ability of an item to perform a required function under a stated period of time".

Manufacturers see reliability as having "a vital effect upon the life-cycle efficiency, profits and market share" [6]. Economic asset management has long recognised the importance of quality and performance indicators to assess whole life performance. A particular item of building services plant or equipment, like a building, will certainly be produced to fit into a particular band of quality. The reliability of equipment is measured in relation to a product quality definition supplied by the manufacturer. It is thus possible to refer to 'good' and 'bad' reliability targets and maintainability figures. This form of asset performance profile modelling allows the establishment of a reliability confidence range or benchmark [5]. Reliability then relates to success or failure in service or use and is attained if the quality provided by the producer is adequate. Manufacturers of mechanical and electrical components investigate their product's reliability, and even demonstrate expected failure rates. They recognise the need to supply data in order to allow the assessment of confidence for life cycle cost estimates. Manufacturer supplied data is available for M & E building components in relation to failure and reliability. The level of information provided in relation to reliability and maintenance data is increasing due to increased competition, complexity of installation, and guarantee packages provided. There is still, however some scepticism in the construction industry in providing service lives. A number of reliability data banks have been set up to provide indications of expected failure rates, which include M&E building components [7], but not building fabric components. In the UK the HAPM Component Life Manual is still unique in giving "insured lives" for building fabric components, and some M&E components.

The information on component failures may be expressed as Mean Time Between Failure (MTBF), Failure Modes, and Failure Mode and Effect Analysis (FMEA). The MTBF is defined as the average life of a particular component [6] which is statistically different from expected service or useful life of a component. The use of MTBF in particular situations is, however not to be relied upon as the sole basis for maintenance decision making, and does not indicate the required frequency of maintenance tasks. It can be used in calculating desired availability, frequency of failure-finding testing, and whether planned maintenance is worth doing, but not how often. It is accepted however that in many cases reliability and maintenance data will not be available. This refers to actual real time to failure which can enable verification of estimated data in relation to the life cycle of M&E building components. This data can also be used to calculate optimum replacement strategies from components using statistical modelling techniques as discussed later.

Durability has long been studied in relation to the performance of fabric building components, but the above definition of durability highlights the absence of the “period of time” aspect. Reliability concentrates on this factor and is used in an engineering context when looking at the service life of M&E services components, and also is :

- Qualitative, as it examines freedom from operational failure in service or use on a comparative scale.
- Quantitative, as it is concerned with the probability that an item will operate in a prescribed fashion for a prescribed period of time under prescribed conditions without suffering any event predefined as a failure.

4 Failure Distribution Patterns

Traditionally the “bath-tub” distribution is used to model component failure. This has been called “the folklore of reliability engineering” [8], and other failure distributions have been identified in other industries, which are of relevance to building components. The following Figure **1** [2] illustrates most of the failure distributions that might be found in a building and its associated components :

A: “Bath-tub curve” with high incidence of failure *(infant mortality* or *burn-in*) followed by random or gradually increasing failure rate, then by a wear-out zone.
B: Random or slowly increasing failure probability, ending in a wear-out zone.
C: Slowly increasing probability of failure, but there is no identifiable wear-out stage.
D: Low failure probability when the item is new or just out of the shop, then a rapid increase to a constant level.
E: Random probability of failure at all ages
F: High infant mortality, which drops eventually to a random or very lowly increasing failure probability.

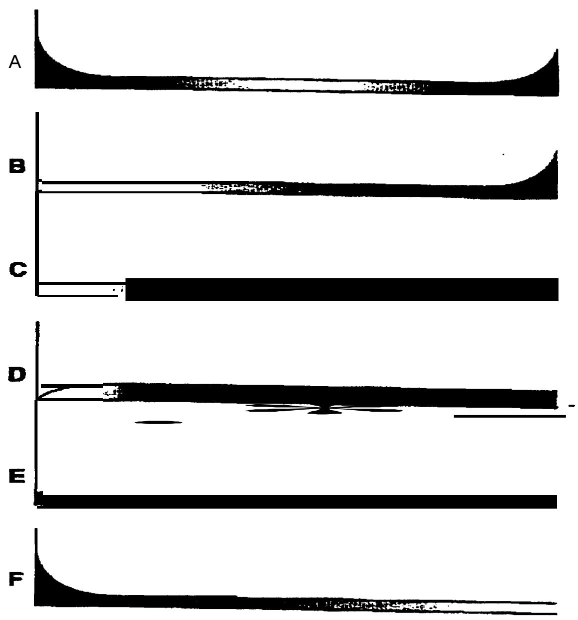

Figure 1 - Failure Patterns [2]

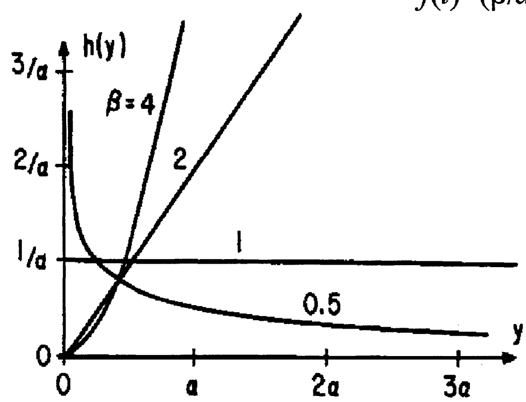
The basis of any maintenance policy or accurate life-cycle analysis is the understanding of the failure characteristics of individual components. Studies in the Civil Aviation Industry [2] have showed that 4% of items conform to pattern A, 2% to B, 5% to C, **7%** to **D, 14%** to E, and **68%** to pattern F. As M&E services components grow more complex, patterns E & F are likely to become more common. These findings suggest that there is not always a link between operating age and reliability and hint at the paradoxes with failure data discussed in Section 2.

5 Statistical distribution and the Weibull function

Several statistical functions can be used to model the failure rates and distributions discussed above including log normal, Gaussian, gamma, and Weibull [10]. The Weibull distribution is suitable for use in this context, and is widely used and preferred as it *"has a great variety of shapes which enable it to fit many kinds of data, especially relating to product life"* [2]. Predicting future trends or patterns associated with a common failure mode affecting a specific component is an essential part of maintenance planning for mechanical and electrical services. A predictive technique must estimate the time at which the failure rate is deemed unacceptable, not simply the time to first failure, which may itself be difficult to anticipate. As a starting point this may involve an assumption that all failures will simply continue at their current rate or perhaps incorporate some element of "educated guess" for a moderate increase.

Predictions of component failures can be made with greater confidence by using the Weibull Distribution Function which is seen as a powerful and versatile statistical tool for the analysis of reliability life data and hazard probabilities. It is uniquely able to model situations irrespective of whether the failures represent part of an increasing, decreasing, or constant exposure to failure mechanisms. Figure 2 below illustrates the 'hazard function' which highlights the variety of shapes which can be attributed to the full range of failure patterns shown previously in Figure **1.** The data required in order to carry out a Weibull analysis is the time-to-failure of the components being studied. Statistically the Weibull frequency distribution (or probability density function) is :

$$f(t)=(\beta/a^{\beta})t^{\beta-1}\exp[-(t/a)^{\beta}]$$



W eibull hazard functions.

Figure 2 - [Source :10]

The Weibull Beta value achieved from the above equation dictates the shape of the curve [10] and where :

Beta < 1 - burn-in failure is occurring, which equates to pattern F [Figure 1]
Beta = **1 -** random failure is occurring, which equates to pattern E
Beta > 1 - wear out failure is occurring, which equates to pattern B

6 New Approaches to Maintenance Management

It is widely acknowledged that once a failure distribution is known or modelled, a suitable maintenance policy can be determined [10]. Recognition of the maintenance policies available have changed much since the early 1980's. Possible failure management policy options available today to improve life cycle performance include:

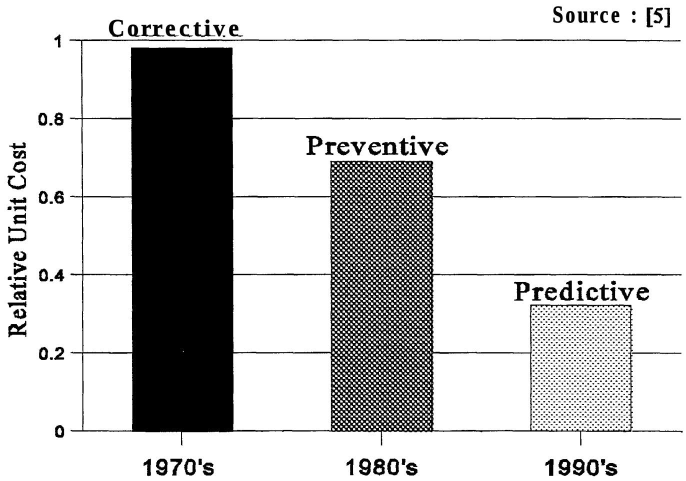
(1) Predictive maintenance
(2) Preventive maintenance
(3) Condition-based maintenance
(4) Failure finding
(5) Change the design or configuration of the system
(6) Change the way the system is operated
(7) Just-in-time maintenance
(8) Run-to-failure

Processes are available to help identify a suitable failure management policy for dealing with each failure mode in the light of its consequences and technical characteristics. One such process is "Reliability Centred Maintenance " (RCM) which finds its roots in the American Civil Aviation industry in the early 1960's, and is used world wide especially in the process, aviation, and defence industries. The RCM process importantly first defines what users want in terms of function (safety, environmental and sustainable integrity, reliability, durability), and then quality (precision, accuracy, consistency and stability), control, comfort, containment, economy, customer service etc. The next step is to identify ways in which the system can fail to live up to these expectations (failed states), followed by an FMEA (failure mode and effects analysis), in order to identify all the events which are reasonably likely to cause each failed state [2]. This allows the selection of the most suitable building maintenance strategy and has been successfully used in a number of major commercial buildings. Recent technological developments in condition monitoring equipment and that can be used to detect failure before it occurs have led to greater emphasis on policies such as predictive, condition-based and just-in-time maintenance. Building services components often have a detectable or measurable progression to failure and are therefore suitable for such techniques. For example the mechanical failure of bearings in a centrifugal pump would be characterised, over regular time intervals, by :

(1) vibration,
(2) noise,
(3) heat,
(4) smoke and possibly fire.

The process industry has done much work in assessing the effect of different maintenance policies in order to lower the life cycle costs of components [5], as illustrated in Figure 3 :

Figure 3 **Maintenance Costs - Process Industry**



7 Conclusion

Policies for the life cycle analysis and maintenance management of mechanical and electrical building services components are being heavily influenced by new technologies from other sections of industry. The actuarial approach to data collection is often less useful than statistical analysis in predicting component failure used in deciding maintenance management policy options. Failure patterns can vary extensively and do not necessarily fit the "bath-tub" distribution. Data on failure rates is certainly available for M&E building components from manufacturers and data banks that can assist in making correct maintenance decisions, but this data is not readily available for building fabric components. It has been shown that incorrect planned maintenance strategies can actually increase life cycle costs, and reduce reliability and service life.

Differences in the data format and the data collection process for fabric and M&E components are evident, and the use of the Weibull function has been suggested as one example method for data analysis. Reliability theory may be used as a single methodology to assess building component performance of both mechanical and electrical services and fabric components. This would allow the development of a common cost-in-use model for life cycle analysis. In order to use such a model effectively, there is still a definite need for data giving actual time-to-failure or replacement in order to verify and explain existing service life predictions for building components in general, and allow more cost effective predictive maintenance.

Material flows in the construction and heavy engineering sector

Nikolaj Tolstoy Christer Björklund and Per Olof Carlson
AB Jacobson & Widmark, Lidingö, Sweden

Abstract
About 90 per cent of all natural stone, sand and gravel in the construction and heavy engineering sector is re-used. Asphalt is 60 per cent re-used and wood is about 80 per cent converted into energy. Concrete waste, on the other hand, is only 20 per cent re-used. These figures come from a study prepared by AB Jacobson & Widmark for the Swedish National Environmental Protection Agency.

In an average year, 6 million tonnes of waste are released by the alteration and demolition of roads, installations and buildings. Of this, 43 per cent is reused, 7 per cent is recycled, 5 per cent is incinerated for energy-production and 45 per cent is dumped or landfilled.

There are different types of landfills, e.g. for building or demolition waste clean fill, etc. often in old gravel pits. Concrete, brick, stone and lightweight concrete are usually counted as approved infill, though lightweight concrete is not approved in the presence of water, because it floats. Plaster is allowed in small concentrations. Metals, plastic and wood usually occur, due to the difficulty of completely separating out these materials.

Three-quarters of the material released consists of asphalt, concrete, sand and gravel. Other materials, then, constitute a minor proportion. Metallic waste has a high recycling rate, about 70 per cent. About 35 per cent of glass waste is recycled. Plastic, board, paint, mineral wool, textiles, ceramics, concrete, jointing compounds, lightweight concrete and screed at present are to a very great extent (80-100%) dumped or used as infill.

The total quantity of material incorporated in buildings, roads and installations is estimated at 2,500 million tonnes (two billion five hundred million tonnes). The estimated quantities include all materials in buildings, roads and other structures in Sweden. Exceptions have been made, for example, for spillage during maintenance and construction, military installations, outdoor and underground utilities, equipment belonging to installations and scaffolding.

The survey of material flows provides an overview of present-day conditions. It conveys an idea of the magnitude of the material flows, how they differ between the categories of in-built quantities, quantities released in connection with building and alterations and quantities released by demolition and alterations. The survey also yields information as to how these quantities of building material released are dealt with.
Keywords: Building materials, dump, energy-production, material flow, recycle, re-use,

1 Priority principle

In its work on producer liability, the Swedish Government's Ecocycle Commission has given priority to building materials. For these it has indicated the following priority principle:

- *Resource conservation,* i.e. testing when the material needs to be demolished and giving priority to measures reducing the amount of residual products.
- *Re-use of products,* e.g. re-using roof tiles fi-om a demolished house as roof tiles on another house. *Recycling of materials ,* as for example when metal is melted down and becomes new metal.
- *Recovery ofenergy,* e.g. incineration of wood waste.
- *Landfill.*

The Ecocycle Committee for the Building Sector, in its "Action plan for environmental responsibility for building materials, a wider producer liability", has, through its enterprises and organisations, pledged itself among other things:

- to identify hazardous waste from building, maintenance, alteration and demolition and to pre-separate the waste so that it can be dealt with in an environmentally appropriate way,
- to pre-separate residual products not later than 1997, partly in order to improve the prospects for recycling industry,
- to halve tipping quantities from the building sector not later than 2000.

The term "building sector" refers to all members of the construction industry. All of us, then, are jointly and severally bound to honour the above pledges. Dependable figures used to be lacking concerning the amounts of material incorporated in all the buildings and heavy constructions of Sweden. Nor was there any overview of data concerning the amount incorporated in connection with building, alteration and enlargement. Lack of knowledge has obstructed the greening of the building sector.

J&W were therefore commissioned by the Swedish Environmental Protection Agency to chart the flow of materials. Material quantities have been calculated by quantifying system-built houses, roads and installations and by processing existing statistics of the number of buildings, total length of roads and volume of other structures.

2 Purpose of the survey

The purpose of this extensive survey was to compile supportive data for the Agency's continuing work on the ecocycling of building materials. The following building materials and sub-groups were included: concrete, lightweight concrete, asphalt, stone, sand and gravel, brick and ceramic materials, metal, plastic, wood, roofing felt, glass, plasterboard, insulation materials, jointing compounds, screeds, asbestos cement, linoleum, paint and textiles.

3 Results and conclusions

3.1 Results

Table **1** Handling of the quantities released by demolition and alterations.

The results of the survey warrant several interesting conclusions, for example:

- Sand and gravel, concrete and asphalt account for the overwhelming proportion by weight of the total quantities, namely **84** per cent in-built and **72** per cent released.
- Released quantities sent for tipping and landfill total 45 per cent altogether, 58 per cent for building and **36** per cent for roads and civil engineering works.

Much work remains to be done in order to compile more accurate statistics on material flows. Subjects for further study are suggested in the report.

The survey provides valuable information on the way in which the quantities of building materials released are dealt with. Management varies a great deal from one group of materials to another:

- Materials extensively re-used are stone, sand and gravel (about 90%) and asphalt (60%).
- 80 per cent of wooden materials are used for energy-recovery .
- Recycling of window glass is at present confined to re-use of windows (35%). Recycling of flat glass is minimal at present, partly because the company for recycling of glass in Sweden (Svensk Glasatervinning) now concentrates on consumer products. It is estimated that less than 1 per cent of flat glass from the building sector is sent for recycling.
- The proportion of metals sent for recycling varies between 60 and 85 per cent, depending on metal prices.
- A very large proportion of the other materials ends up in various dump sites or landfills (SO-100%).

In the accompanying table, results have been compiled concerning amounts released for buildings, roads and civil engineering works during an average year in the course of an economic cycle (= normal year). According to the survey, a total of 6 million tonnes are released annually, of which 45 per cent are being sent to a dump site or a landfill, 5 per cent for energy recovery, 7 per cent for material recycling and 43 per cent for re-use. These figures for the handling of quantities released refer to 1996.

The same table summarises results concerning in-built quantities up to and including 1995. According to the survey, 2,500 million tonnes of materials are built into houses, roads and installations. Sand/stone, concrete and asphalt account for the overwhelming proportion (84%) of total quantities.

3.1 Estimated uncertainty of the calculated data

Inaccuracy is due to the uncertainty of the statistics regarding the number of buildings, roads and installations and of the method of quantified system-built houses, roads and installations.

The uncertainty regarding the number of houses in existence is estimated at ±10 per cent. In addition to numerical calculations from Statistics Sweden valuation units, results from statistical sample surveys of the house population, conducted at the Institute for Building Research in Gävle, have also been used in selecting the number of buildings.

The uncertainty of the quantification of materials in system-built houses has been estimated at ±10 per cent. For individual types of material occurring in small quantities, e.g. jointing compound containing PCB, the error may be greater.

In the case of roads and installations, it proved unexpectedly complicated to find relevant figures for in-built quantities or quantities added to or disappearing from the system, the reason being that the available statistics do not normally include material quantities: often they give investment and maintenance costs only.

In the report, uncertainty is estimated at ±20% for in-built quantities and ±40% for turned over quantities (new production, alterations and renovations and quantities released). This means that the right values for in-built and turned over quantities respectively should come within the interval between 0.8 and 0.6 times the stated value to respectively 1.2 and 1.4 times the stated value.

3. 2 Delimitations

The quantities include all materials in buildings, roads and other installations in Sweden, with the following exceptions:

- maintenance of buildings,
- waste in connection with maintenance, new building and the national Housing Improvement programme (ROT),
- military installations,
- water and sewerage mains,
- power and telecommunications lines outdoors or in the ground,
- local soil in connection with road and railway construction,
- water heating and sanitation pipes below ground, light pressed brick, rendering, putty and glue,
- equipment in harbours, at airports etc.,
- pre-standing wardrobes, white goods, furniture, textiles other than permanent carpeting,
- scaffolding, shuttering and telephone/electricity poles.

3.3 Examples of material quantities:

An account is given below of quantities and of the disposal of released quantities for a number of building materials selected from the report.

3.3.1 Jointing compounds

Hazardous waste is not always disposed of in the prescribed manner, due often to ignorance of where the materials are and which materials are classified as hazardous waste under the Chemical Products Act. One relevant problem here is the PCB-containing jointing compounds which were used in buildings, above all during the 1950s and 1960s.

The figures concerning residual jointing compounds presented in other reports are of the order of 100-500 tonnes of PCB (Hammar, 1992). In another study, Boije and Markensten (1993) state that 70490 tonnes of PCB have been used for jointing compounds. Certain compounds included PCB in concentrations of 10-50 per cent. According to Öberg, 1994, the amount of PCB in double-glazed panels could be estimated at about 170 tonnes originally and the residual quantity at SO-100 tonnes. Given a PCB content of 25 per cent, this corresponds to a glued joint quantity of 200-400 tonnes.

In this survey of jointing compounds in prefabricated façades and in double-glazed panels from the period when PCB could occur, we estimate that there are about 5,000 tonnes ofjointing compound containing PCB. According to our calculations, 2.2 tonnes of jointing compound containing PCB are released every year as a result of demolition and modernisation.

The total quantity of jointing compounds, according to the above mentioned investigations, comes in the interval between 1,000 and 5,000 tonnes of jointing compound containing PCB. Our figure touches the upper limit.

In a recent report to the Swedish Environmental Protection Agency, researchers at Stockholm University advocated clearance of these joints, the reason being that they were able, from measurements in soil, to show that seepage and spread are considerable. Removing and replacing the joints would probably cost about MSEK 2,000.

Öberg estimates the amount of PCB in remaining Acrydur floors at 20-30 tonnes. The proportion of PCB in a complete Acrydur floor from 1950-60 (certain types of Acrydur flooring only) is about 12 per cent. The remaining flooring compounds containing PCB would then come to about 150-250 tonnes.

3.3.2 **Asbestos cement**

After 1976, asbestos cement was not used in new production except under certain exemptions granted up until 1982. Production of asbestos cement in Sweden began in 1920. Imports during the 1970s were running at 20,000 tonnes per annum up to and including 1976. The survey shows 1.8 million tonnes of asbestos cement to be in-built and 40,000 tonnes to be released by demolition and rebuilding every year.

3.3.3 Concrete

Over 550 million tonnes of concrete are in-built and 8.7 million tonnes are added annually. Just over a million tonnes of concrete are released annually as a result of demolition and alterations, and most of this (75%) is turned into landfill.

Cementa have kindly supplied material showing total cement consumption in Sweden and the market sectors in which cement is sold. Up until 1996, according to these statistics, cement sales in Sweden totalled 142 million tonnes. Ninety per cent of the cement manufactured in Sweden was used for manufacturing concrete. The remaining 10 per cent is used for mortar, tunnel grouting, deep stabilisation etc.

Sweden in 1996 produced about 2,2 million tonnes of concrete elements annually. Deliveries of concrete from the members of the Swedish Ready Mixed Concrete Association to on-site casters amount to some 6 million tonnes. About 5 per cent is delivered by non-members. Buildings dating from between 198 1 and 1990 contain almost 80 per cent concrete.

In many municipalities, a large proportion of concrete etc. is used for road building at refuse disposable plants. In Luleå and Helsingborg, nearly all concrete is crushed for recycling. In other municipalities, remaining, un-recycled concrete is deposited on landfill sites, some of which are municipally owned while others are private. It is not possible to distinguish the quantities deposited at municipal and privately owned landfill sites respectively. Conditions differ a great deal between regions, with certain municipalities also receiving and recording waste sent for landfill, while others have no dealings with landfill at all.

3.3.4 Plasterboard

At present 9.6 million tonnes of plasterboard are in-built and 0.2 million tonnes are added every year as a result of new production, alterations and maintenance. Plasterboard has been manufactured in Sweden by Gyproc, which between 1958 and 1994 produced 7 million tonnes. There have also been some imports of Danish and Norwegian plasterboard, accounting at present for some 30 per cent of the total use in

Sweden.

Plaster recycling takes place in Bålsta and will soon be starting up in Åhus. Soil improvement is a new application for plaster, and this is expected to increase in the next few years, plaster having proved to have a very beneficial effect on soil and crops. If use for soil improvement gets under way as expected, probably at least 50 per cent of plaster residues from new buildings and demolition can be recycled before 2000. At present 95 per cent is dumped.

Plaster is approved in most regions as filler if it is mixed with "mineral" material. It is not possible to distinguish the quantities dumped on municipal and private landfill sites respectively. Conditions differ a great deal between regions, with certain municipalities also receiving and recording waste sent for landfill, while others have no dealings with landfill at all.

3.3.5 Mineral wool

About 5.6 million tonnes of mineral wool were sold in Sweden between 1958 and 1994. This is the same quantity as the present authors estimate to be in-built. Every year, 127,000 tonnes of mineral wool are added and 3 1,000 tonnes released. At present Rockwool, Gullfiber and Roxull sell about 120,000 tonnes of mineral wool per annum.

Recycling in the form of loose wool insulation will increase over the next few years. Gullfiber and Rockwool have signed contracts with loose wool contractors all over the country. The target is 50 per cent recycling in 2000 (including recycling of waste from new buildings). It is estimated that recycling can already reach about 10 per cent (of the mineral wool released by demolition) in one year's time.

3.3.6 Lightweight concrete

Deliveries of reinforced and unreinforced lightweight concrete from Siporex, Durox and Ytong between 1958 and 1995 give 27.7 billion m^3, while production pre-1958 amounts to 4.2 million m^3 for Ytong and similar quantities for Siporex and Durox. Given an average volumetric weight of 0.6, the total quantity manufactured comes to 24 million tonnes. Our calculation in this survey gave 28.8 million tonnes. New production and renovation, according to the present survey, given 128,000 tonnes per annum, whereas Ytong produces only 60,000 tonnes annually. Here we have probably overestimated the amount of lightweight concrete turned over every year in the building of new single-family dwellings and alterations to industrial facilities. In many municipalities, lightweight concrete is used together with concrete etc. for road building at the refuse dump site (estimate 10% approx.). Lightweight concrete which is not recycled is deposited on landfill sites.

3.4 The first attempt

This is the first attempt at charting the material flows of the building sector in Sweden. The figures are subject to a great deal of uncertainty, due to the shortcomings of the statistics, but the material still conveys a good picture of quantities and composition. The comparisons we have made for control purposes show that several of the figures used previously may be incorrect or highly inaccurate. For example, the figure of 2.5 tonnes of plastic per dwelling unit frequently figures in the literature. It emanates from all national plastic output divided between dwelling units and does not refer solely to the plastic present in building materials, structures and installations.

3.5 Further studies needed

The report describes the need for further studies:

- Better statistics concerning the number of buildings are needed, with a view to more reliable calculations. Within the near future, the buildings register of the National Land Survey will probably afford a sound basis for statistics of this kind.
- Quantification of some additional materials not included in the present survey, e.g. heating, water and sewerage pipes below ground, light pressed brick, putty and rendering.
- Further comparisons of the results of this survey with other available statistics and analysis of any differences between them.
- Inclusion of spillage from new production and maintenance of buildings in the material quantities.
- Statistical field studies are a viable way of obtaining a good, accurate picture of the flow of building materials.
- Construction of a database for material flows.
- Lucid presentation of material flows.
- Quantities in new building and civil engineering projects, through a number of studies of different typical projects.

The life cycle simulation method EQUER applied to building components

Bruno Peuportier
Ecole des Mines de Paris, Centre d'Energétique, Paris, France

Abstract

Sustainability objectives influence the development of products by adding supplementary quality criteria. Some of these criteria can be evaluated by quantitative indicators, according to the life cycle assessment (LCA) method. An evaluation tool, based on numerical simulation of buildings life cycle, is presented in this article with an application example.

This life cycle simulation code (EQUER) is linked to a thermal simulation tool (COMFIE) and to a data base including many processes (fabrication, transport, energy transformation, waste management, etc.). Renewal and recycling of products is taken into account. The results (e.g. GWP, acidification potential) are presented in the form of spider charts. Technical solutions can be compared in order to evaluate the benefit of innovative techniques in relation to a reference, and to improve products. The interest of this process is to consider the whole life cycle of components and to account for possible interaction with the rest of the envelope, the site, and the occupants' behaviour.

The methodology is illustrated by an example of transparent insulation. A cellular polycarbonate structure is studied and characteristics needed for thermal analysis are determined. The inventories for glass, aluminium, wood and polycarbonate are used for a first evaluation of the fabrication impact of the component. Interaction between the component and other parts of the envelope is taken into account : the radiation collected through the component is stored in a masonry ; comfort requirement and maintenance issues lead to have also opaque insulation in the wall, with a corresponding impact. The environmental benefit of the transparent insulation component, in relation to a reference wall, depends on the location of the building, the occupancy pattern (dwelling or office building,...) and the characteristics of the envelope (thermal inertia, solar aperture). The distinction between generic characteristics and specific performance is discussed. Sensitivity studies can support product development, e.g. reducing the thickness of material lowers fabrication impact but increases heating energy consumption, and these effects can be balanced using LCA.

Keywords : life cycle assessment, simulation, building materials, environmental impacts

1 Introduction

The emerging sustainable construction practices raise many questions concerning technical choices, and particularly the characterization and selection of building components. Various tools are proposed like guides, lists or labels but the underlying criteria and hypotheses are often not transparent. Comparing materials or presenting the environmental benefit of techniques requires explicit criteria and verifiable assessment.

The environmental benefit of a technique (e.g. the reduction of CO2 emissions obtained by an insulation material) is related to a reference (e.g. a typical wall with or without insulation). This reference should be representative and correspond to a standard in terms of construction techniques. But such a standard is related to a specific location. Also, in the previous example the amount of CO2 emissions depends on the climatic conditions, the-use of the building in which the wall could be included, etc. Comparing alternatives might provide different results for different locations and buildings. Tools ranking materials on a general basis are thus hardly credible, and the aim of the work presented here is to study how technical alternatives can be compared and on which level -component or whole building- the various properties and performances should be assessed.

2 Principle of the life cycle simulation

Assuming that the environmental performance of building components may not be generic and may vary according to the location, building use etc. implies to assess the environmental performance of whole buildings and to rank alternatives using sensitivity studies. If all sensitivity studies, in every climate and every case give the same results, the ranking is then general and the assessment can be regarded as a generic performance of components : it depends on the component itself and not on the location or the building.

Previous studies have shown that the environmental performance of a building is the result of several factors like integration in a site and urban design, architectural design, technical choices and occupants behaviour. Environmental assessment methods should account for these various interacting aspects in order to provide a relevant help to decision makers.

Environmental quality criteria can be very broad, including comfort and aesthetical aspects. We limit the present study to quantifiable aspects. Also, comfort issues have been the subject of many previous studies, and we are focussing here on environmental impacts which is a more recent concern.

Life cycle assessment (LCA) seems to be the least criticable method at the moment to assess the environmental impacts of products [1,2], and we have chosen this approach. But the specificity of the building sector has to be taken into account. In many cases, a building is unique and its design cost is limited. LCA must then be automatized to reach this productivity constraint. We developed a computer tool, which makes comparison of alternatives easier.

Because this model has already been described in previous publications [3,4], we only give here a summary presentation. The functional unit considered is a building located in a certain site and occupied for a certain use (e.g. dwelling, offices,...), with an appropriate level of comfort and quality in general. The system boundary is defined according to the needs of each study and may not be limited to the building. For instance if the purpose is to compare various building sites for the same project, transportation issues may be taken into account. Processes like electricity production, domestic waste treatment, transportation of building materials are taken into account, so that the system is broader than the building itself. Energy consumption for heating has a major contribution in the global balance, and our LCA tool has been connected to a thermal simulation tool (COMFIE, [5]).

The model comprises entities (or classes) corresponding to technical objects of the building (materials, components,...), to processes (transportation, energy use, water utilisation, waste management,...), to the site (selective sorting, collective transportation,...) and to environmental indicators (inventories, energy and water flow meters,...).

A complete description of the corresponding data structure has been established using the formalisms defined in the STEP-Standard, NIAM (cf fig. 1) and EXPRESS [6].

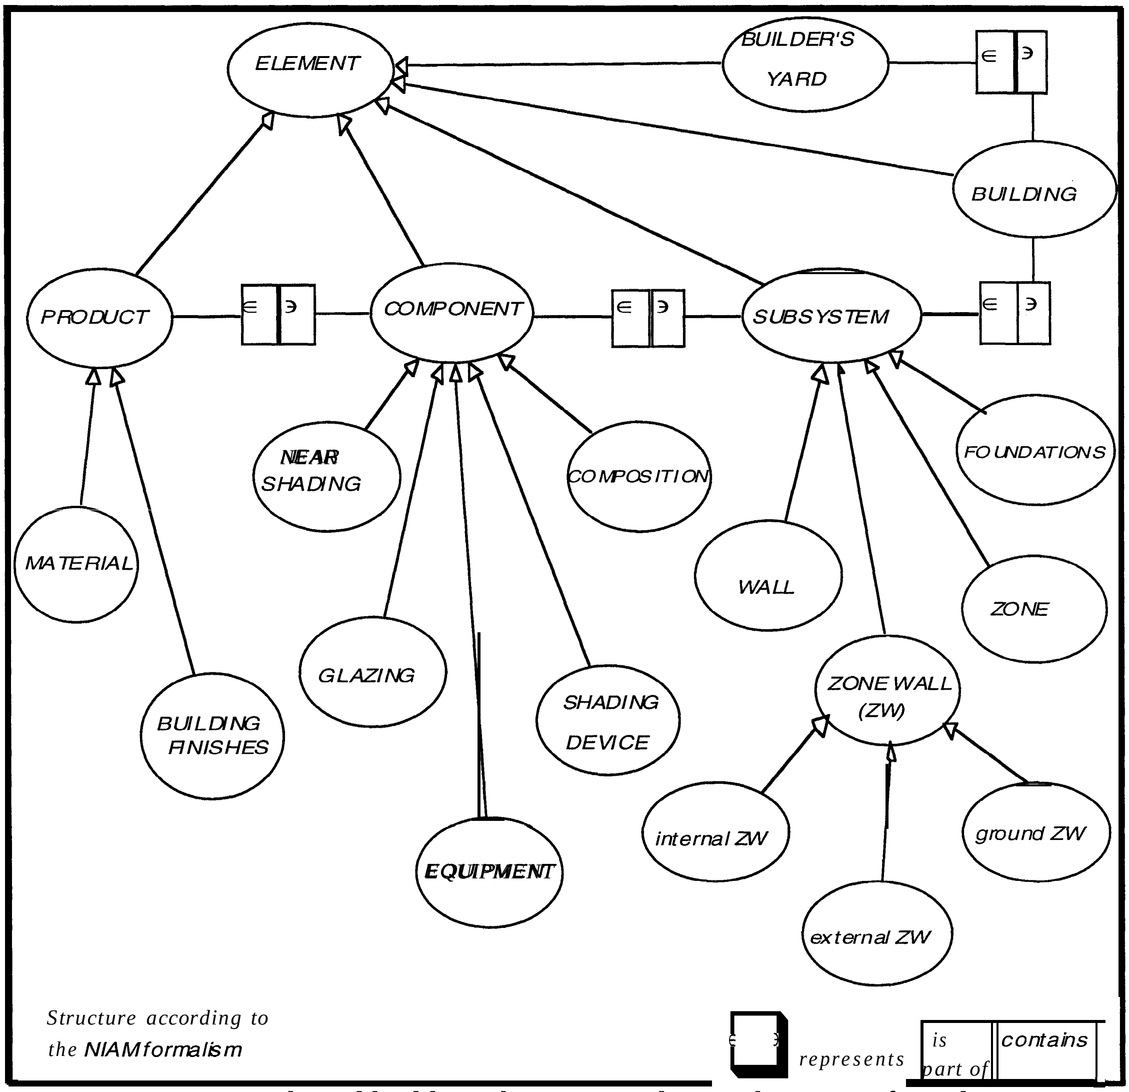

Figure 1 : Technical building objects according to the NIAM formalism

The different phases considered for a building life cycle are:

- the fabrication of components
- the construction
- the utilisation
- the renovation and the renewal of components
- the final dismantling

- the treatment after use of components (the possible reuse and recycling of components is taken into account).

The environmental impact of building components or processes (e.g. energy use, transport) can be evaluated on the basis of inventories. An inventory is a table of elementary fluxes, indicating the quantity of each emitted or used substance with regard to the unit of the component or process. The used inventories, collected in the Oekoinventare or similar data bases [7,8], contain the following categories of elementary fluxes :

- the used resources (e.g. rare materials, primary energy, water)
- the emissions into air, water, ground (e.g. CO_2 into air, ammonia into water, oil into ground)
- the created waste (e.g. inert, toxic, radioactive).

These inventories, in the form of excel files, have been used here thanks to the REGENER project [9]. The excel files are transformed into an access file (data processor). This allows to derive C++ objects and to evaluate component inventories by combining materials and processes (e.g. 1 m^2 of window is obtained by adding 20 kg of wood and 13 kg of glass). This data processor also transforms the inventories into impacts (characterization step) in order to simplify the data before transmitting it to the simulation tool. The CML indicators are considered [9].

The overall impacts of a building system, occurring during its life cycle, are calculated by the tool by a one year time step simulation (cf fig. 2) and constitute the ecoprofile of the building.

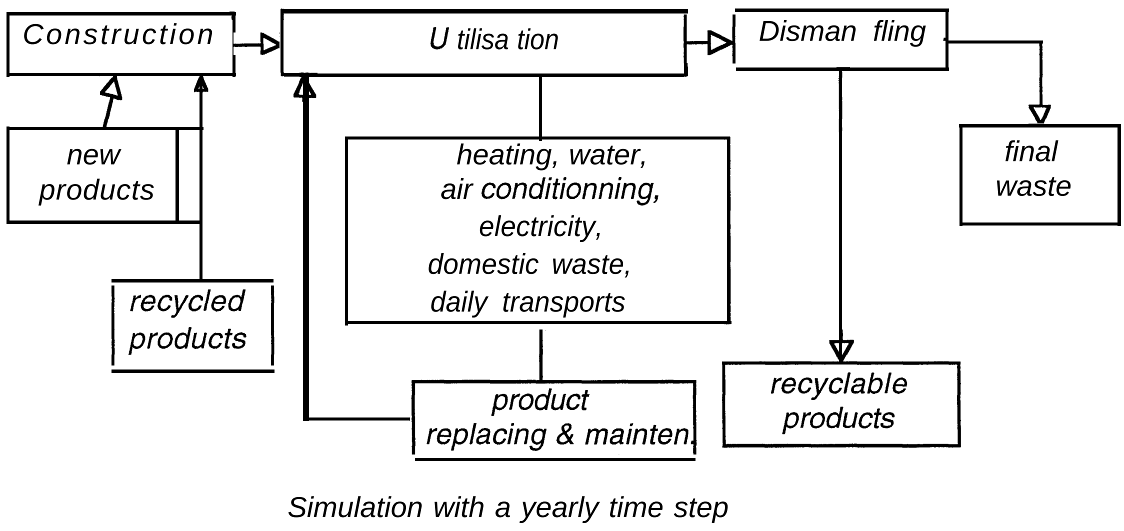

Figure 2: Principle for calculating the overall inventory of a building

This ecoprofile includes 12 environmental themes :

- resources used (abiotic resources, primary energy, water),
- planetary effects (global warming potential)
- regional effects (acidification, eutrophication, smog, human and eco-toxicity, odours)
- waste produced (radioactive or other).

These indicators are represented using a web diagram, in which either the different phases of the life cycle or alternative designs can be simultaneously shown.

3 Example application to transparent insulation

The tool desbribed above can be used for various purposes, e.g. comparing different building sites, occupants' behaviours, architectural designs.. . We illustrate here a possible use concerning the comparison of building components. The objective is to evaluate the environmental interest of two transparent insulation techniques.

3.1. Description of the system

Transparent insulation materials (TIM) have been proposed in order to collect solar gains on opaque walls [10]. A polycarbonate capillary structure, encapsulated between two glass panes, has been integrated in Trombe walls according to fig. 3.

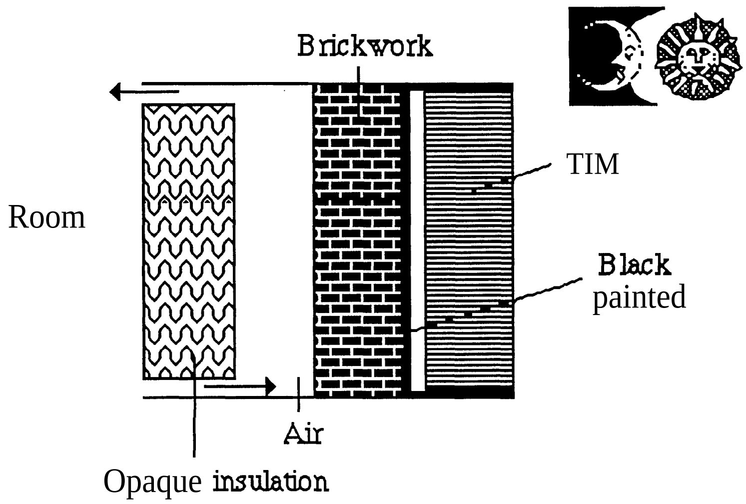

Fig. 3 : schematic principle of a Trombe wall with transparent insulation

A part τ of the incident solar radiation is transmitted through the transparent insulation layer, partly absorbed on the black painted surface of the wall and the heat is transmitted to the brickwork This heat is stored in the masonry (11 cm thick) and transmitted to an air flow, and thus towards the dwelling, with a time delay. In summer or during cold and overcast days, the air flow can be stopped thanks to movable louvers. When the louvers are closed, the opaque insulation layer (10 cm of glasswool) reduces the undesired heat flux. A movable shading device is thus not necessary, which avoids maintenance problems. An alternative has been compared, in which the TIM is replaced by a cheaper polycarbonate plate.

3.2 Generic performance of the components

The physical properties of the components, which are needed for the thermal analysis and eventually for LCA, are the transmission factor and the heat loss factor of the whole transparent insulation layer (polycarbonate structure and glass panes). The transmission factor in terms of the direction of incident radiation has been measured using a " megasphere " [11].

Table 1 : physical values for the two transparent covers considered

material	mean heat loss factor $W.m^{-2}.K^{-1}$	transmission of solar radiation (diffuse-hemispherical)
10 cm encapsulated capillary structure	0.8	0.67
16 mm polycarbonate plate	2.4	0.64

3.2 Productivity of the components

Using these characteristics, we performed in parallel a thermal simulation and measurements on monitored houses [12]. The measured heating load in the two single family houses with TIM are 3,560 kWh and 7,037 kWh. In the first case, the occupants had stopped the mechanical ventilation, and the mean temperature in the house was 16,3°C, compared to 18,8°C in the second house.

Simulation was used to predict the heating load with the same ventilation pattern, a mean temperature of 19°C, the same internal gains and a typical year. The result is 7,000 kWh. This allowed comparison of various systems, a similar analysis giving 7,700 kWh for the houses with the polycarbonate plates. The houses concerned here include 11 m^2 of Trombe walls.

In order to evaluate the productivity of the component, we defined a reference : the same wooden frame house, replacing the Trombe wall by the wall constituting the other facades, i.e. a wooden wall with 10 cm glasswool insulation. With the same climatic data and occupancy pattern, the heating load of the reference house is 8,360 kWh. The energy saving obtained by the Trombe walls with TIM is approximately 1,360 kWh (approx. 120 kWh/m^2) and half this figure using polycarbonate plates.

This productivity varies in terms of the area of component, particularly in the case of wooden frame houses because of their low thermal inertia. This illustrates the interaction between the different parts of building envelopes. Thus, the productivity cannot be presented as a generic characteristic of one particular component.

3.3 Comparative life cycle assessment

Compared to the reference, the passive houses (with a Trombe wall) have a larger impact during the contruction phase because of the supplementary component and a lower impact during the utilisation phase thanks to energy gains. This can be balanced using LCA. The inventory of the TIM (resp. polycarbonate) component has been estimated by combining wood, aluminium, glass and polycarbonate inventories (resp. wood and polycarbonate).

The system limits have been adapted to the objective of this study, focussing on the comparison of two components (with electric heating) : transportation of persons from home to work, management of domestic waste, water consumption have not been considered. A 3,150 kWh yearly electricity consumption for electric appliances and lighting has been accounted for. The life time considered in the analysis is 80 years. The results are the following (fig. 4) for the reference house and the houses with a Trombe wall.

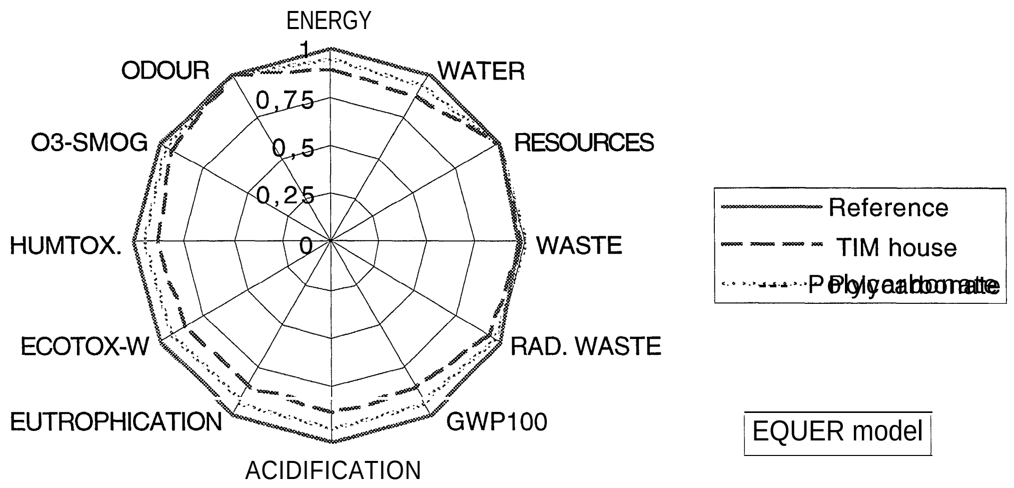

Fig. 4 Comparative ecoprofiles of two different components and a reference

The Trombe wall with a TIM cover leads to a 16% reduction of heating load and 10% reduction of the GWP of the house (about 77 tons of CO_2, or 7 t/m^2). The reduction of GWP related to the utilization phase (78 tons) is much higher than the increase during construction and renovation (about one ton). The performance of the house with a simpler polycarbonate cover is between the reference and the TIM house.

4 Discussion

For components influencing the thermal balance of buildings, life cycle assessment shows the importance of energy related aspects concerning most environmental impacts. But other aspects like depletion of resources could become more important in the future. The characterization of components should concern only generic performance indicators, e.g. physical properties, fabrication or disposal inventories. Performances like the reduction of CO2 emissions depend on the site, the use of the building and the rest of the envelope. It seems thus difficult to provide designers with environmental assessment of components which could be used in every building projects.

Life cycle assessment does not address all issues, and particularly human or eco-toxicity aspects are difficult to assess because the location of the emissions is not considered in LCA. Risk assessment methods would be more appropriate concerning these topics, but require a more detailed modelling of air and mass transfer in buildings.

5 Conclusions

A life cycle simulation tool has been developed and linked to a data base on building materials. This tool has been applied for various projects and studies, concerning different actors (architects, clients,...) and phases (urban and building design, management,...). The example given here concerns a comparative assessment of transparent insulation materials. This example shows that energy related impacts play a large role in the case of components influencing the thermal balance. Environmental performance of components (e.g. the reduction of CO2 emissions compared to a reference) is not generic and depends on building location, on the reference chosen, the use of the building etc. so that characterization of components should rather concern physical properties or fabrication/disposal inventories.

Because energy related aspects are essential in the global balance, energy saving or solar technologies should be considered when studying improvement of the environmental performance of buildings.

Acknowledgements

This work has been supported- by the French ministry of dwelling, the Agency for environment and energy saving, and the Commission of European Communities (DG XII). Our partners in the development of the life cycle simulation tool are INERIS, DUMEZ-GTM, SPACE and Pierre Diaz Pedregal. ETH-Zurich and IFIB (University of Karlsruhe) have kindly made their data base on building materials public, e.g. in the frame of the European project REGENER.

The interrelationship between performance and service life of building products

E. Brandt
Danish Building Research Institute, Hørsholm, Denmark

Abstract
The paper discusses the interrelationship between the performance of building materials and components and their service lifes. The paper suggests to take advantage of the methods and tools developed in working with the performance approach in building for assessing what sort of data is needed, how much information is desirable and what are the minimum requirements. A proposal for a systematic procedure is given. The paper discusses the problems connected with whether testing should be performed on materials or components level, the difficulties of "translating" results from materials to components or from degradation indicators to performance properties.
Keywords: Performance concept, performance data, durability data, service life.

1 Introduction

When we are dealing with the question of predicting service life or assessing long term durability, it is always a prerequisite that the building and its parts has a satisfactory performance. It is without interest to discuss service life or durability if it is not first ensured that the building will function properly under its intended in-use conditions. Performance and service life are therefore closely related and it is impossible to talk in depth about the one without mentioning the other. Service life may then be defined as the time during which at least the essential performance properties are maintained at a satisfactory level.

1.1 The performance approach in building - CIB W60

For quite some years international cooperation on "The performance approach in building" has taken place in CIB comrnision W60. The work has mainly focused on the performance of building materials and components. A number of publications have been issued by the commision including CIB report 64 "Working with the Performance Approach" [1].
The publication gives the basis for a methodology to be used in listing performance properties and criteria for building materials and components.

1.2 Prediction of Service Life - CIB W80

Similarly international cooperation regarding prediction of service life has taken place in the joint CIB W80/RILEM committee working with "Prediction of Service Life". The first result published by the committee is now a RILEM recommendation on Techniques for Service Life Prediction [2]. This recommendation is a methodology for how service life can be predicted using different paths.

1.3 The purpose of this paper

This paper should be seen as an attempt to:

* account for the relationship between the performance of materials and components and the service life
* account for the performance data that are necessary in service life prediction
* give guidance on how and where performance data may be found.

Hopefully this wil make it possible to focus investigations more on achieving results on properties related to the requirements of the user and the authorities. The manufacturers should thereby be better suited to design and use the results of durability tests and the material specifiers better suited to select the best solution.

2 The interrelationship between performance of materials and components and durability

The trend towards the use of the performance approach and performance specifications in building arises from higher expectations of the conditions to be provided by the building, from the availability of improved space planning and design techniques and from the accelerating rate of change of building techniques. The performance concept is a particularly valuable tool especially when new innovative solutions are proposed and consequently the behaviour in use is unknown.

2.1 The interest of the end user

For the end user the major interest in a building he owns or occupies is that it functions properly in accordance with his requirements - and that it continues to do so for a long time. How the performance is achieved is not a matter of concern. The user might not even be interested in what type of roof covering is used or whether a comfortable in-door climate in winter is achieved via insulation or via a good heating system.

Performance of entire buildings is very complex and a lot of the performance requirements of whole buildings are more or less independent of building materials and components e.g. type and size of rooms. On the other hand, in an actual building the proper functioning of materials and components have at least indirectly a big impact on the performance of the entire building, e.g. the proper functioning of the thermal insulation material ensures a comfortable temperature in winter and the roof covering ensures that water is not entering the building. Therefore it is important that materials, components or other building products have properties that ensure the overall performance of the entire building. For the user, one important "property" of all building products is their ability to maintain their performance over at least a specified time.

2.2 Performance over time

To maintain the overall performance of the building each one in the set of building products that constitute the building shall possess certain properties on a sufficient level. This means that some properties, e.g. for a material or component, are critical and can only decrease to a certain level without affecting the overall performance of the building. For example, the watertightness of a roof covering shall remain unchanged over the entire service life. Other properties of the material on the other hand might well decrease without affecting the performance of the building. For example, change in the colour of the same roof covering might not necessarily be considered a problem.

2.3 Common parts of the methodologies

The two CIB committees have each developed a methodology for how to deal with the performance concept and service life prediction respectively, as shown in figure **1** and 2 respectively. In the latter figure the first step is problem definition which includes specification of the user needs, identification of the building context and, identification of the performance requirements. This is inspired by and consequently is very similar to what was done in the work of the CIB committee W60: "Working with the performance approach in building".

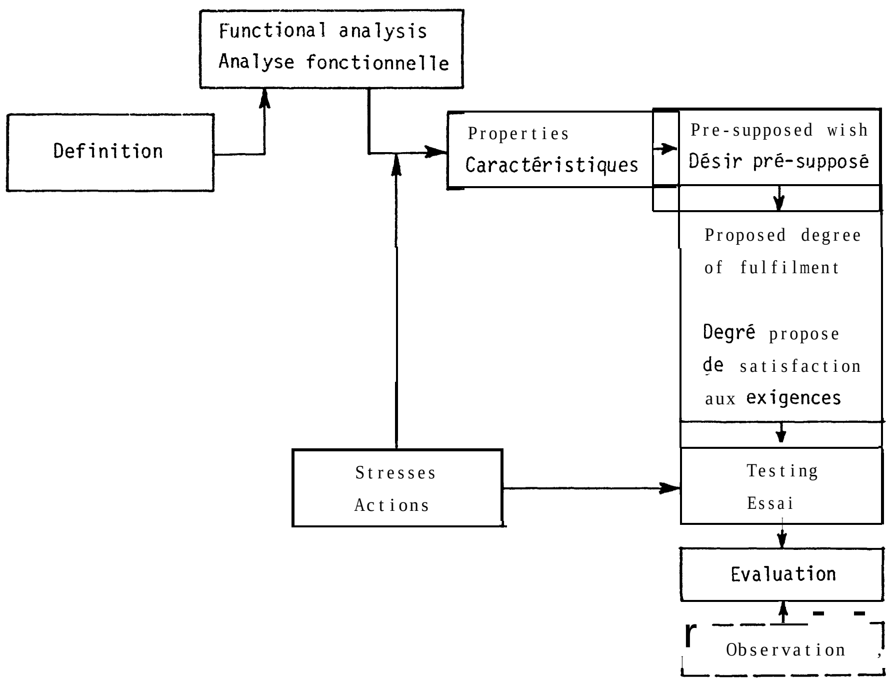

Figure 1. The methodology for working with the performance concept.

It is suggested to take more advantage of the tools developed by CIB W 60 when working with service life prediction thereby making the evaluation of test results performed by the two different methodologies more consistent and more valuable to the user.

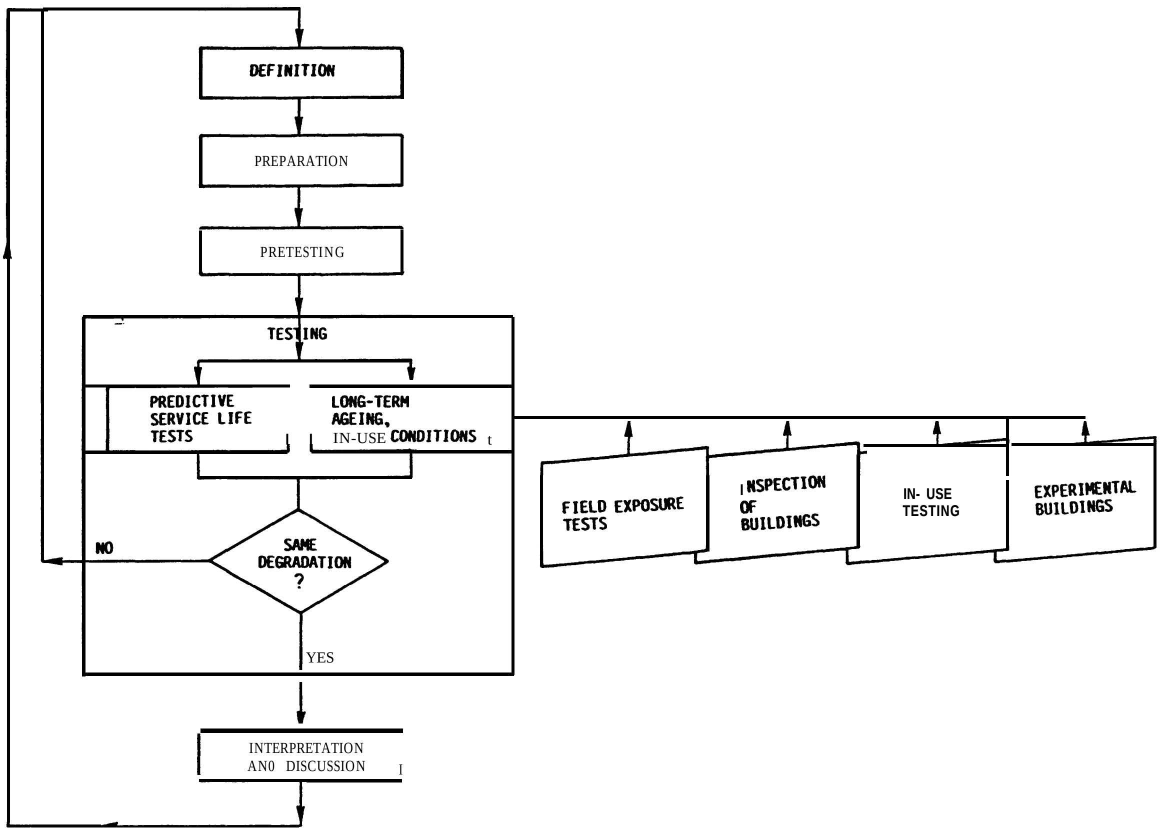

Figure 2. The service life prediction methodology.

3 How are performance properties identified and assessed?

The performance concept has been in use for quite a long time now, and it has found widespread use e.g. in building codes, for specification and as the basis for development of test methods and standards. The methodology ensures that the work is done in a systematic way so nothing is overlooked. This means reducing the risk of being deceived by new products with some apparent and convincing assets but lacking other less obvious, but important, properties which might prove to be fatal to the performance or the service life. The parameters of greatest importance for achieving and maintaining the performance will be determined and we are dealing with those parameters only, whereby it is ensured that time and money are not wasted.

In order to find the performance properties of a building product it is common to carry out an analysis where the functions of the product and the influence from the use are found. On basis of this the properties are determined. The results of the analysis are a natural basis for the design of the necessary performance test methods which are, as far as possible, simulations of the stresses on the product in use. Evaluation is based on whether the functions are maintained under the influence of the antipated stresses from the use. For products meant for general use the influence from the use should be determined as the factors and on the levels most unfavourable to the product, e.g. if a window is intended for general use in a variety of countries the one with the highest level of wind driven rain should be decisive for the requirements to that specific agent.

The requirements must be specified in conjunction with the test methods and should reflect for instance the ability to withstand external load, demands for comfort by the end user and requirements to health and safety as set up by the authorities. The user requirements are independent on the location in which the object is used, whereas the requirements from the authorities and the influence from the environment might vary depending on the location. This procedure is described in detail by CIB W60 in CIB-publication **64** [1].

4 Performance data and ageing tests

The information gathered in finding the performance properties and requirements of a product can be used again in the design of ageing tests. The agents and stresses that were found to be acting on the material or the component during the use and which were of importance for the performance, include the stresses of importance to the service life. The knowledge of these stresses must be combined with information about the actual materials and/or components in order to assess the possible degradation factors of the actual product in the intended use.

In order to limit the number of possible ageing tests it is an important issue to assess which of the performance properties are most critical and which are most vulnerable to the possible degradation factors. The result of this assessment is a decision about which performance properties are going to be used as decisive for the service life. At the same time the stresses/degradation factors that are anticipated to be important are revealed.

When designing an accelerated ageing test it is important to keep in mind, that the service life of a material or component is under the presumption that the use is “normal”. Service life for products which are abused e.g. exposed to greater load, more UV-light or vandalism is impossible to predict.

4.1 Key performance properties

Property	Stress
Air tightness	Wind pressure
Tightness against driving rain	Driving rain
Geometric compatibility	
Ease of opening	Passage of person in case of fire; general use; attempted burglary
Reliability in use	Mechanical movements

Figure 3. List of key properties for a “normal size” wooden window. "Normal size is defined as less than 1500 mm in width or height. The window is with double-glazed panes and are primarily intended for housing not exceeding three storeys.

CIB's Master Lists [4] may be of great help for an analysis of building materials and components and so may information about exposure environment, e.g. IS0 6241. The intention is to set up an exhaustive list of 15 - 20 properties for a component - possibly somewhat fewer for a material - based on every imaginable function of the product and every imaginable stress from the use including the degradation agents from the exposure environment.

Ideally, all performance properties mentioned shall be maintained at a satisfactory level for the prescribed life time. In practice this is, however, very difficult and expensive to achieve. A more pragmatic solution is to work on a more simple basis and look at the most important properties - key properties - for the product. For windows ths more simple basis could for instance be "normal size" wooden windows. For these an evaluation of the properties could result in a reduced list of properties, e.g. as described in Figure 3.

4.2 Performance over time

When working with the performance approach requirements of the product are marked on so-called banded levels, i.e., open ended scales designated with the letters (J), K, L, M, N, 0, (P). The further to the right the property is on the scale the "better" it is. This should, however, be compared to how much is really needed - the "necessary" should be strived at. For example, there is no reason for requiring a window which is airtight to high wind loads if it is intended for use in one-family houses on protected locations. Or, in other words, there is no reason for paying extra for a quality which is not needed. An example of the scales is shown in figure 4. Also shown is an example of how a performance profile is used for characterization of the product and how the profiles can be used for comparisons between a possible solution and the requirement as set up by the specifier, see Figure 5.

K L M N 0

Air pressure 200 300 500 700 Pa

Figure 4. Example on banded level for airtightness of a window (expressed as the pressure at which a certain amount of air passes the window per hour).

It is suggested to take advantage of this approach when dealing with assessment of durability. For the key performance properties the minimum acceptable levels are marked on the scales, and one should never go below these minimum values. In ageing tests the key properties should be tested at intervals to give an indication of how the minimum values are approached. For the properties that turn out to approach most rapidly an assessment or a mathematical model of the service life might be made. Even if this is not possible, the results of the repeated tests might give basis for a qualified assessment of the durability. For the wooden window, for instance air and watertightness might be tested every now and then.

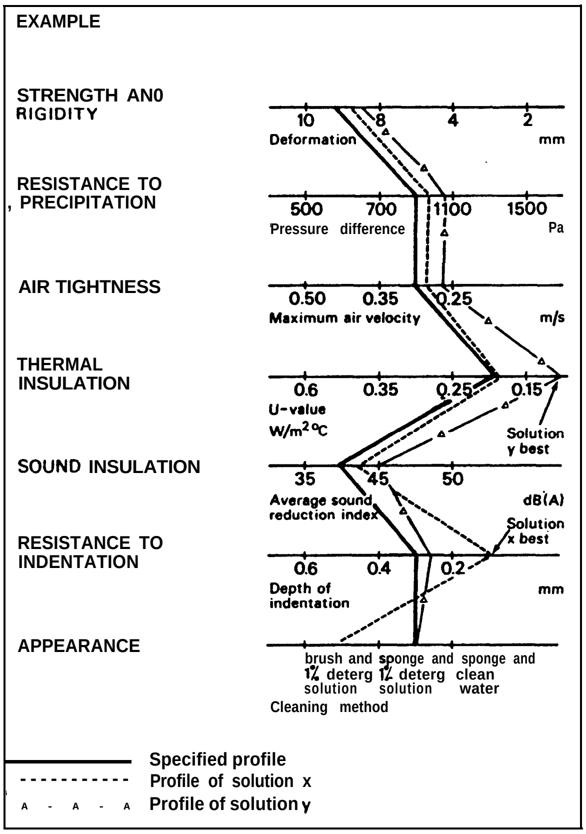

Figure 5. Comparison of performance profiles

5 From test results to performance

When performing ageing tests it is always a question whether tests should be on a material, component or even building level. Normally, testing on a material level is easiest because test specimens are small, the number of specimens can consequently be increased which is an advantage to statistical treatment of results. Besides, it is easy to maintain, for instance a uniform UV-exposure on small surfaces. The difficulties appear when test results on a material level is "translated" into performance of, for example, a component. For a wooden window - as an example - the performance should be put together by the results from the paint (or maybe paint on a wooden substrate), the hinges, the wooden joints, the weather strip etc. Each of these materials has been evaluated on basis of one or more relevant degradation indicators and it is obvious that it is hard to use the results to give any clear statements about the window. On the other hand, materials test are excellent to compare different paints on wood, different weatherstrips etc.

Testing on component level is normally restricted to few specimens due to the size which restricts the statistical use of the results. Due to the size of the test equipment the possibilities of accelerated tesing may be limited. On the other hand the testing takes compatibility and design into account and when it comes to "translation" of test results the difficulties only refer to the uncertainty of the acceleration.

6 Conclusion

Very little exploration on the subject of this paper and especially on the problem of coming from test results to performance has taken place and much needs to be done. Any contribution to a discussion including any possible information on performance descriptions for materials and components, descriptions on how results from ageing test are used in practice etc. will be very much appreciated.

Release and flows of metals from building materials due to corrosion and degradation

D. Persson and V. Kucera
Swedish Corrosion Institute, Stockholm, Sweden

Abstract
Runoff measurements of heavy metals from different material surfaces used in buildings and other materials were conducted to identify potential sources of heavy metal emissions due to corrosion and degradation. The runoff was collected from different metal containing materials during two runoff periods with a total duration between one to two weeks. Elevated concentrations were found for zinc in runoff from galvanized steel, aluzink and paint containing zinc compounds, for lead from PVC surfaces and red lead based painted surfaces, for chromium from new concrete tiles and chemically passivated aluzink surfaces, for nickel from asphalt roofing felt and older concrete tiles and for copper from older concrete tiles. This study was performed on relatively small samples, with a single orientation and during short exposure periods and further research is needed to establish realistic runoff rates from materials exposed on buildings and other constructions during longer exposure periods and with different orientations and inclination of the surfaces.
Keywords: Heavy metals, runoff, corrosion, degradation, building materials.

1 Introduction

Metals are important components in the modern society and are used in large amounts in buildings, in constructions and in vehicles. In the ongoing accumulation of metals in urban environments an increased risk of detrimental effects due to emissions of heavy metals to the environment can be suspected in the long-term perspective. Metals runoff from materials on buildings and other constructions can give a significant contribution to metal emissions in urban enviroments. In recent studies [1] the aqueous emissions of metals such as zinc, cadmium and lead have to a large extent been attributed to emissions from diffuse sources, to which corrosion and degradation of materials containing metals belong. Although the rates of corrosion and degradation of different materials have been studied extensively investigations of runoff from metals are rare. However, realistic values of metal emission rates are essential in order to estimate the contributions from different materials and products to the total flow of metals to the environment.

Metals are used in a wide range of materials and components used in buildings and other constructions and many of these materials are exposed to environments where they can be subjected to corrosion and degradation, for instance roofs and facings, poles and barriers, plumbing installations and motor vehicles. Examples of building materials which are composed of metals or contain significant amounts of metals are shown in Table 1. **As** shown in this table a wide range of materials are possible sources of metals emission when they are subjected to corrosive environments. Metal coatings and metallic materials are obvious candidates, but other materials such as paints, plastics and concrete which are used in large amounts on buildings and constructions may also be potentially important sources of metal emissions.

In a research programme initiated by the Swedish Environmental Protection Agency [2] the flow of different metals from buildings, constructions, vehicles and other products to the environment is evaluated for the greater Stockholm urban environment. As a part of this programme, investigations of metal emissions and runoff rates of different materials are conducted, in the first place to identify materials which significantly contribute to emissions of heavy metals, and secondly to determine realistic values of metal emissions from common building materials. This paper presents results of a study of metal emission from a wide range of these materials containing metals in order to provide a basis for further investigations of metal emission rates from important materials.

2 Experimental

2.1 Performance of field exposures

The samples were exposed at a test site close to the Swedish Corrosion Institute which is located at the outskirt of central Stockholm. There are no local sources of metal emission close to the exposure site except a road with dense traffic approximately 100 m from the exposure site.

The metal samples, the coil coated samples, the asphalt roofing felt and the concrete samples were exposed from the end of April until the middle of May and the PVC samples and the painted samples in September 1997. The materials were exposed 19 days in total, but runoff from the first rain events was not collected. Runoff from three samples of each material was sampled during two periods, each about one week long. The samples were mounted on polycarbonate holders and the runoff was collected quantitively from the samples in containers of the same material. The surfaces were oriented with 45° inclination facing south except for the concrete surfaces which were exposed at 60°.

Table 1. Important applications of materials containing heavy metals in buildings and other constructions

Metal	Materials	Applications	Chemical form
Zinc	rolled zinc sheets, galvanized steel	roofs, faces, gutters, barriers, poles, pipes	zinc
	paints (pigments)	barriers, poles	zinc, zinc phosphate
		roofs , faces, windows	zinc oxide
	brass	plumbing, fittings	zinc
	rubber	tyres	zinc oxide
Cadmium	polymers (stabilizers,pigments),	PVC gutters	cadmium compounds
	glass	traffic signals	"
	coated steel	fasteners	cadmium
Lead	lead pipes	plumbing installations	lead
	fittings	"	lead
	PVC pipes (stabilizers)	"	lead stearate, ...
	anti rust paint	steel constructions	lead oxide
Chromium	stainless steel	roofs, faces	chromium
	concrete	constructions, roofs	Cr^{3+}-,Cr^{6+}-compounds
	surface protection of metals	steel constructions, fasteners, roofs	"
	paints	roofs, facings	"
	wood impregnation	buildings, constructions	"
Nickel	stainless steel	roofs, faces	nickel
	asphalt tar felt	roofs	nickel compounds
Copper	rolled copper sheet	roofs, faces, gutters,	copper
	brass	plumbing, fittings	copper
	wood impregnation	buildings, constructions	Cu^{2+}-compounds

2.2 Materials

The materials used in the field study were chosen from common building materials used on roofs, facings and other components in buildings and other constructions. Most of the materials used were new but a few samples have been exposed to atmospheric environments before the start of the runoff experiments. The following materials were exposed in the investigation:

- Galvanized steel (new)
- Aluzink steel with a coating of 55% Al, 43% Zn, 1.8% Si (new)

- Coil-coated steel, PVC-plastisol coating (new)
- Stainless steel (new)
- Asphalt roofing felt, coated with gravel (new)
- Concrete tiles, pigmented with iron oxide (both new and old)
- PVC gutter (old)
- red lead paintcoated steel (new)
- linseed oil based paint on steel containing zinc oxide (new)
- alkyd paint, anticorrosive paint containing zinc phosphate (new)
- Polyethylene, new, applied as inert surface (new)

The Aluzink is protected with a passivating solution which creates a thin layer containing chromium on the surface; the coil-coated material is chromium rinsed and has a chromium containing primer and a PVC plastisol topcoat which does not contain any heavy metals. The lead content of the PVC gutter was analysed with atomic absorption spectroscopy after dissolving the material. The sample contained 0.6 weight % lead, originating probably from heat stabilizers added to the material during manufacture.

2.3 Analysis of runoff

After collection, the runoff water was acidified with HNO_3 corresponding to 1 ml acid in 100 ml solution and stored in polyethylene bottles. The analysis of the runoff was performed with ICP-AES or ICP-MS (plasma emission spectrometry or plasma mass spectrometry) for all surfaces except the runoff from painted materials and the PVC material which were analysed by atomic absorption spectrometry.

3 Results and Discussion

Concentrations in runoff from different materials are presented in Figures 1 to 8. The concentrations of metals in the runoff from two periods when runoff was collected are presented as mean values and standard deviations of the three samples from the two runoff periods. For the painted materials and the PVC material are the concentrations in the runoff for the two runoff peroids presented separately because of the lrge difference in concentrations between exposure periods.

3.1 Zinc

Significantly higher concentrations of zinc in the runoff compared to the inert polyethylene surface were observed for galvanized steel and Aluzink, see Figure 1 and 2. Zinc concentrations in the runoff from the paints which contain zinc were considerably higher compared to the inert surface and were of the same magnitude as the runoff from the galvanized steel and Aluzink surfaces. However, the differences are considerable between the runoff periods which indicates that the values may not be representative for average concentrations in the runoff from surfaces exposed for longer periods.

It should be noted that the concentration in the runoff from the inert surfaces during the runoff period in April-May 1997 are remarkably high, however, similar values have been reported in rainwater in industrial environments [3] and in roof runoff from residential houses [4]. During the runoff period in September the zinc concentration in the runoff from the inert surface was lower, 0.1-0.3 mg/l which is similar to the concentrations found in other studies [5,6]. An explanation of the high zinc concentrations from the inert surfaces in this study is deposition of zinc containing particles. A possible emission source could be the dense traffic on the road close to the exposure site, which give rise to abrasion of tires containing zinc oxide.

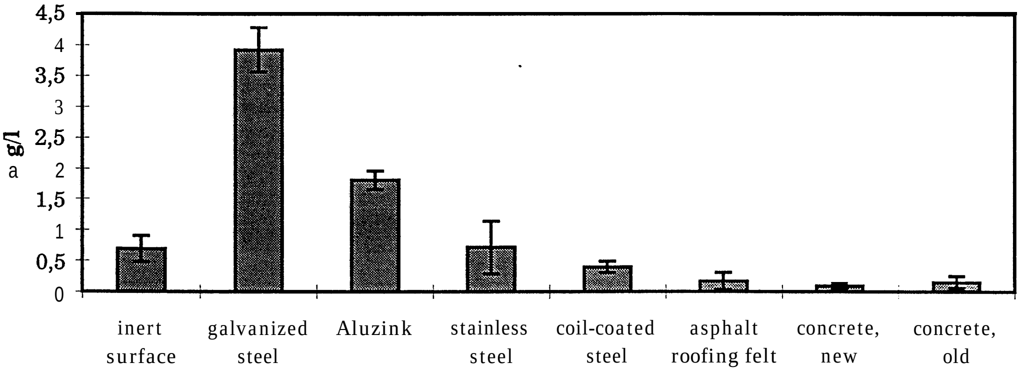

Figure 1. Concentration of zinc in runoff from different materials, exposure April-May 1997.

From materials such as the asphalt roofing felt and the concrete the concentrations of zinc in the runoff lower compared to the inert surface. This is probably due to adsorption of the deposited zinc ions on these surfaces, which is to a large extent influenced by the pH in the runoff and the acid-base properties of the surfaces and the metal ions [7]. In the study mentioned above, the pH in the runoff from surfaces of asbestos cement [5] was slightly alkaline, which is probably true also for the concrete surfaces in this study. The sorption of metal ions on the materials is also influenced by the roughness of the surfaces and the porosity of the materials. This can account for a part of the capability of concrete surfaces and the asphalt roofing felt to retain metal ions. The fact that lowering in concentrations in runoff was not observed for the other metals in this study can probably be explained by the differences in pH-dependence of the adsorption of the cations of the metals.

The amount of zinc released from the galvanized steel during the exposure period was estimated at 120 mg/m^2 if the amount of zinc in the runoff from the inert surface is subtracted. This corresponds to 5.5 g/m^2, year which should be compared with the corrosion rates in Stockholm measured by the Swedish Corrosion Institute which are approximately 3.6 g/m^2, year during 1995-97. The values of metal runoff obtained under the present conditions, i.e. 45° inclination, facing south, is probably representative of a higher value of runoff compared to surfaces with other orientation and inclinations. Other studies [S] have shown that the corrosion rates can differ up to five times for surfaces with different inclination, orientation and degree of sheltering.

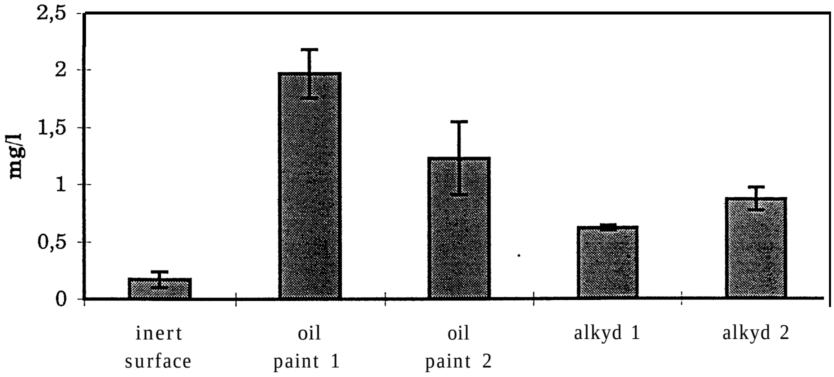

Figure 2. Concentration of zinc in runoff from inert surfaces and materials painted with oil paint and alkyd paint for two runoff periods (denoted as 1 and 2), exposure September 1997.

3.2 Cadmium

As seen in Figure 3 increased concentrations in runoff were not observed for any of the materials investigated in this study. However, in an analogous way as for zinc runoff from asphalt roofing felt and concrete surfaces, also lower concentrations of cadmium were found compared to the inert surface and the other surfaces. The chemical behaviour of cadmium is in many respects similar to zinc and the lower concentrations can be explained by the adsorption of cadmium ions on the surfaces of the materials. The cadmium concentrations are similar to the values reported in the study by Quek and Förster [5], where the effect of lowering of cadmium concentrations in runoff was observed for surfaces of asbestos cement and gravel.

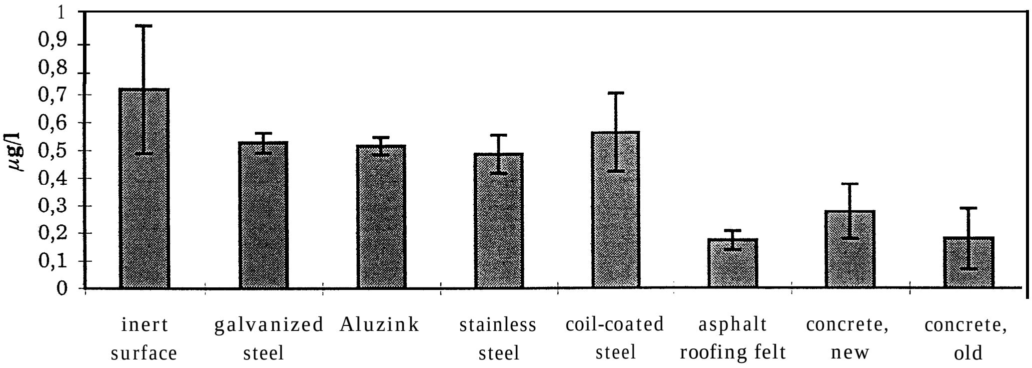

Figure 3. Concentration of cadmium in runoff from different materials, exposure April-May 1997.

3.3 Lead

The concentrations of lead in the runoff given in Figure 4 and 5 show that elevated concentrations compared to the inert surface were only observed for the lead containing PVC materials and the red lead based oil paint. For the PVC material and the painted material significant differences were observed between the first and second runoff period, possibly because of a decreased content of lead compounds in the outer layers of the materials due to the rapid dissolution in the beginning of the exposure period. The lead concentrations for the inert surface were similar to the values in rain bbtained in the studies mentioned above [3,5].

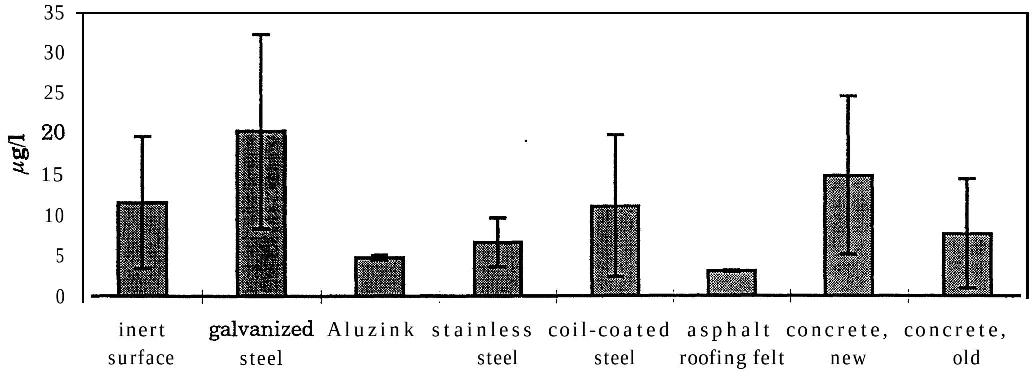

Figure 4. Concentration of lead in runoff from different materials, exposure April-May 1997

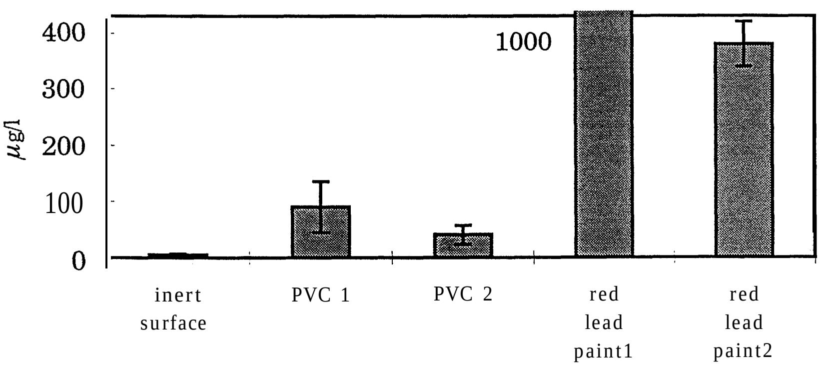

Figure 5. Concentration of lead in runoff from inert surfaces and materials painted with red lead based oil paint and from PVC for two runoff periods (denoted as 1 and 2), exposure September 1997.

3.4 Chromium

For chromium, higher concentrations in the runoff were found for the Aluzink material, which is chemically passivated and for the new concrete tiles. The natural chromium content of cement is about the same as in the earth crust and are depending on raw materials used, usually in the range of 10 to 100 ppm. The older concrete tiles did not exhibit elevated emissions of chromium probabaly because of the lower content of soluble material in the outer layers of the material. The chromium released from the concrete is both in the form of dissolved ions and as particles, probably most in the latter form, but these are not discriminated in the analysis performed in this work. Very low concentration of chromium were found in the runoff from stainless steel.

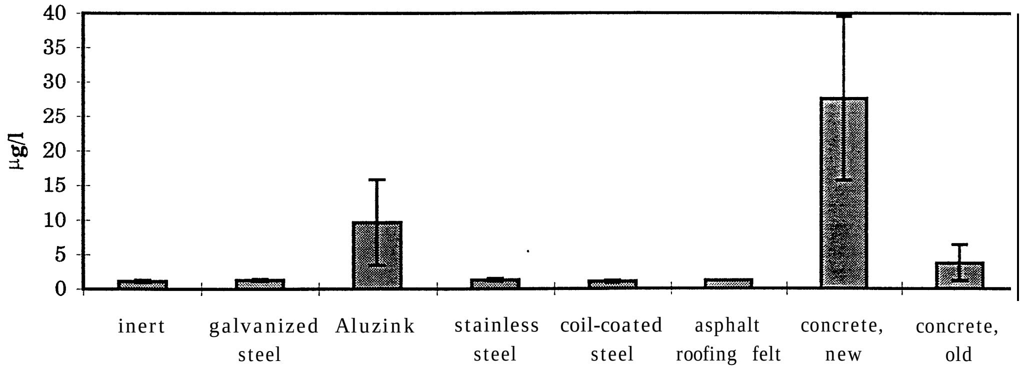

Figure 6. Concentration of chromium in runoff from different materials, exposure April-May 1997

3.5 Nickel

Nickel was found in higher concentrations compared to the inert surfaces in runoff from asphalt roofing felt and from the older concrete tiles. Nickel concentrations in asphalt higher than 1000 ppm have been reported [9] and nickel emissions from the asphalt roofing felt arise probably from the natural content of the material. The source of nickel in the runoff from the older concrete tiles is unknown, but the nickel may origin from raw materials, from contamination in the iron oxide pigments or from added metal slag used as filler. This illustrates the fact that concrete constructions and products in this respect can not be treated as materials with uniform composition and content of metals.

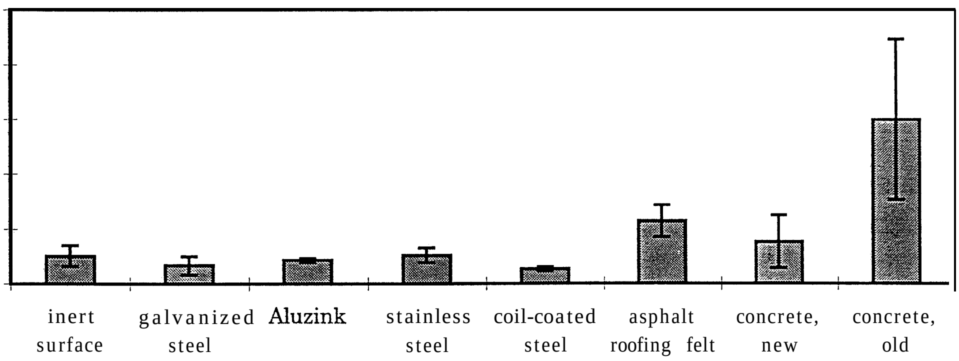

Figure 7. Concentration of nickel in runoff from different materials, exposure April-May 1997

3.6 Copper

The copper concentrations were all quite similar for the different materials except for the concrete tiles for which significantly higher concentrations in runoff were observed for the older concrete tiles. The copper concentrations from the inert surfaces were similar to the values in rain obtained in the study by Quek and Förster [5]. Further studies are currently performed on copper surfaces on buildings in order to determine metal emission rates from copper roofing materials during longer exposure periods.

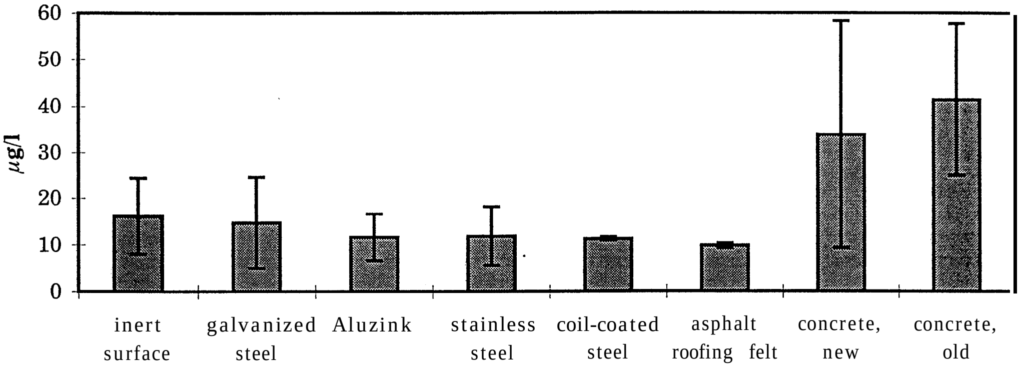

Figure 8. Concentration of copper in runoff from different materials, exposure April-May 1997

4 Conclusions

Investigations of runoff from different building materials have been performed and elevated concentrations in runoff were obtained for zinc from galvanized steel, Aluzink and zinc containing paints, for lead from PVC surfaces and red lead based painted surfaces, for chromium from new concrete tiles and chemically passivated Aluzink surfaces and for nickel from asphalt roofing felt and older concrete tiles and for copper from older concrete tiles. The concentrations of zinc and cadmium in runoff from concrete surfaces and asphalt roofing felt were lower compared to the concentration in runoff from inert reference surfaces of polyethylene, probably as a result of adsorption of zinc and cadmium ions on the former surfaces.

The emission of heavy metals due to corrosion and degradation of materials is a complicated process and is dependent on severals factors such as levels of air pollution, rain chemistry and intensity, inclination and orientation of the surfaces and the age of the material which can lead to build-up of protective layers or depletion of the surface layer of the material. The data collected in this work were obtained during relatively short runoff periods and thus does not permit any conclusions about the rates of metal emissions over longer periods of exposure. Further studies will be performed on materials surfaces on buildings and other constructions over longer exposure periods in order to determine metal emission rates that can be used for- estimation of metal flows from materials to the environment

An Assessment Protocol for Historic Wooden Buildings

J. Veit
German Center for Crafts and the Preservation of Historic Monuments (ZHD),
Fulda, Germany

Abstract
In all countries with historic wooden building tradition, investigations, assessment and documentation of wooden building parts are executed in rather similar ways. National differences are mainly existing for the reason of maintenance skills and modernization measures. Lack of inspection, lost .of carpentry skills and impropper modemization measures are nowadays the main reasons for damages. Changes of building parts and applications made it necessary to evaluate climatic and environmental conditions new.
Anassessment protocol 1s developed as a harmonized system for maintenance tasks of wooden constructions. It includes the interdisciplinary approach for investigation, planning and documentation as well as the concerning techniques. In Germany, Norway, Sweden and Poland practice has been researched and components which are reasonable to be part of „the system" were adopted. The result of this eclectic and supplementing approach was multidisciplinary discussed on workshops at „pilot" buildings of the participating countries. The assessment protocol was developed on the occasion of the tasks at this buildings including representatives of the target users.
The assessment protocol refers to four different user levels of owners and inspection personnel, of architects and other „generalists", of wood specialists and of scientific and „calibrating" persons. The assessment is structured in aspects, like construction and static, wood substrate and also treatments. For each combination of this aspects and user levels adequate working tools are given. The system structures also the timely development of the various tasks during a restoration project and in the course of the subsequent maintenance phase of a building.
Documentation takes an important role for the integration of various results of investigations, assessment and planning and the information transfer to the concerned parties. A key role plays the hierarchical ,,orientation system", which is a code system of the building to link information. A legend for the condition mapping and an atlas with standardized damage types and damage degrees are examples for documentations under user level 2 and 1. Algorithm for the use of this and other tools are developed and prepared for a PC-based application on a geographic information system and a handheld-computer for data collecting on site.
Keywords: historic wooden construction, inspection, documentation, maintenance

1. Introduction

1.1. Wooden building stock and practice of maintenance

1.1.1. Characterization of the Wooden Building Stock

In the historical development wooden construction types became comparable structures all over the world due to climates, resources and use. Even reactions to occuring weak points in the construction were managed in similar ways. In the past there were enough experience which made the maintenance sure in technique and esthetic. Today the building trade and environmental conditions are changing rapidly, there is no time for evolutional development. We are concerned with historic wooden constructions like roof constructions, ceilings, towers, bridges, foundations and mainly half-timbered houses and log buildings with different coverings. In all countries with historic wooden building tradition, investigations, assessment and documentation of wooden building parts are executed in similar- approaches and techniques. National differences are mainly existing for the reason of maintenance skills and modernization measures for nowadays living comfort.

1.1.2. Problem Situation

Wooden buildings have a long history of repair techniques, mostly executed by carpenters. With a well developed maintenance-program the durability of wooden buildings can be several hundred years. Lack of inspection, lost of carpentry skills and impropper materials and modernization measures are the main reasons for damages. Due to changes of building parts and applications it became necessary to evaluate the construction, the climatic condition and the environmental impact new. The situation of about two million German half-timbered-houses is exemplary [3]: In the seventies the interest in protecting these buildings increased and additional requirements for better energy-saving, sound insulation, etc. improved. The removal of plasters and other claddings of the fassade in order to show the wooden construction became en vogue. These conditions together were combined with wrong assessment and improper maintenance-measures. The results were damages and loss of historical building substance.

1.1.3. Investigation, Assessment and Documentation

The causes and motive to define a project for restoration and rehabilitation can differ in a wide range: damages, new requirements for the use of the building or changes of the building and its use are common. A systematic approach is very necessary to keep the budget in limit and to avoid loss of original building substance. The uncertainties about the condition of historic buildings are great. These facts are the reason of the importance of investigations. Although the importance is evident, investigations should not been executed for its own sake. In practice in nearly all restoration projects it is necessary to build up a documentation from its beginning. Fundamental research in archives and files is an - often not understood - urgent need to avoid unnecessary investigations. It is common, that the informations are not linked, they are widespread over the owner, architects, officials, restorators, special experts, craftsmen, etc. due to their different aims. It would be ideal to work on a harmonized concept to acquire and update data continualy in long terms.

1.1.4. Maintenance and Restoration Projects of the Buildings

Historic buildings should have a continuous maintenance with small remedial measures for restoration and conservation as far as necessary. The various terms in the monument preservation give an impression of different activities: maintenance, repair, rehabilitation, restoration, conservation, technology of saveguarding, renovation, restoring, replacement, reconstruction, rebuilding, etc. [2]. Projects, approaches and measures must adjust to the philosophies and requirements behind these terms. Monument preservation has a rich history and regional very different shapes that make a „harmonized system" for an assessment protocol difficult.

1.2. Objectives

An assessment protocol should be a computer aided guideline for inspection tasks and the preparation of restoration projects. For the basic information it is necessary to categorize types and degrees of damages, harmonize phases and levels of investigation, describe investigation methods, define a system for graphical condition mapping and make the assessment rules clear. Of great importance is, that the requirements of the target groups and the implementation in their organizational environment is taken into consideration.

1.3. Methods

In Germany, Norway, Sweden and Poland practice has been researched and components which are reasonable to be part of „the system" were adopted (e.g. [1]). It can be understood as a interim bottom-up solution of best practice, because up to date there is no international harmonized solution achievable. The result of this eclectic and supplementing approach was multidisciplinary discussed on workshops at „pilot" objects of the participating countries. The assessment protocol was developed on the occasion of the tasks at this buildings including representatives of the target users. The pilot objects were wooden buildings in Ebersbach (Germany), Lillehammer (Norway), Stockholm and Gävle (Sweden) and Swidnica (Poland). There were not more time then three days at every object.

New technologies, like the geographic information system „Arcview", and an inspection handheld computer, were also adapted in a pragmatic way to work on solutions of best knowledge and conscience. The team handled the challenge to be multinational and multidisciplinary.

This approach was choosen to get results in this rather complex working field in the frame of one comparatively small project. For that reason the result is scientificly a thesis, in an economic view it could be a first step towards a product.

2. Content and Background of the Assessment Protocol

2.1. Structure of the Assessment Protocol

The assessment protocol is a harmonized system for the maintenance tasks of wooden constructions. It includes the interdisciplinary approach in investigating, planning and documenting as well as the concerning techniques. The assessment protocol refers to four different levels of owners and inspection personnel, of architects and other „generalists“, of wood specialists and of scientific and „calibrating“ persons.
Part of the assessment protocol are information about causes for investigation, investigation techniques, assessment rules, documentation, procedere at objects and maintenance management, examples and references, as well as information about the implementation and use of the system in the organizational environment.

2.2. Assessment Background

2.2.1. Assessment Aspects

To investigate a building means to search for the reasons of its conditions with the aim for predicting the long term condition after executing a remedial measure. The phenomenons have to be categorized, whether they are depending on the construction, on the materials or on chemical applications. Basic assessment procedures are structured in 5 assessment aspects, some examples are given. The detailed assessment criterias are beyond the frame of this paper.

- construction
    - load bearing principles
    - cracks, fractures, deformations, squash, fixtures, joints, etc.
    - constructive wood protection against moisture diffusion and weathering
- timber condition, destroying agencies, wood substrate
    - wood quality
    - fungies and insects
- wood preservative chemicals and paintings
    - wood treatments (tar oil, water-borne, organic solvent, etc.)
    - paints (cracking, flaking, blistering, fading, chalking, etc.)
- adjoining materials
    - fillings in half-timbered houses
    - rising moisture from the ground
    - waterproof layers in connection with wood
- environmental aspect aund climatic conditions
    - phenomenons due to weathering (i.g. driving rain)
    - use (heating, unused rooms, etc.)
    - nearby trees, climbing plants, etc.

2.2.2. Typical Building Parts

Assessment rules are also necessary for more complex building situations: e.g.: in the course of rehabilitation of half-timbered fassades, it is often a „historical“ guided aim to take the covering plaster away to show the wooden construction. A secound aim is also to add a heat insulation on the inner side. Research has shown that such facades should yearly not have more than 140 Liter/m² driving rain. In addition diffusion must be able to the inner side. Air in the wall can have very negative effects, because they interrupt capillarity. Requirements borrowed from standards for modern waterproof facades lead up to use sealing materials which are partly the sources of damages on half-timbered facades. These „assessment rules”, and a lot more constellation of moisture limit values and relations are necessary besides the elementary assessment via the aspects of the previous chapter [3].

2.2.3. Predictions for the Conservation State and General Design Rules

Calculations for historic buildings are rather complex, the materials are different from modern ones and material coefficients are not precise known. In addition the construction principles of old buildings are not following the nowadays standards on which our evaluation is based. For this part of the assessment protocol great uncertainties do exist, in practice its the only way to scrutinize the single case by using „experience“.

2.3. User levels

Investigations should be orderd in precise tasks thematically, economically and in the necessary depth. Here is an urgent need in practice. The workshare and synergetic effects between the concerned parties must be improved. The following table gives an overview of the user levels for the assessment protocol.

Level	Purpose	Minimum User Qualification
1	• Inspection (every 1 to 2 years)of weak points at the construction according to plan	identify critical phenomenons, technical education
	• Inspection (every 5 years) planning of renovation, control of adequate use, cost estimates for maintenance measures	architect, facility manager, craftsmen, technician
2	• Inspection (every 10 ore more years) • begin of a restoration project: basis of design and preparation of tenders • system keeper for documentation and integration of experts recommendations • defining the inspection plan	architect, engineer, restorer, facility manager
3	• order of L2 after definition of special tasks	proofed/certified specialist
4	• very difficult and not usual situations • not object oriented research work	scientist, laboratory engineer

2.4. Investigation due to User Levels

The investigations of all aspects can be executed as

- visual investigation,
- visual investigation with the aid of instruments,
- long and short term investigation measurements at the building, investigation on samples in the laboratory and monitoring
- calculations based on investigation results

A matrix of the levels and the aspects of investigations gives for every combination the aims, methods and tools and the characterizing data of the results. Annex to this matrix containing a short overview over the various „tools“. These are ranging from a damage atlas as a calibrating system for visual inspection in level 1 and 2, over the drilling resistance method for timber sections (level 2 and 3) up to microscopy means for level 3 and 4. It is obvious, that tool boxes are defined for each combination of level and aspect that represent common working fields.

2.5. Documentation of Work and Objects

2.5.1. General Role of Documentation

Documentation plays an important role in the preservation of monuments. Documentation can become a „secondary“ monument when the building is destroyed. Layer techniques on basic drawings and maps are coming more and more to use for the multidisciplinary preservation task. Documents (text, fotos, drawings) on every scale occure and have to be stored. There is neither an international nor an national standard to harmonize the island solutions for the different documentation tasks. A common data base could be ideal, but the question who the systemkeeper could be is very difficult. All who are working at objects are making island solution documentations. It is absolutly necessary to pass a structure to all concerned orders by the owner or representative.

2.5.2. Orientation System

Orientation system is a code system, which identifies every building, building part, element, material and, if necessary, every smal spot. It is an urgent need, that this code has a form, that a user can understand and complete it at the object. The different building types demand typical forms, from which easily the individual orientation system for an object can be generated. Following this the assessment protocol is concerned with:

- generic orientation system (general definition rules)
- specific orientation system (half timbered houses, log houses, etc.)
- individual orientation system (single individual buildings)

2.5.3. Information and Documentation Structure

The assessment protocol is open for various documentation systems. Regional or organizational requirements are acceptable. Three elements are building up the basis of documentation:

- orientation system (code and links)
- object data sheet (basic data of the object)
- system for condition mapping (condition visualization; samples, photos and comments „user surface“)
- inspection question and results

It is obvious that all information are with strict time series information.

3. Application of the Assessment Protocol

3.1. Computer Aided Assessment Protocol

A geographic information system was choosen as the PC-based platform for the assessment protocol. On the GIS are all elements with the basic knowledge for restoration projects and all, which are necessary to do the assessing work in the maintenance inspection sampled.
For the reason of various target groups it can only be a modul system, containing e.g.:

- measurements database on ,,geographical scales“
- modules for characterizing and mapping of the exposure risk factors
- information and user guides for investigation, documentation and assessment
- examples, containing specific results and experiences of objects.

A complementary inspection system has the following moduls:

- handheld computer and main computer program for handling observations at the building site
- library for condition assessment of wood, containing the structure, questions and answers linked to observations of damages on wood

3.2. Consequences for the PC Assessment Protocol in Practice

3.2.1. Possible System Keepers and Organizational Prerequisites for the System

The vast possible system keepers or users make clear that the system can only be a component system: facility managers, owners, architects, restorers, engineers, offcials, funding institutions, education institutions.

3.2.2. Workflow at Objects

The workshare and organizational environment of the system keepers and experts, which deliver information to the system, has to be taken into account to reach synergetics. This means that not only the pure content but also the acceptance and implementation of the assessment protocol is of great importance. For that reason a standardized networkplan is developed, which gives a frame that can be adopted for restoration projects. It distinguishes the 9 following phases. Each of the phases contain between 10 and 20 serial and parallel activities. The activities are subdivided by checklists for various aspects of economic, technique and organization. The connection to the documentation is checked within this system. The items of the check list have information leaflets as far as necessary.

Phases of the standardized network-plan:

1.) development of the project (orientation, objectives, feasibility check)
2.) object identification (acquiring the basic data, responsibilities)
3.) objective analyzation (user requirements, necessary investigations, first concept for the building)
4.) building and condition survey (orientation system, building history research, condition assessment, correlation of results)
5.) restoration and rehabilitation concept (utilization, general concept, building component measures, priorities, test application, monitoring, consequences)
6.) commitment and execution of remedial measures (drawings, descriptions, time scale, tenders, cost planning, placing, execution of work)
7.) acceptance and final documentation
8.) starting the maintenance management (user guide, inspection concept, responsibilities)
9.) maintenance (inspections, assessment algorithm, service and repair)

4. Conclusion

A concept for a PC-based assessment protocol for historic wooden buildings has been developed. The lack of harmonized regulations and working tools became obvious. For all that it was possible to reach a harmonized working platform. The next step should be to work on objects, included in their daily practice. The sticking point is the acceptance and implementation of the svstem in pilot user organizations.

5. Acknowledgements

The European Comission made it possible to start this work in the frame of the project WOOD ASSESS under their Environment and Climate - programme by partwise funding. The assessment program was workpackage 1 in this project. Gratitude should be given to the new built international and interdisciplinary team that was able to handle this complex challenge with great commitment.

Longtime performance of plastered external walls made from autoclaved aerated concrete

K. Nygren
Yxhult AB, Kumla, Sweden

ABSTRACT
The article describes the state of the art in this Swedish project, aiming to identify degradation factors and mechanisms of plastered AAC wall systems. The scope covers both inorganic and organic based plaster systems intended for exposure in some European countries for a period of 5 years, with the final goal to predict durability and service life from research work following the methodology provided in CIB/RILEM technical recommendations and IS0 standards.

The article describes the various parts of the project, the performance criteria and characterisation of materials used in the system. The main part of the article refers to observations and conclusions made from experiences and field inspections of thin plaster systems applied to industrial buildings in the area of Örebro and Kumla. Observed damage types and possible degradation processes in organic and in-organic based plaster systems are described and discussed.

Based on theses studies it was concluded that inorganic plaster systems generally degrade to a lesser degree than organic systems. The duration and level of moisture content in the surface area are seemly a very important reason for the increased risk of degradation; inorganic systems seem to stay dryer in the outer part of the walls between periods of saturation. Another important factor is that the difference in need for maintenance between different plaster systems is not often considered by asset owners. Design detailing is also very important to achieve durability and long time performance. The micro climate on building facades in combination with unexpected effects of detailing are seemly much more important for degradation processes than knowledge of the average macro climate in the area.

Finally some future research work is outlined and some possible degradation mechanisms are provided for organic and inorganic plaster systems.
Keywords: Autoclaved Aerated Concrete, Durability, Plasters

1 Introduction

1.1 Background

Autoclaved Aerated Concrete (AAC) is a commonly used building material all over the world. In Sweden, AAC is mainly used in the external shell of buildings and the external walls are often plastered as an aesthetic and protective measure. As for most materials, research work for AAC has usually concerned mechanical and physical properties in fresh material. Little is known about the degradation processes of AAC and the system plastered AAC under long time exposure to environment. The aim of this Swedish project is to identify degradation factors and mechanisms of plastered AAC wall systems based on long term exposures and accelerated short term ageing tests. The final goal is to predict durability and service life in these systems from research work following the methodology provided in CIB/RILEM technical recommendations and IS0 standards.

1.2 Standards

The methodology and a decision tree for conducting the research work on durability has been developed by CIB/RILEM and subsequently adopted by ISO/CEN. The existing guidelines are in the form of two drafts from ISO/TC59/*Sc14*-DESIGN LIFE. The first two of five documents in the series “Buildings-Service Life Planning” are: “Part 1: General Principles” and “Part 2: Service Life Prediction Methods”. The different steps to be carried out are described in a scheme obtained from ISO/WD 15686-2.2.

2 Project Definition

2.1 General

Within the overall project the degradation in plastered AAC systems will be determined at an European level. The AAC material in the exposures will be taken from one single factory and will be combined with a number of organic and in-organic plasters. The whole project consist of a number of sub-projects whereof the ongoing projects are mentioned later in the text. Exposures in different climates in Europe and related laboratory tests will start in 1998 and continue for a period of 5 years. The intention for the final work of the project, comprising all the steps in ISO/WD 15686-2.2, are to establish damage functions for the systems being studied.

2.2 Performed project parts

The following project parts have been carried out by researchers from the Royal Institute of Technology, Gävle and those from the industry involved in the project.

- A pre-research project was started in the autumn of 1995 by Yxhult AB and KTH, with laboratory tests in order to determine suitable methods for measuring moisture in AAC walls under field conditions.
- In October 1996, Yxhult AB and Optiroc AB, equipped a part of a plastered wall to a house in Kungsbacka, Sweden, with instruments for continuous monitoring of moisture conditions and surrounding climate for one year.

- In August 1997 the second part in the project just mentioned was started by laboratory testing of physical properties of 12 different plastered systems. Tests for water vapour diffusion and water uptake were completed and freeze-thaw tests are being conducted.
- In December 1997 a first inspection of industrial buildings in different ages was carried out in the area of Örebro and Kumla, Sweden, with the aim to verify the status of different systems of plastered AAC components.
- As one of three sub-projects, microscopy technique is being developed for a potentially more accurate and quicker analyse of physical material data. The other sub-projects deal with the effects of water repellents to the properties of plastered or non-plastered AAC and as well, the development of mathematical models for moisturing flow processes in the system plastered AAC.

2.3 Field exposures

The intention for the choice of environment for field ageing exposures are to give the spectra of the outer limits for some systems of plastered AAC. The different climates for planned exposure tests stations have been chosen mainly considering the amount of precipitation, range of temperatures, solar radiation and pollutants such as SO_2 and NO,.

The field stations shall be designed as ventilated and heated, closed cabins. Monitoring of temperature and moisture conditions in and on the exposed plaster systems will be carried out continuously. Material analysis will be done yearly based on drilled cores taken from the test samples. The first reference exposure station will be built in the first half of 1998 in Gävle, Sweden. RH, UV-diffuse and global radiation, wind speed and direction, precipitation and SO_2 and Cl- contents can be measured at this site.

2.4 Specification of performance criteria

The function fulfilled for external walls are in general terms loadbearing and / or as protection against the climate as well as architectural values.

In this project identifying of early warnings of degradation related to properties and composition are a central interest and may lead to developing criteria for maintenance needs and estimating renewal costs. Inspections of buildings may give the pattern of damage types and possible degradation mechanisms.

The performance criteria for the system plastered AAC should be based on loss in physical properties, loss in protection against weather factors and loss in appearance. Properties that are of interest to measure are water vapour permeability and water absorption rate. Loss in these properties to a certain extent may serve as a basis for a classification of plaster systems. Micro cracks and chemical decomposition in the system are early warnings to these degradation mechanisms. Loss in strength can also be judged by direct measurements. Loss in aestetic performance can be judged by a classification system that considers colour degradation, gloss loss, fungus and algae growth and cracks.

Critical values of the properties previously mentioned depends on the type of plaster system and the intended in-service environment for the system.

2.5 Characterisation of materials

2.5.1 AAC

AAC is formed mainly by siliceous fine materials, usually fine ground sand, calcareous materials such as lime, cement and / or minor amount of additives like gypsum. The materials are mixed in water and the slurry is cast into steel moulds and rised by hydrogen gas from the reaction of aluminium, powder or paste, in the alkaline slurry. Finally the curing is performed by an autoclaving process, saturated steam at roughly 12 bar and 190 ^oC.

AAC is recognised by its high porosity, ca. 80 % of the volume consists of pores. The pores are usually classified as micro capillary, macro capillary and air pores. The first two classes of pores include pores with diameters from ca. 10 nm to 100 μm and correspond to about 40% av the pore volume.

Chemically, AAC consists of calcium-silicate-hydrates and oxide compositions. The pH-value, ca. 10 in the fresh material, is less than in dense concrete. The structure in MC, is micro-crystalline and formed mainly by tobermorite platelets which are more stable than normally cured concrete [1].

2.5.2 Plasters

2.5.2.1 Organic plasters

Organic plasters for AAC are normally based on an acrylic resin binder with siliceous fillers and grains forming the surface texture. The normal system in Sweden consists of two treatments and starts with a primary coating followed by a secondary spraying of the surface with a texture forming layer. The recommended weight of plaster material to apply is at least 1.8 kg/m^2.

2.5.2.2 Inorganic plasters

Before the 1980´s, a two-layer lime-cement mortar was often used in Sweden as a thin plaster system. The first layer was cement rich in comparisson to the subsequent layer to strengthen the surface of AAC and to prevent moisture suction from the fresh mortar applied as the second layer (total thickness of maximum 3 - 4 mm). The second layer served as the aestetical treatment forming the texture. For dwellings usually thick, three layer lime-cement plasters are used (total thickness of 12 - 20 mm), especially for block walls.

3 Degradation agents

Degradation agents are listed in IS0 6241: 1984, Table 4. The agents are classified according to their own nature and origin, as mechanical, electromagnetic, thermal, chemical and biological. All agents reported in the CIB W80/RILEM140-PSL report “Environmental Characterisation including Equipment for Monitoring” [2] are applicable and possibly involved in the degradation processes of plastered AAC. However moisture, temperature, UV-radiation, air pollutants and acid rain likely forms the most active part in the degradation process for plastered systems.

4 Field inspections of built environment - industrial buildings

4.1 General

Inspections of the status of build environment is an important part in the process. **A** first inspection of industrial buildings have recently been carried out in the close surroundings of Örebro and Kumla. These inspections and experiences from many other single inspections have made it possible to formulate some conclusions over the degradation process in thin layer plaster systems. The buildings studied included light mechanical industries or office buildings. All buildings had a normal heated, indoor climate and seemingly dry activities.

4.2 Systems

The component system observed in the field inspections consisted of homogenous reinforced AAC wall components coated with thin organic or inorganic plaster systems. The AAC materials in the inspection round had various ages and therefore different densities. Due to the adoption of higher requirements in thermal properties in Sweden, most delivered components had a dry density of about 390 kg/m³ after the end of the 1970's. Before that time, normal dry density of such components was about 480 kg/m^3.

4.3 Specification of environment

The environment at a macro and meso (urban) level in this region of Sweden is characterised as an inland climate with moderate SO_2 levels ($< 20\ \mu g/m^3$) and driving rain of 300 kg/m^2 (annual mean value) and a maximum day and night mean value of 45 kg/m^2 [3]. The landscape is flat with an open terrain. Orebro is located 5 1 m above SL and at the following geographical position: Lon. E $15^o3'$, N$59^o15'$. Analysis of rain pollutants is not yet available.

4.4 Selection of buildings

The buildings were chosen in an area with as uniform environment as possible. From each decade beginning in the 1950, 5 representative buildings were chosen in order to see possible changes in behaviour of the systems due to age, plaster system and different composition of AAC. The plasters applied were of different chemical compositions. Among the buildings inspected there were lime-cement plasters as well as organic plasters with acrylic binders. All plasters were, however, of the thin art masters with thicknesses varying from 1 to 4 mm.

4.5 Sampling of information

The presence of algae growth, crack types and widths, mechanical and structural damages around the buildings was documented made by photos, video tapes and notations. Frequent measurements of the moisture conditions in the outer 15 mm of the AAC material were carried out in different heights around the buildings by a conductance type electric moisture meter equipped with non-insulated pin-electrodes of 15 mm length. Sampling of other building information such as year of construction, wall thickness, AAC density and indoor climate was also carried out.

4.6 Damage types

4.6.1 Algae growth, fungi growth and discolouring by fungus

Most algae growth was noticed on organic plasters. The algae attacks were noticed especially in North and North-East facades together with the indication of a high moisture content. Especially severe algae growth was observed on several base elements. Discolouring was noticed in organic plasters in the same facade directions as mentioned. Fungi growth, lichen, was noticed on a few buildings, but only on mineral based inorganic plaster systems. The reasons for the difference in the level of fungal attack when comparing organic and inorganic systems may be that inorganic plasters have an alkalinity that restricts fungal growth and as well are on average kept dryer.

4.6.2 Cracks

In systems with inorganic plasters there were very few cracks observed. The surface moisture content indicated in these systems were relatively low at the inspections and were of the same magnitude in unprotected damaged spots as in plastered areas. The conclusion from this is that these systems are open for moisture diffusion and moisture absorption and that the system do not contribute to a built up moisture content. The duration of a moist state is also likely shorter than in organic systems.

Systems with organic based acrylic plasters showed a high variety of crack patterns. Some buildings were free from cracks and other showed many cracks. South and West facades were the most cracked sides and particularly the bottom base elements up to number 2-3 were cracked. Components bridging over longer openings were also often cracked. Very few buildings were maintained by repainting. Thus most buildings with organic plasters, also from the end of the 1980’s showed the need for renewal of the plaster. Indicators for maintenance need included beside cracks, chalking and colour loss.

4.6.2.1 Crack patterns

4.6.2.1.1 Vertical cracks

The most frequent type of cracks in horizontal components were vertical and regularly spaced within the length of the components. The width of the vertical cracks were mainly 0.05 - 0.20 mm. In inorganic plastered components very few cracks were noticed.

4.6.2.1.2. Horizontal cracks

Horizontal cracks were related only to organic systems and near the horizontal reinforcement or the centre line of the components. The actual facades for these type of cracks were South and West facing. The indicated moisture content in these parts of the facades where generally higher than in other sides of the same building.

4.6.2.1.3 Irregular crack pattern

This type of crack pattern was only related to organic plasters and especially to highly moistured parts of the facades. The crack width were of 0.05 - 0.10 mm in size. This type of crack pattern in walls seemed also to be more frequent in areas of the building without heating.

4.6.2.1.4 Structural/design cracks
Structural cracks due to mistakes in design and unsatisfactory work were clearly evident and could be seen where joints between building parts were sealed with a too stiff sealant product or having an improper width. Also damages of components supported on wrongly designed steel plates was common.

4.6.3 Freezing damage
Freezing damages were rare, but more evident in buildings from the 1960's. In the surfaces to a framing of an industrial door, typical unevenness in the AAC surface was noticed in the damaged parts and also small micro cracks. An other freeze damage, crack and tendency of splitting, was noticed in a base component in contact with a snow-drift.

4.6.4 Mechanical damage
A considerable number of locations where mechanical damage was evident was observed on the entrance sides of buildings. Normally there is an asphalted transport surface on one side of an industrial building. These areas generally cover the ground close to the base components due to transports through the doors to the manufacturing locals. The damages noticed are derived from trucks, damages from pallets and steel sheets against the walls, snow clearance machines and so on. All these damages could be avoided by careful design and by considering barriers in front of the walls.

4.6.5 Blisters
Blisters were noticed only in one case. It was in an organic acrylic system and the reason were judged as a combination of a too water vapour tight system and a high humidity in the wall. Some blisters were cracked and had peeled off.

4.4.6 Peeling
Peeling of the plaster was noticed in the case mentioned before under blisters and also in some other buildings where the degradation of the surface had not been repaired.

4.4.7 Dirt
Dirty components were noticed where elements were used in base components due to splashes from open ground or asphalted areas.

5 Conclusions of field inspections

5.1 General
Though the climate in the region of Örebro is considered moderate, the visible effects of a more severe micro climate were found to dominate in all damages seen in the inspection of buildings. Especially the parts of the wall close to the ground level were often attacked by algae, moisture and cracks. Since crack formations were frequent the reasons therefore should be further investigated. The higher density and strength in old AAC components had further a positive effect to the level of damages in organic plaster systems but usually the same pattern and importance of the location are valid.

5.2 Degradation due to type of plaster

Inorganic plasters showed the best performance in the inspections and very few signs of degradation were observed. The moisture properties in these systems therefore seem to be suitable in moderate climate. Visible damages in these thin systems were seen as vertical cracks from shrinkage, which in comparison with those in organic systems were much more widely spaced. The observations of surfaces in connection with cracks gave no signs of deterioration in inorganic systems. The reason therefore is probably a levelled moisture content over the surface independently from eventual crack formations. Inorganic plasters also have a good tensile strength and a thermal expansion close to that of AAC.

Organic plasters, acrylic based, showed many types of degradation patterns and most of them were cracks and algae attacks due to a high moisture content. Observations of surfaces close to crack formations showed in many cases also severe signs of deterioration. The reason for the observed differences in status between inorganic and organic systems seems to be that the time for renewing treatments of organic plasters is much shorter than for inorganic plasters but this fact has not been considered by the asset owners. If regular maintenance had been adopted in accordance with the type of plaster, the problems observed from the inspections would have been much less. You can also say that the sensitivity for degradation affects in this type of organic plasters is much higher than in the inorganic systems studied.

5.3 Degradation due to moisture conditions

Generally it can be stated that the inspections have shown that degradation by environment is always more severe where there is a high moisture content in the surface of the components. The duration and the frequency of the moist states are probably also two very important factors for the degradation rate in a plastered AAC facade.

The highest indicated moisture content during the inspections has been found in acrylic plaster systems, followed by visible signs of degradation such as cracks, peeling and algae growth. The acrylic systems are likely to have a higher moisture content in average than inorganic systems even when the latter might have higher peak values, for shorter times however. The time between attacks from driving rains is of course essential, but the region of Örebro is quite moderate in this aspect. A parallel can also be drawn to analysis by scanning electron microscopy of acrylic paint applied to wood specimens which have shown a great number of capillary pores in the acrylic paint with a diminishing size from surface to bottom that indicates that a capillary suction effect is possible in newly applied systems without imperfections [4].

The maintenance intervals, the detailed design of buildings as e.g. the base height and the performance of the facades are very important factors to consider for durability. These design factors combined with the micro climate in certain points to a building, can affect the plaster system more severely than estimations made from the average macro climate given from weather stations for the area may indicate.

5.4 Degradation due to freeze-thaw damage

Very few damages were deemed to be caused by freezing and thawing. Small localized damage areas were noticed with an origin from freezing at some exposed positions of a few buildings. Non-plastered AAC usually possesses a good resistance to freezing [1] and in this part of Sweden freeze-thaw damage is considered rare which was understated by this inspection. However, in the past in this region, a considerable industrial area with buildings of vertical components were damaged due to freezing effects. In that particular case the water outlets from the roofs were improper designed and the applied organic plaster was much thinner (paint coating) than that required and therefore perforated by pin holes, acting like strainers for water. Other parts of Sweden such as the West coast, have also very few reports of freezing damages. The reason for this can be found in the moisture properties given by the percentage and size of the active pores in the pore system [5]. Several theories for freeze-thaw processes in AAC have been established.

6 Possible degradation mechanisms in plastered AAC

6.1 General

Theories for the deterioration process in plasters may be based on the descriptions of agents in the CIB W80/RILEM 140-PSL report [2] and experiences of the behaviour of different AAC systems.

6.2 Chemical degradation in AAC

The moisture content in AAC materials depends on many environmental factors besides the climate, e.g. the type of plaster. Since the knowledge of moisture conditions is important for assessing the possible decomposition by chemical attacks, the critical moisture content should be determined for the effect of e.g. sulphur dioxide solutions, forming sulphurous acids, which are known to lead to a slow decomposition of AAC. Carbon dioxide gas in solution with water also forms carbonic acid which is a slight acid solution which dissolves calcium carbonate. The synergistic effect of different combinations of e.g. these agents to AAC and plaster systems are not fully known and should therefore systematically be studied in the future. Spicker has studied the chemical resistance of AAC to alkaline and acid solutions and found that AAC has limited or little resistance to weak acids [6]. Furthermore, the need for recording degradation over long periods is also pointed out.

The process of carbonation is not quite explained for the entire range of moisture conditions in AAC. Thus, the reaction rate has been observed to be slow both in dry and saturated materials [1]. This turns to the thought that there might possibly be an increased rate of carbonation in the external surface layer and / or in the crack surfaces due to a certain critical moisture content. In the inspections, the observed moisture content related to cracks has been higher in organic plaster systems compared to inorganic systems which also makes the carbonation rate in crack surfaces interesting to study more closely.

6.3 Degradation in inorganic plaster systems

The degradation in inorganic systems may be caused by chemical or physical incompatibility between mortars and AAC materials. These cases are known and should, however, be avoided by proper specifications in design of the systems.

The long term degradation of inorganic systems are likely to originate from leaching procedures, in the plaster as well as in the AAC, with water as the main solvent. The leaching process causes gradually degradation of the properties in the system as well as a change of the composition in the matrixes of the materials. The rate of the leaching processes in walls very much depends on the moisture conditions. In areas affected with a moderate level of driving rain the rate of degradation are probably slow due to short moist state periods but signs of degradation should possible be more easily recognized in the crack systems there moisture migration are more intensive.

6.4 Degradation mechanisms in organic plaster systems

Organic plasters based on acrylic resin are affected by UV-radiation and thermal variations. Chalking, fading and embrittlement by chain scission are known as visible and mechanical signs of ageing for these systems. Degradation by these factors can be assumed to affect the moisture protection properties of the plaster. Cracks noticed in this inspection have also been found to be more apparent in organic compared to inorganic systems. The formation of the first crack in the system may be caused either in the plaster or in the AAC material. Cracks starting in the plaster are likely depending on degradation of the plaster itself causing embrittlement and fatigue due to movements caused by variation in moisture content and temperature. Cracks starting in the AAC material cause the same increased water uptake and accelerated degradation in organic plaster systems. Cracks starting in the AAC material may be caused by many degradation agents, e.g. mechanical as well as chemical ones. The frequency, amplitude and duration of the moisture content to a certain critical level may be a basic assumption in forming cracks. Cracks propagate due to the local stress situation over the cracks as described in [7]. Agents forming the stresses may be caused by e.g. thermal and moisture actions.

The negative effect of cracks on the moisture balance of organic plaster systems applied to AAC has been shown by Sandin [8]. Cracks give the effect of increase in water uptake and are also followed by increase in movements from wetting and drying out procedures which secondary will cause more severe cracks. Then the water transport is relatively much higher through cracks than through the surface; the importance of water penetration in cracks may also be essential for degradation by leaching in surrounding materials. Water available in the crack system absorbs into the AAC material with a possible increase in the process of leaching and leachate transports caused by acid rain or dissolved pollutants. Cracks originating from carbonation should give the same latter process of deterioration in the AAC material.

6.5 Degradation by freezing

Theories for freeze mechanisms and determination of the critical moisture content in AAC for freeze damages are earlier established and referred to in several articles. Severe freeze damages are considered to occur when at least the micro and macro capillary system has been filled with water which corresponds to a moisture content of 44 % by volume. Above that moisture content an expansion in specimens have been measured and specimens with less saturation have shown even more contraction than expected from the temperature [9]. Another earlier source states that micro cracks in the structure of MC occur already at 60 - 70 % by weight (ca. 25 - 35 % by volume)

[10]. In the capillary pore system water is liquid at temperatures considerable below zero and therefore freezing starts in adsorbed water to surfaces of air pores or water filled small air pores forming a pressure in the system. When the average pressure in the matrix becomes higher than the tensile strength cracking will occur.

The lowest critical moisture content at which freeze damages may be detected in a micro scale is not yet defined. Fatigue and a succsessive degradation by freeze-thaw cycles at a rather low moisture content may be a possible degradation mechanism.

The difficulties to fill enough air pores in AAC to cause deterioration by freezing is well known, but a surface considerable frozen below zero and normally saturated may increase the moisture content in a following thaw period if ice in the pore system is melting in the outer parts and suction of melted water is prevented further inwards by a still frozen area. If the surface is covered by a film of water, melting ice will probably cause a suction in the pore system due to decrease in volume which will give a possibility for a higher degree of saturation. By these reasons a thin layer of MC probably will reach the critical saturation needed for freeze damages by scaling.

Prediction of Durability for Performance-based Codes

A. F. Bennett
Building Research Association of New Zealand

Abstract

New Zealand has had a performance based building code [1] for four years. The code superseded a prescriptive building system which effectively defined in detail how houses and low rise buildings should be built. The code sets out required performance levels in 35 areas which must be achieved in order for a building consent to be issued. These areas include structural design, weatherproofing, energy efficiency, plumbing and durability. The durability clause differs from the others in that it contains specific default minimum service lives for buildings and their components. The durability provisions apply to any part of a building which is fulfilling another code requirement (eg. structural stability), but do not cover aesthetic considerations.

Acceptable solutions and verification methods have been developed for most parts of the code which specify ways of meeting the building code or ways of establishing compliance through test or calculation. In the durability area however, methodologies and test procedures for predicting service life are still the subject of intensive research. Despite many hundreds of test methods published in reports and Standards, few accurate predictive techniques are available. As a consequence, the verification method for the durability clause provides guidance on the ways in which a durability assessment should be carried out rather than referencing test methods. This approach is also seen in the draft documents produced by the ISO TC 59 "Building Construction" subcommittee SC3 Working Group 9 looking at service life prediction methods. The New Zealand experience shows that while specific test methodologies which would enable durability predictions to be made for a wide range of materials would be preferred by industry, continued development and refinement of guidance documents such as those produced by TC59, offer the most realistic chance of improving service life prediction within the building industry.
Keywords: durability, performance, codes, prediction, test methods

1 Introduction

Ensuring that buildings have an appropriate service life has always been an important aspect of building design and maintenance and regulation. In New Zealand, traditional building regulations were based around standards produced by the national standards body. These regulations were adopted and amended by each local city and town council as they saw fit. Durability was implicitly recognised through tight adherence to prescriptive standards and limited availability of alternative designs and materials unless "approved by the engineer". These standards specified materials and construction methods which were designed to produce buildings with an undefined but acceptable life.

In 1992, the New Zealand Building Code (NZBC) [2] was introduced. The New Zealand Building Code is a performance-based building code which replaced the previous regulations and centralised the development and administration of building regulations. The rationale for building regulation reform was to simplify and to reduce the cost of building control. The basic tenets of the New Zealand Building Code are health and safety, with some consideration also for protection of neighbouring properties, the safety of fire-fighting personnel and energy efficiency. Aesthetics, quality and amenity issues, unless related to health and safety, are not considered. The NZBC contains 35 clauses defining building performance requirements. The NZBC is a performance based code rather than a prescriptive code. This means that it specifies performance levels which must be achieved in a building rather than specifying how to build the building and what materials to use. There is one exception to this philosophy, the durability clause (NZBC B2), sets default lifetimes for buildings and their parts. The reasoning behind this is that without some provision for ensuring that a building continues to meet the performance requirements, the durability of buildings would be set by market forces. Since a significant proportion of building owners can be expected to have little expertise in assessing materials and system performance, a minimum degree of consumer protection was considered appropriate.

2 NZBC B2 Durability

B2 effectively demands, that materials or components required to meet a performance level specified in any other NZBC clause, must continue to meet that performance level with normal maintenance for a stated time. Typical examples are; elements contributing to structural stability, weather-tightness, insulation, acoustics and fire resistance. The durability required is defined by default as 50 years for items; contributing to structural stability or, that are difficult to access or replace or, where failure would not be detected during normal use and maintenance. Elements which are moderately difficult to access and replace and where failure would be detected during normal maintenance, have a 15 year durability requirement. The remaining categories have a 5 year requirement.

Alternative building lifetimes can be specified at the building consent stage. For example, with some agricultural buildings a 15 year life may be appropriate. In these cases the building would be subject to a demolition order after the 15 year period unless appropriate reports where provided to show that it would continue to meet New Zealand Building Code requirements. With other structures, such as hospitals or bridges, a 100 year or more service life might be specified. In these cases this becomes a matter of specification and contract between the client and the design/construction companies.

3 NZBC compliance

Prior to the start of construction of any building, a building consent must be obtained from the local territorial authority. Before issuing the consent, the authority must have reasonable grounds to believe that the building as planned would meet the NZBC. While the New Zealand Building Code allows for innovation, it was recognised that many buildings would be constructed along traditional lines. To assist with this process "Approved Documents" were also published with the NZBC. These include "Verification methods" and "Acceptable Solutions". These documents set out methodologies which allow builders and designers to show approving bodies that they have met the performance requirements of the New Zealand Building Code. The approved documents are largely based on traditional building standards which have proved largely satisfactory over a long period of time. B2 Durability contains both a Verification Method (B2/VM1) and an Acceptable Solution (B2/AS1). B2/VM1 includes a statement to the effect that materials and building elements complying with a publication referenced in the Approved Documents are, subject to their appropriate use for the conditions likely to prevail in the specific building, deemed to satisfy the durability performance. This means that materials listed in an acceptable solution for B1 Structural Stability, will under the appropriate usage conditions satisfy B2. Only recently has B2/AS1 referenced specific standards setting out materials and their uses which are deemed to satisfy B2. These are NZS 3602 [3] which covers the selection of timber and wood-based products in building, and NZS 3101 [4] which covers the design of concrete structures. These two documents are prescriptive standards which have been developed from many years of research and actual service history in New Zealand. B2/VM1 provides generic guidance on how to assess the durability of materials, but does not provide specific advice for any particular class of material.

4 Assessment of durability

One of the main criticisms of NZBC B2 Durability by industry, is the lack of detail in the Approved Documents. Manufacturers' frequently want to assess the durability of a new material or system or, may be using a conventional material in a new application. They find the lack of a list of specific test methods which can be carried out on a product which will give them a durability rating of 5, 15 or 50 years frustrating. Those involved in materials testing will appreciate the difficulties inherent in such a simplistic approach. There are thousands of test methods available covering almost every material and application imaginable. Many of these tests are designed to show compliance of new product with a performance standard. Others involve some form of accelerated ageing such as; heat, wet/dry, freeze/thaw or UV exposure. Others compare performance to historically durable reference materials. Relatively few tests allow the prediction of durability to the precise levels that end users would like. Even if such tests are available, they often do not take into consideration issues relating to the usage of a material on each specific building (eg. macro and micro climates, materials interactions, usage intensity etc).

Some standards have been developed which instead of prescribing a set testing regime, give guidance on how to develop test procedures. ASTM E632 [5] is a good example which sets out a process for devising accelerated test methods. Lewry and Crewdson [6] discuss some of the issues involved in devising test procedures and relating these to real applications. Other standards and documents have been produced which take a wider view than testing and focus on the process of determining service lives for buildings and components. CIB and RILEM committee RILEM 140-TSL/CIB W80 committee has produced publications [7- 11] covering both service life prediction and the gathering of data for use in service life prediction. The British Standards Institution published BS 7543 [12] and the Architectural Institute of Japan a guide [13] both providing guidance on service life planning. Much of the previous work on service life prediction is being used in the development of ISO standards on service life planning. ISO/TC59/SC14 (previously TC59/SC3/WG9) currently has a draft standard on service life prediction methods in development [14]. Lacasse and Vanier [15] review work in this area in a paper presented at the most recent "Durability of Building Materials and Components" conference.

The approach taken in the durability verification method VM1 is to provide guidance on the principles involved in durability assessments. Three approaches are outlined:

- history of performance
- lab testing
- looking at the performance of similar products

4.1 History of performance

B2/VM1 recognises that a successful history of performance is recognised as the most reliable method of evaluating whether a product will be durable in any given application. Even if the period that the material has been used for is less than that required by NZBC B2, valuable information can still be obtained. A number factors are raised which need to be considered when assessing the history of performance of a material.

4.1.1 Climate

For products used on the exterior of a building the general climate is the main factor. General climatic influences are described but no data is provided on degradation agents in contrast to BS 7543 which includes air temperature maps and driving rain indices [12]. VM1 emphasises the need to ensure that the performance history and usage must be representative of the proposed new usage. This is particularly relevant where materials are imported from other countries because differences in climatic conditions and building practices can result in significant differences in durability.

4.1.2 Microclimate

General climatic factors can usually be assessed with the aid of meteorological records and local knowledge. However, building details and surrounding topography and vegetation create a number of localised micro-environments particular to each building. These micro-environments can have a major influence on materials performance. Some common examples are, the sheltered corrosion effects on under roof eaves, brick veneer cavities and sub-floor spaces. The sheltered corrosion effect results when parts of a building are sheltered from direct rain washing, but open to wind blown salt and dirt. The accumulation of salt and dirt causes rapid corrosion of metallic components unless they are regularly washed. Recent reports of failures of brick ties in masonry veneer cavities have also raised concerns that insufficient data is available on this microclimate [16].

4.1.3 Materials Interactions

- Individual materials that may be largely inert and durable by themselves, can, when in contact with other materials, degrade quite rapidly. This means that the specific use in building systems should be assessed as well the durability of each individual building material in question.

4.1.4 Changes in Formulation

It is very common for the formulation of a product to change over time. Changes may be made to improve properties, reduce costs, utilise new raw materials sources, or comply with health and environmental regulations. Whatever the reason, it is necessary to evaluate what the likely effect of any changes will have on new products compared to those used in the past. Major changes (eg. changing the resin type in adhesive) will make the past history of performance effectively irrelevant and the product will need to be evaluated as new. The effect of minor changes may be able to be accounted for by expert evaluation and or laboratory testing to confirm the relevance of previous formulations.

4.1.4 Degree of Degradation

New Zealand Building Code B2 requires that "elements and buildings must carry out their intended function for the life of the building. Simply showing that a product has survived for 20 years does not necessarily prove that it will still carry out its intended function for 50 or even 20 years. In obvious applications such as claddings, it will generally be easy to determine if a failure (ie, leakage, impact damage or wind damage) has occurred. For structural or fire applications, the design loading event may not have occurred over the history to date, and hence an appearance of soundness may not equate to adequate retention of physical properties to meet the original design loads. Retrieving samples from buildings and testing to establish whether deterioration has occurred and the nature of any deterioration, is highly recommended when assessing durability. This can give clues to the mechanism of degradation and also allow estimates of retained properties at the required lifetime.

4.1.5 Usage Intensity

Usage intensity refers to items (often mechanical hardware) which undergo some form of wearing action during use. One example would be closers on fire doors. The frequency of opening of the door over the life of the building will have a significant effect on the wear rate of the closer and the service life and maintenance requirements will vary accordingly. Usage intensity is most important in institutional, commercial and industrial buildings but may also be a factor in domestic housing (eg. specifying deck membranes where foot traffic occurs).

4.2 Laboratory Testing

In the event of a service history not being available, the only option available may be to carry out testing. The most reliable testing method is to set up natural weathering trials using the materials in question and attempting to simulate the actual exposure conditions as closely as possible. One of the drawbacks with this technique is that it can take a very long time to see any results. Manufacturers introducing products usually cannot wait more than 6-12 months so accelerated techniques then have to be employed. The key point in designing or assessing a "so called" durability test, is whether the test accurately reproduces the degradation mechanisms that take place in service. For this reason B2/VM1 requires expert interpretation of accelerated laboratory test results when used in determining likely service life.

5 Practical issues resulting from implementation NZBC B2

Acceptable solutions are intended to provide methods of construction which will meet the NZBC over a wide range of locations, building types and usages. As such, they are usually robust and provide solutions which may be very conservative in some applications. In most acceptable solutions, a material is selected from a table or list of options, or if it can be shown to meet set performance criteria. In contrast, when specifically designing a building, the opportunity is available to tailor each component to achieve the desired durability/cost/maintenance balance. In this case, durability assessments are just one source of information which can be used by the designer/engineer. Rather than a simple pass/fail scenario, the information required is what degree of degradation is likely to occur, how extensive will the degradation be over the building and what effect on physical properties will the degradation have. The decision on acceptability can then be made by the designer in light of the information provided by the durability assessment/testing and the other design parameters set by the client's requirements and the appropriate loading conditions. An unresolved issue associated with the NZBC is that it does not state what an acceptable level of risk is. Since it is impossible to completely eliminate defects in a construction process, the level of risk is never zero. Historically, the level of defects which can be tolerated is set largely by the market or by society through codes and standards and tends to be very small. The actual value being a compromise between quality or safety and cost. NZBC B2 Durability does not provide any guidance of what level of risk is acceptable in assessing durability. However, since the purpose of B2 is to ensure that the other NZBC functional requirements are maintained over the life of the building, some guidance on the degree of deterioration allowed can be found in the other functional requirements. For example, concepts of reliability are covered in the B1 Structure verification method B1/VM1. Engineers typically design fixings using a 5 percentile value for resistance. This means that there is a 95% probability that the resistance of any particular fixing will exceed the design parameters and that the mean of all the fixings will be well above the design level. Similarly, the design loads are set at a level which ensures a low probability of them being exceeded over the life of the building. In this context, one argument is that that the conservatism associated with the terminology "reasonable evidence" is in place and need not be duplicated in a durability assessment. However, the levels of risk that can be inferred from B1/VM1 are not necessarily minimum risk levels, but they have been deemed acceptable. Work being carried out in Australia on timber durability, is attempting to bring engineering concepts such as reliability theory into durability design [17]. This approach requires quantification of agents causing degradation for each material as well as models which can predict degradation under a range on environmental conditions. Work is being carried out in New Zealand this areas [18].

6 Conclusions

While B2/VM1 provides general guidelines for assessing durability, and additional information is available in documents referenced previously [5-14], there are few organisations with sufficient expertise and resources in New Zealand able to carry out assessments of materials durability and service life prediction. This becomes particularly evident when new building systems utilising a range of traditional materials (steel, timber, concrete) are combined with polymeric materials such as plastics and resins. As well as materials expertise; structural, weathertightness, thermal, fire and buildability issues need to be worked through. The construction industry has placed a good deal of reliance on fitness-for-purpose system appraisals similar to the European Agrément system.

From an industry perspective, the realisation of the innovation and potential economic benefits offered by a performance-based building code will be enhanced by the development of improved acceptable solutions for B2 Durability. Improvements need to be targeted at three levels;

1. standards providing guidance on durability assessments and service life prediction
2. test methods for individual materials and systems
3. development of reliability-based models

The international effort going into the work of ISO/TC59/SC14, offers the potential of a unified approach being adopted for the process of assessing durability and service life for buildings and their components. A common methodology will assist those involved in assessing information presented as part of the compliance process particularly when material from another country is presented.

Improved predictive test methods for individual materials and their applications, continue to be developed by manufacturers, researchers and national standards bodies. These tests will eventually find their way into acceptable solutions when they become accepted by national standards bodies or major research organisations.

The incorporation of durability into the engineered design of buildings is still some distance away and requires considerable background work in each country as well as cooperative efforts within the international community. The eventual availability of reliability-based service life prediction techniques will mean explicit durability provisions in performance-based codes are likely to become more widely accepted.

Abstract
The present report summarises activities in relation to the EU-project ENV4-CT95-0110 Wood-Assess. One part of that EU project focuses on methods for measuring the surface time of wetness and the resulting moisture content inside wood on a continuous basis. In this report we present measurements of the Wetcorr currents, from both traditional surface moisture sensors and Inwood sensors, on selected positions at some objects chosen in the project. The traditional Wetcorr sensors are used to estimate the time of wetness. The currents from the Inwood sensors give the corresponding moisture content inside the wood. The measurements presented are from two of the objects in the project and from all of the facades.
Keywords: Wetcorr, Moisture content, Time of Wetness, Microclimate, Wood

1 Introduction

The present report summarises the results of work package two in the EU-project "Wood-Assess". The full name of the project is "System and methods for assessing conservation state and environmental risks for outer wooden parts of cultural buildings". The second work package in the RTD-project has the following objectives:

Develop and validate methods for measuring:
1. continuous surface time of wetness (TOW) and corresponding moisture content inside wood (INWOOD)
2. integrative damage to wood.

In this report we present results relating to the first of these two objectives. The following main issues were addressed as part of work package two:
- Develop a robust electrode system for measuring the long term moisture content of wood under field conditions.
- Theoretical and practical investigations of the measuring technique in terms of electrode geometry and configuration, moisture content and gradients, differences between WETCORR and more conventional techniques.
- Calibration of WETCORR INWOOD in climate cabinet using three different wood species.

The second of these points has already been described in another report [1]. The present report is in principle divided into two different parts. The first part, given in sectors 2-4, describes the measuring system, especially focusing on the new sensor technique; WETCORR INWOOD. It also describes the calibration procedure used for translating the measured currents in the wood into a corresponding moisture content. The second part, presented in sectors 5-6, describes some of the different objects where the field measurements are performed and results from these measurements. It also includes a brief discussion of how the measured currents are influenced by the positions chosen for the measurements.

2 Electrode system

The use of the WETCORR measuring system for long-term monitoring of moisture content of exterior wood requires certain considerations to be made in order to obtain reliable and consistent data. The electrodes should be easy to install and should perform well throughout the measurement period without any need for adjustments or maintenance.

Since there is some concern about nail electrodes not maintaining electric contact with the wood with time because of moisture induced movements and relaxation of the wood, it was decided that some kind of screw should be employed. A suitable screw in austenitic stainless steel (SS2347, 17.5Cr-11Ni-2.3Mo) was used which is readily available from hardware stores. The original screw has a flat, blade-like head through which there is a hole used for mounting the connector for the leads from the measuring equipment. The connector is made up of a crimp red sleeve terminal eyelet attached to the screw with a blind nut. The stem and part of the threaded area of the screw is protected by heat-shrinkable tubing containing an adhesive lining designed to provide a moisture proof encapsulation. In order to avoid penetration of moisture along the screw/wood interface, a thin layer of one-component polyurethane glue is applied circumferentially on the stem of the screw close to the wood surface. Holes for the electrodes are pre-drilled using a 6.5 mm drill-bit and stopper which ensures a constant depth of 12 mm. The distance between the electrode-pairs is not critical but has been chosen to 30 mm for all installations made in the field as well as in the lab tests. The leads from the WETCORR equipment are connected to the electrodes with a crimp tool. All parts of the electrode including the connector are protected by the same type of heat-shrinkable tubing as used for the actual electrode. Finally, the electrodes and leads are taped with white plastic tape to minimise pick-up of heat from radiation during sunny days.

3 Theoretical and practical aspects of wood moisture measurements

The WETCORR system [2] in its present version was not developed specifically to be used as a wood moisture monitor. Since all of the four moisture channels in each sensor adapter have a common ground, the paths for the recorded currents cannot easily be separated unless the electrode pairs are galvanically isolated from each other. Unfortunately, this is not the case for building facades. Consequently, if more than one INWOOD sensor is hooked up to the sensor adapter the readings obtained are generally not representative of the MC in the location where the electrodes are mounted. In the short term these difficulties can be overcome simply by not connecting more than one electrode pair per sensor adapter at a time. In the future, however, up-dated versions of the WETCORR system will most likely be designed with galvanically isolated moisture measurement channels.

Tests in the lab have been performed using multiple sensors and long distances between the electrodes of the same pair and between the pairs. It may be concluded that the channel interference ***cannot*** be avoided by long distances between the pairs. Refering to Figure 1, even the resistance between electrodes that are mounted at very long distances from each other is small compared with the resistance associated with the wood/electrode interface [3].

Re1 and Re2 are associated with the wood/electrode interface and Rw with the bulk resistance of wood. In the presence of moisture gradients, large differences would also be anticipated between Rel and Re2. The moisture reading results obtained are from the total resistance in the electric circuit. Consequently, the electrode that is situated in the driest part of the wood will give the dominating contribution to the moisture reading.

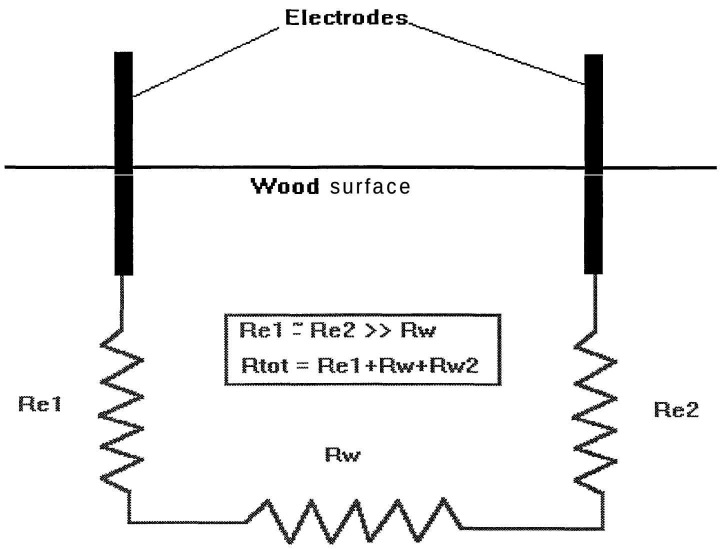

Figure 1. Schematic showing the distribution of electric resistance across two wood moisture electrodes (after Ref [3]).

The high resistance associated with the wood/electrode interface will prevail as long as the surface area of the electrode is small compared with the minimum cross-sectional area of the wood anywhere between the two electrodes. This effect arises as a result-of the propagation of the electric field between the point-like electrodes combined with the volume resistance of wood. From geometrical considerations the highest current density will occur close to the electrode surface which then causes a much higher voltage drop than in the bulk of the wood [1]. In general, this means that for measurements in wood with large cross-sections, the distance between the electrodes is of very little significance.

4 Calibration of WETCORR INWOOD under controlled conditions

The most common way of expressing moisture content of wood is as the percentage ratio of the weight of moisture to the weight of dry wood. Since most experience and all moisture related criteria for physical and biological aspects of wood are expressed in this way, the current measured with the WETCORR INWOOD system has to be translated into moisture content.

A 5 m long board measuring 8”x1½” in cross-section was dried from the green condition of 30 % Moisture Content (MC) to about 15% MC. The WETCORR INWOOD currents were correlated with the readings obtained with a Protimeter Timber-master, as shown in Figure 2. As these experiments were done in a room without temperature control a variation between 23 and 25°C was not possible to avoid. Still there is a fairly close fit of the data to a power function. Further tests have been performed to correlate the WETCORR INWOOD currents with the true moisture content established by weighing after exposure to various humidity and temperature conditions in a climate cabinet [4].

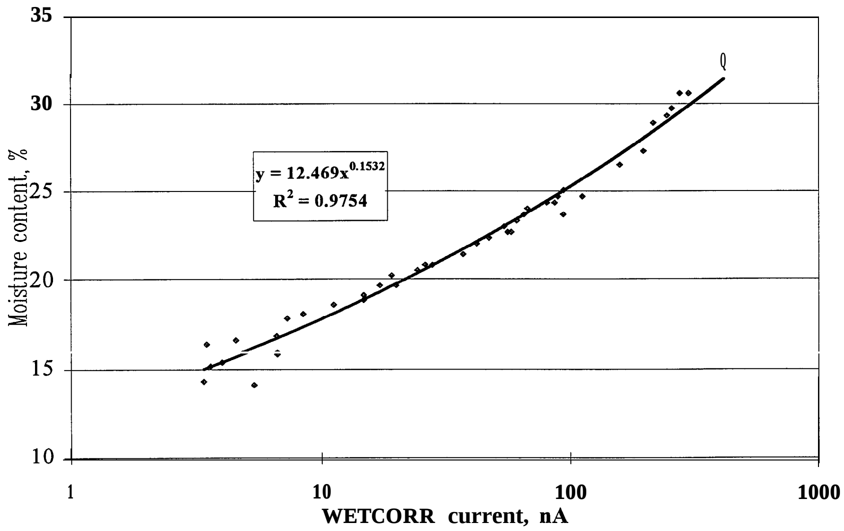

Figure 2. Moisture content according to Protimeter Timbermaster plotted against the WETCORR INWOOD current at 23-25°C.

The TOW is calculated using a current level of 1 0nA [5] and according to the calibration the MC is calculated using the formula given below [4]:

$$\log MC = A + B \log I + C/T + D\rho$$

where A, B, C and D are constants, I is the measured INWOOD current, T is the measured INWOOD temperature in degrees Kelvin and ρ is the dry density of the wood.

5 Description of the objects chosen

In the project, measurements are performed on four out of five objects. Below a short description of two of the measured objects together with their climatic situations are given.

The two objects presented in the report are both situated in Sweden. One house is in the town of Gävle, Berggrenska garden, and the other close to Waxholm, Norrkulla, which is north-east of Stockholm. Berggrenska garden is a log house construction with two floors and a basement. The house has dimensions 3 1.2 x 12.8m. The walls are cladded with wood and the roof is of a mansard type originally with tile but today it is covered with black painted steel sheet. The house was slightly rebuilt after the city fire in 1869 and the latest refurbishment of the house occurred in the mid 1980's. At that time the cladding was in some parts replaced and on the other parts, only repainted. The original roof was replaced in 1896 and then again in 1977. The wall cladding was also repainted in the summer of 1997, during the period when measurements were taken. The house is comprised of a main building and two wings which were erected at approximately the same time as the main building.

The climate in Gävle is urban coastal with cold winters. The house Norrkulla is a timber framed construction with exterior wood cladding. The building technique used is corner timbering where the logs of two adjoining walls are interlocked. Walls on the first floor are reinforced by vertical walling. The logs had dimensions of 150x200mm. The supporting structure of the roof is a Swedish roof truss lying on the timber framed walls and covered with roof tiles. The foundation consists of stones in each corner. The major difference in climatic situation compared to Gävle is that the house is not in an urban environment.

6 Results from measurements

The measurement methods for moisture are based on the NILU WETCORR measuring device. The existing gold sensors measure a surface current, which after calibration gives the surface time of wetness (TOW) [2]. The nail electrodes were developed into a new sensor application, WETCORR INWOOD, previously described. The measured currents in the wood after calibration give the moisture content in the wood [4]. In this report we present TOW and moisture content at certain positions chosen on the objects. As an example we present the different positions at Berggrenska garden in some detail, given in Table 1. The division into different categories and the numbering of facades, fields, boards etc. are explained in another report from the Wood-Assess project [6].

Table 1 Wetcorr installation "Berggrenska gården", location of sensors

Sensor adapter	Sensors	2nd category	Elements in the Categories 3rd category	4th category	5th category
01	WC 1.1*	facade 1.2	field 3	board 12	40 cm right side of window

	IW 7.4	facade 4.2	field 3	board 7	50 cm under the counter batten

The measurement period for the investigated objects starts from the autumn of 1996 until the end of 1997. During that period the object Berggrenska garden has been repainted, June 1997, which gave us an opportunity to study the moisture content in wood before and after painting.

6.1 Berggrenska gården

For the Berggrenska garden house we present results from measurements in October to December for both 1996 and 1997. The major difference between the two years is that during the summer of 1997 the house was repainted. Figure 3 shows the Time Of Wetness (TOW) and the Moisture Content (MC) for one of the sensors.

We have not measured the INWOOD temperatures for all the sensors and not for the entire measuring period. The reason is simply that the INWOOD temperature sensors were not developed when the measurements started and we also had less than ten of them, some of which were used at Norrkulla, the other Swedish object in the project. In instance where we did not have INWOOD temperatures we used the WETCORR temperatures closest to the Inwood sensor. As can be seen from Figure 3 the first couple of weeks had no precipitation and the MC remained at the same level. With an increase in the TOW an immediate increase in MC occurred. Then there is a period of rather low TOW and during that period the MC is almost stable. A rather high TOW around 19-20/1 1 gives an increase in the MC once again. The MC level is now around 30% which is almost at the fibre saturation point. After, the MC slightly decreases, but the value reached at the end of the period in question is still very high.

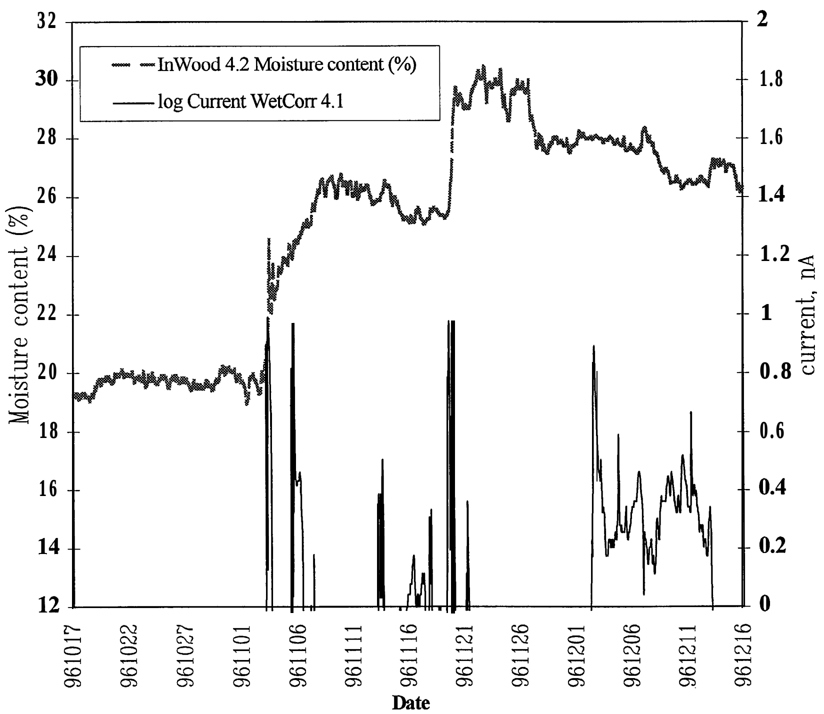

Figure 3. Moisture content (%) and Time of Wetness at SA04 on the north facade of Berggrenska gården October-December 1996

With the measured temperatures and currents we can calculate the MC's for all the sensors. In Figure 4 we give the TOW and the percent of time when the MC is above 20% and 25% for all the seven sensors (Table 1). As can be seen in Figure 4 the TOW between the autumn of the two years differ, with a much higher impact for SA02-SA05 in 1997 and for SA07 in 1996. The main difference between the two years regarding the precipitation is the main direction from where the rain came. In the autumn of 1996 most of the rain came from west or south-west and in the autumn of 1997 almost no rain at all came from those two directions.

If we observe the MC instead we find that the values of 1997 are significantly lower than for 1996 even for the SA's with the higher TOW in 1997. The main reason for the lower MC's for 1997 is the application of a new paint on the wood surface. The penetration of moisture into wood is lower with a fresh paint compared to an old one. We can also study the MC's from the different positions on the object. The different positions are given in Table 1. The results given in Figure 4 are based on one of the Wetcorr sensors and also one of the Inwood sensors, marked with a * in Table 1. If we study the sensors on the south facade, SA01 and SA02, we find that MC's over 20% are reached approximately 40% of the time while for SA02 some 15% of the time period MC's are even over 25%. The sensors SA01-02 are placed almost on the same height on the facade and they differ with 8-l Om with SA01 on the left and SA02 on the right part of the facade. There are at least two reasons for the higher levels reached at SA02, one is the distance to the counter batten which is shorter and the other is the more degraded paint and wood at SA02.

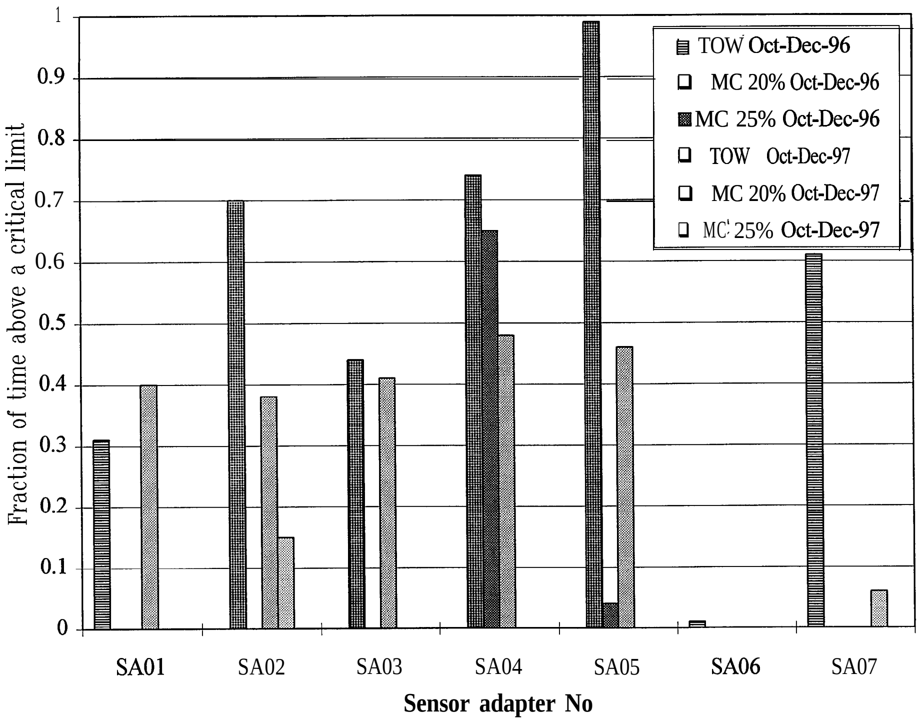

Figure 4. A comparison between the amount of Moisture Content over specified levels and Time of Wetness for seven positions at Berggrenska gården in the autumns of 1996 and 1997.

The MC for SA03 is of the same order as for SA01-02 even though the position on the house is different. SA03 is situated at the same level above the sea but not on the same level above ground. SA03 is much closer to the ground and also somewhat protected from sun by vegetation. SA04-06 are all situated on the north facade with the former two close to the ground are rather well protected from any kind of sunshine. SA06 on the other hand is situated in the middle of the facade and rather open but under eaves. The MC's for the three differ accordingly with a really high MC for SA04-05 and a low MC for SA06. It can also be seen on the wooden parts that the region close to SA04-05 is very much deteriorated while the region close to SA06 is in seemingly good condition. In the last case a rather high amount of rain reached that part of the facade were the sensor is placed, as can be seen from the TOW, even though a very low **MC** was still measured. The reason is that the sensor is situated on an unprotected part of the facade which implies a good possibility to dry out the surface moisture.

6.2 Norrkulla gård

Results from the measurements at Norrkulla gård for the period October 1997 to December 1997 is presented in Figure 5. The moisture content is high for all of the sensors, frequently near or above 20 %, except for Inwood sensor 5.4. The Inwood sensor 5.4 is located on the south side close to the east gable. The only other Inwood sensor located on the south facade is located on the west side of the facade and in a higher position.

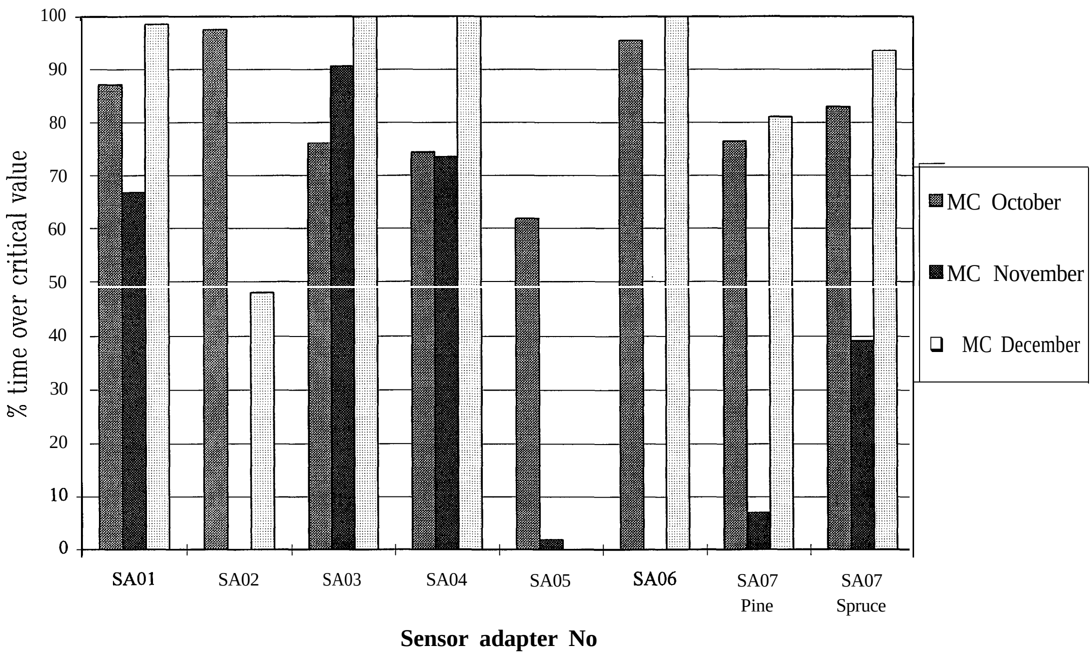

Figure 5. The results from the measurements showing the time in % when the Moisture content inside the wood is over 20% during October to December at Norrkulla gård

The reason for the difference in moisture content for the two Inwood sensors on the south facade is not clear from measurements of TOW at either position. A slightly lower TOW can be found at the position of Inwood sensor 5.4. The difference in TOW is, however, to small to explain the rather high difference in moisture content. We believe the difference instead can be found in the quality of the wood at both sensors. Sensors 7: 1 to 7:4 are applied on a rack with wood panels (spruce and pine) which is located about 20 m from the west facade. The sensors are exposed in a horizontal angle of 45 degrees facing south. The results show a rather high difference in moisture content for October and the difference is gradually decreasing for November and December. The difference is most likely due to the prehistory of the wood material and also to the overall quality of the wood samples.

7 Discussion

The measurements performed at the different objects show the potential of using both the WETCORR sensor and the new INWOOD sensor. The importance of positioning the sensors on to a facade is not fully studied in this project. The positions of the sensors are very important in order to predict, for instance, the service life of a wooden facade. For such service life estimations the climatic impact on the facades must be known or at least approximately known. The WETCORR and INWOOD sensors can be used for making models of the climatic impact by measuring the climatic impact on some facades and connecting measurements to local climatic data. Some work have been done in this field in the Wood-Assess project [7].

Abstract
There are great differences in temperature and precipitation regimes in Europe, resulting in equally differences in the potential wood decay rates. This paper describes the work carried out in the EU project ENV4-CT95-0110 Wood-Assess to develop and validate methods and technologies for mapping and assessing environmental risk factors and areas to wooden buildings in macro, local and micro scale. Due to the very complicated nature of the degradation system for wood, very few quantitative dose-response functions exist to day. The assessment of risk factors has therefore one hand been based on calculating Scheffer's index from existing meteorological monthly data for chosen regions and to model the results into a geographical information system (GIS) based information system for regional prediction of wood rotting. The index has on the other hand been tested and linked to micro-environmental exposure by the use of WETCORR measurements. The WETCORR instrument has been used to map the temperature and time above critical moister in the micro-environment. The results indicate that the rotting process is more complicated that the Scheffer's index is able to explain and that that the duration and amount of precipitation must be taken into account. By using a WETCORR instrument these problems can be partly solved.
Keywords: wooden buildings, rotting, moisture, mapping of risk factors, geographical information system (GIS).

1 Background

The deterioration of wood structures is influenced by a large variety of factors. The most common and often the most serious damage on wood is the rotting process. To be active the fungi involved need sufficient water and the right temperature regime. Beside capillary absorption of water from the ground, the main water source for the fungi is the amount of rain fallen on the structure. Due to the climatic changes throughout Europe, there will also be changes in the risk for rotting across Europe. Since meteorological data for temperature and precipitation are measured and reported in all European countries, the idea of using existing data for the prediction of risk of rotting has been put forward. A well known equation for this prediction is Scheffer's Climatic Risk Index (CRI) [1].

$$CRI = \frac{\sum_{Jan.}^{Dec.}\left[(T-2)\,(D-3)\right]}{17}$$

T= monthly average temperature
D= average values for days with rain

A problem for assessing the rotting of wood is the observed local variation in the parameters through out a region and in the micro environment on a building. It is therefore necessary to do measurements both on a local scale as well as on the micro scale on the actual building.

In WOOD-ASSESS one of the tasks has been to compare CRI calculated at the nearest meteorological measuring site with CRI calculated T and D values obtained locally and the real time with wet surface on a building. To study these events the instrument NILU WETCORR has been used [2]. This instrument is specially designed for measuring the time of wetness on surfaces.

A second task has been to use available meteorological data and to model these data and CRI for rotting on a regional scale taking into consideration the topographic impact on the climatic parameters.

2 Field studies

To study changes in the wetness impact on local and micro scale field test sites were put up at four locations:

- Hjeltarstua, Maihaugen in Lillehammer Norway
- Berggrenska Gården, in Gävle, Sweden
- Norrkulla Garden in Stockholm, Sweden
- Alte Mange1 in Ebersbach, Germany

The principle of the set up is shown for Hjeltarstua in Figure 1.

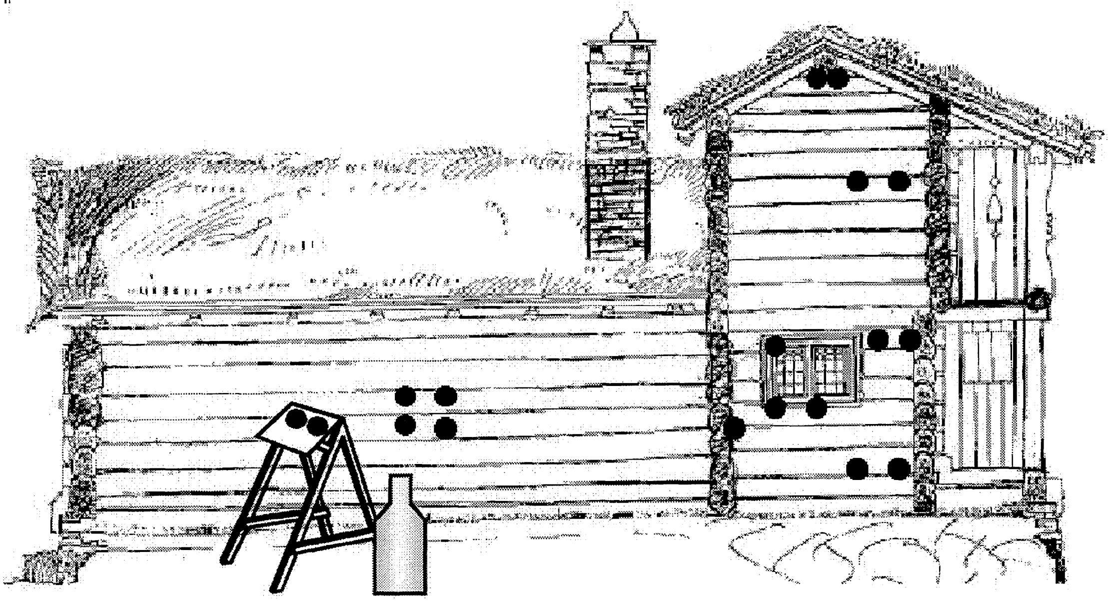

Fig. 1. The experimental set up for measuring the wetness impact on Hjeltarstua.

The local set up consists of a pluviograph for measuring the number of rain events. A test rack where four wood panels, two Norwegian spruce and two pine, were exposed to the climatic conditions facing south with an angle of 45°. A WETCORR instrument with one WETCORR sensor for measuring the real time with wet surface on the wood panels, two INWOOD sensors for measuring the moisture content inside the panels and one temperature sensor for the air temperature.

3 Results of wetness impact at different levels

3.1 From regional to local level

In this paper the results are illustrated by providing the results from the Norwegian site at Maihaugen. The nearest meteorological site Sætherengen is located approximately 0.5 km from the test rack but at a lower altitude. One complication for the comparison was that the local pluviograph had a precipitation sensitivity limit of 0.5 mm, whereas the meteorological authorities normally reports 0.1 mm. At Sætherengen 0.5 mm data were also available. In Figure 2 the monthly data for days with rain above 0.5 mm for Maihaugen and 0.1 and 0.5 mm for Sætherengen is presented. During the spring, autumn and winter months the-variation between monthly values were minor, only one to two days, while during summer the variation is much higher between the sites. In July there is also a large difference between 0.1 and 0.5 mm precipitation at the meteorological site. On a yearly basis the 0.5 mm daily values were 24% higher for the meteorological site than for Maihaugen. The pluviograph at Maihaugen recorded the rain events as change in the weight of the collector. Since the pluviograph was situated in the sun the uncertainty will be higher with smaller amounts of precipitation and warm weather due to evaporation. If we take away the months July, August and September from our calculation, the difference between the two sites drops to 6%.

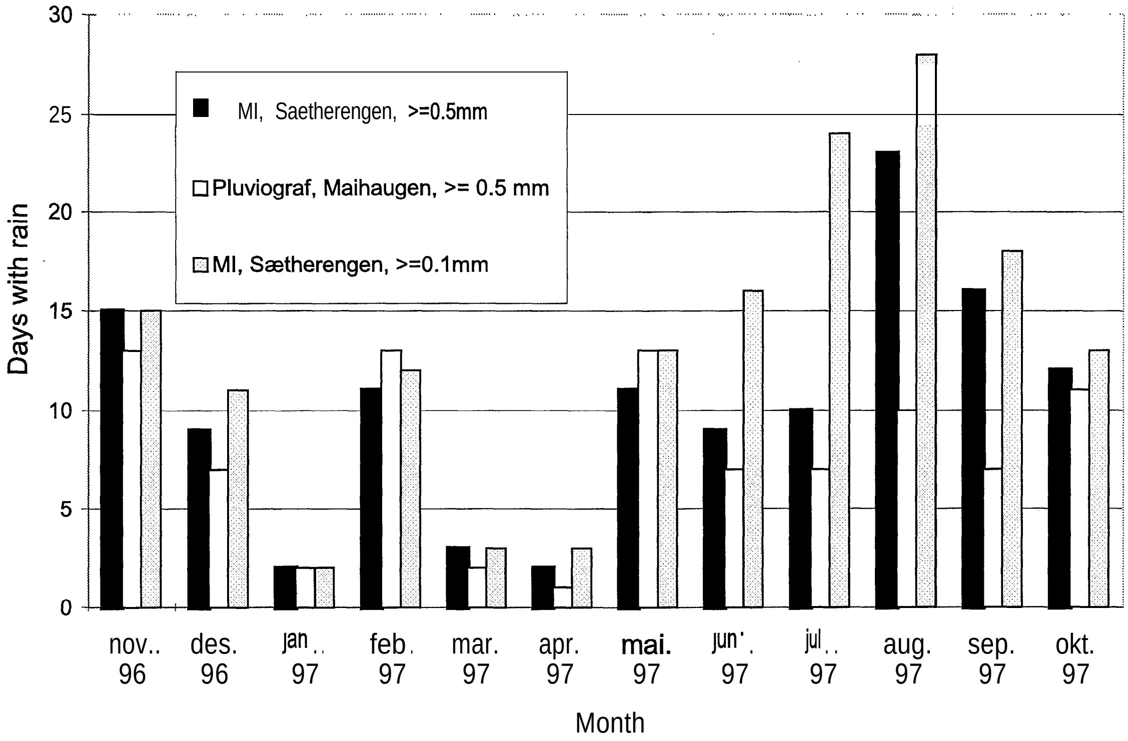

Fig. 2. The results of "days with rain" reported from Sætherengen and the pluviograph at Hjeltarstua, Maihaugen.

The difference between days with rain calculated with 0.5 mm and 0.1 mm was on a yearly basis 35 days or 28%. Most likely this percentage will be the same for Maihaugen. In Figure 3 the pluviograph data from Maihaugen is compared with the WETCORR results from the rack. Two different current limits for detection of surface wetness were used. At Maihaugen where the pollutant level is low, a current level of 15 nA gives a good indication of periods with rain. current limit 10 nA will also include other types with wet surface such as dew and gives a slightly higher value for the time with surface wetness. Days with rain over 0.5 mm recorded gave a lower number than days measured with the WETCORR instrument. However if we adjust for the uncertainty in the Summer results and add the corrections for the precipitation limit 0.1 mm, the WETCORR data and the pluviograph data will be close. A freely exposed WETCORR sensor will therefore give days with rain which are comparable with the pluviograph data.

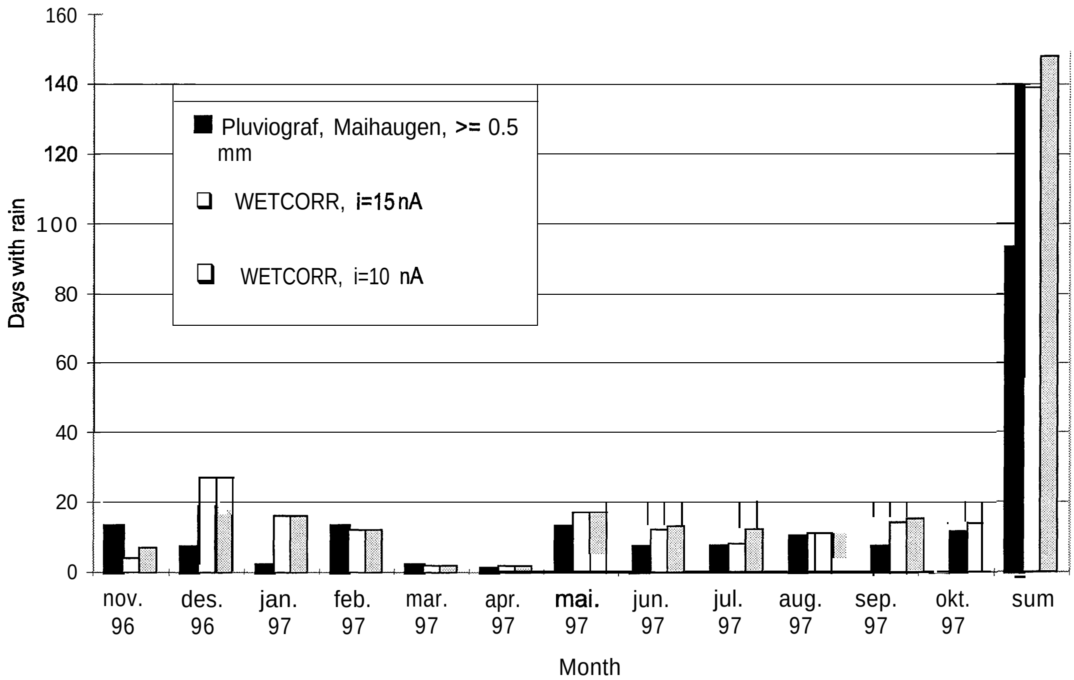

Fig. 3. Days with rain measured with pluviograph and WETCORR sensors at Hjeltarstua, Maihaugen.

3.2 From local to micro level

On Hjeltarstua the surface wetness was measured at 17 selected outdoor locations in the micro environment on the building and on 3 locations inside. The moisture content of the log construction was measured with INWOOD sensors at 20 locations. Table 1 gives an overview of the selected sites.

Table 1. Selected micro environment locations on Hjeltarstua and the type of sensors used.

	Sensor					
Adapter	a	b	c	d	Comments	Direction
SA01	IWT,BS	IW, P	IWT, BS in	IW, P	external gallery	North, N
SA02	WC, BS	IWT, BS	WC, P	IW, P		North, N
SA03	WC, in	IW, in	WC, out	IWT, out	external gallery	East, E
SA04	WC	IW	WC	IWT		South, S
SA05	WC	IW	WC	IWT	c, d; shelter	South, S
SA06	WC	IWT	WC	IWT	shelter	West, first floor, W
SA07	WC window frame	IWT window frame	WC	IWT	inside	South in, S
SA08	WC window frame	WC window frame	WC window frame	IW EGW		South, S
SA09	WC	IWT	WC	IWT		South, S
SA10	**WC**	**IW spruce**	**IW pine**	**T**	**rack**	**South, S**
SA11	WC EGW	IW EGW	WC window frame	WC window frame		West, W

WC = WC-sensors
IW = IW-sensors
T = temperature
IWT = IW-sensor with temperature

BS = bottom sill
P = post
EGW = end-grained wood

Cultural houses have their design based on traditions and experiences for protecting the building against rain and snow. The results obtained from measurement on a rack can hardly be expected to be representative for the wetness impact on the building parts. By using a current level of 15 nA as a limit for days with moisture on the wood surface, the WETCORR sensors will give both monthly average temperature and days with moisture. Scheffer's climatic risk index can then be calculated for all selected micro areas of the building. In Figure 4, CRIs for the period of November 1996 to October 1997 for all micro sites are shown.

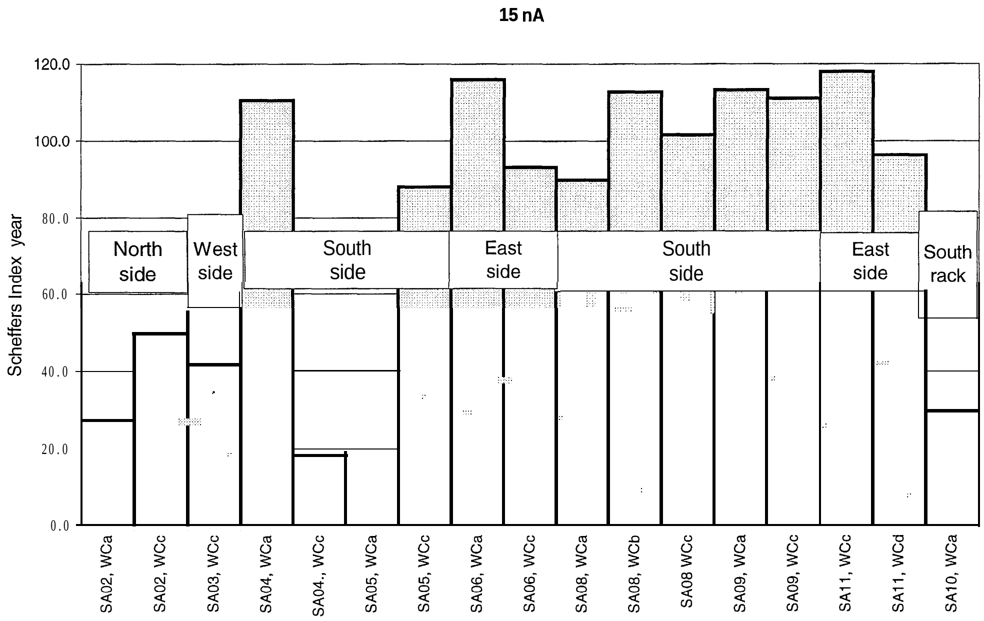

Fig. 4. Scheffer's Climatic Risk Index (CRI) for all micro sites measured on Hjeltarstua, Maihaugen

For most building locations CRIs are approximately 4 times higher on the wall than on the rack. However, a study of continuous measurements shows that there are only a few episodes and a few places where rain itself hits the wall. Mostly the wetness on these sites was formed by moisture adsorption in the deposited of hygroscopic dust particles on the walls and on the sensors. This effect is illustrated in Figure 5, where the number of days per month with current above 15 nA for four sensors on the wall and one on the rack are given. SA10 is the sensor on the rack where rain wash the sensor regularly and the number of days is the same as for the pluviograph. For the sensors SA04 on the south side and SA11 on the west side, dust deposition increases over the months and after six months almost all days have periods with current above 15 nA. On the north side (SA02) the effect is similar, but in July a rain event washed both sensors. The north facade has a wood gutter where the run off will be concentrated at leaks and at the ends. This creates water splash from the gravel ground. This part is also the only part where the INWOOD sensors indicated high moisture content in the structure.

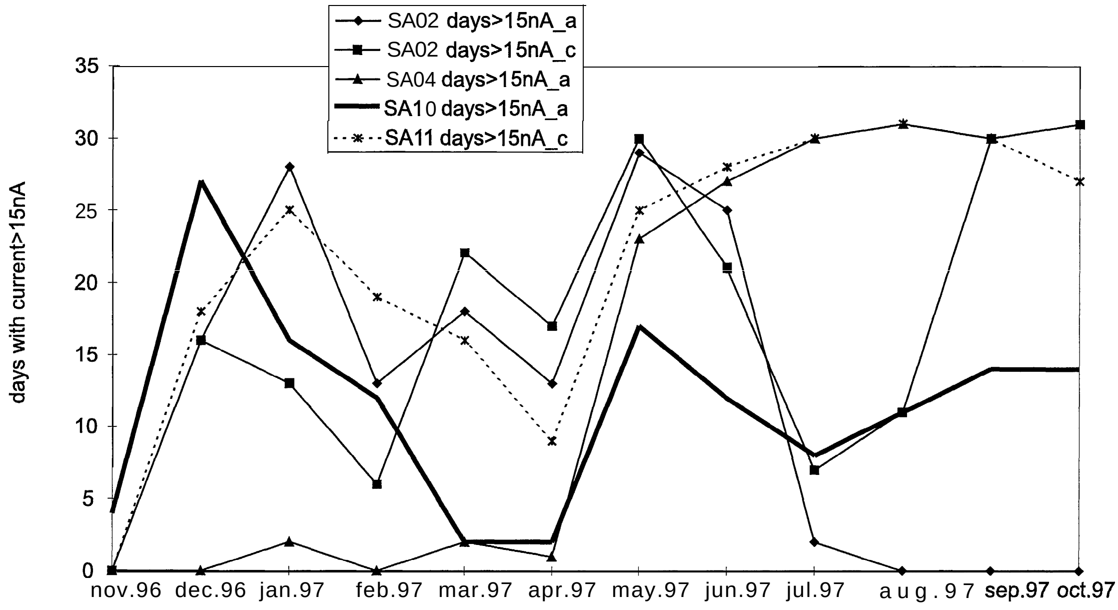

Fig. 5. Days with current respond above 15nA for sensors on the walls SA02, SA04, SA1 1 and on the rack SA10.

Inland, in the East part of Norway, driving rain is fairly rare. Walls seem to be wetted mostly by deposition of hygroscopic dust and rarely by a rain event. Since old log houses were built from resinous pine the water adsorption into the log is minor. The observed surface moisture will therefore react on the surface and quickly dry out in sunny weather causing only minor effects. Risk for rotting occurs mainly on parts with risk of standing water or capillary absorbed water present. This is observed on the north side connected to leakage from the gutter and to small parts of the stone foundation where water was running to the logs instead of away from them. On the micro level, either days with rain or the amount of rain seem to be as important as the duration of wet structures. The duration of wetness is more affected by the building techniques used and the craftsmanship. Old houses having low foundation are susceptible to water slash from the roof and gutters like that observed on the north side of Hjeltarstua.

The rain impact on freely exposed panels differs from the impact on a building facade. The effect of a rain event on freely exposed wood is shown in Figure 6. During the rainy episodes 1 and 2 of July the moisture content exceeded 25% for both spruce and pine panels and it took two days before the moisture content came under the 20% limit for fungi growth.

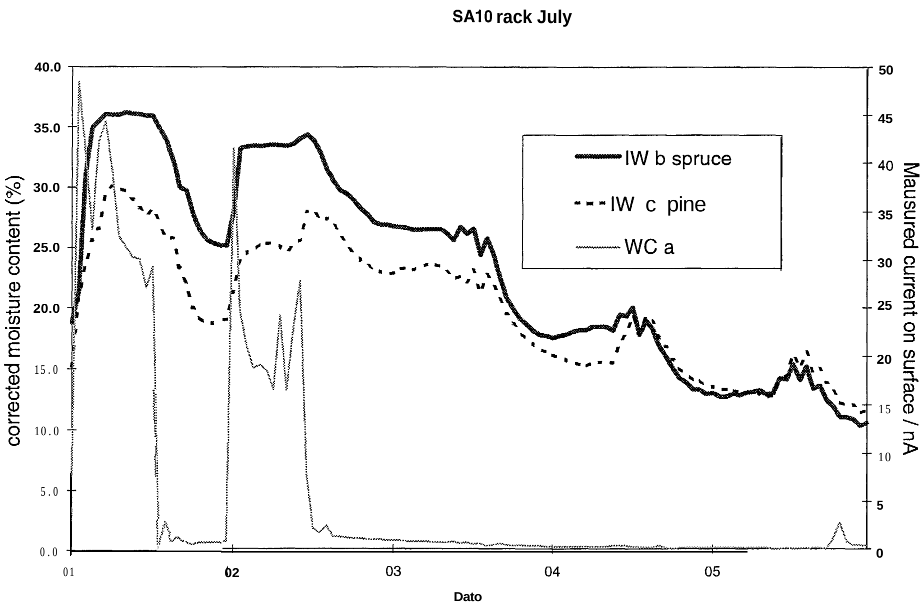

Fig. 6. The variation of the moisture content (%) in freely exposed panels during the period 3-6 July 1997 compared to the current on the WETCORR sensor.

4 Modelling climatic parameters

Scheffer's concept of using available meteorological data for estimating the risk for rotting is a good approach for predicting the rotting risk of wood. However, meteorological observations are collected at a limited number of places and different parameters are reported from different sites. To calculate the weather impact on wooden houses at a given location, several weather parameters are needed. To obtain these parameters it is necessary to generate values from the observation sites to all points in an area.

The GRID application in ArcInfo is a suitable tool for modelling of climatic parameters. GRID is a cell-based GIS system with several mathematical and geographical functions for calculating cell values.

4.1 Method

Based on the observations gathered within a given region, a statistical interpolation method (KRIGING) is used to distribute values to every cell. The dependence of local topographic effects on the meteorological observations is taken into account as well as the shadded and sunny sides of hills and mountains. Temperature cell values are recalculated from the differences between the height levels of the cells.

4.2 Input data

The objective in the development of the pilot version was presenting regional maps for temperature, amount of rain, and Scheffer's index for a part of the South-East region of Norway. Within this region the following data was collected:

- Temperature, amount of rain and days with rain as monthly and yearly data for 105 meteorological sites.
- Geographical points with height values for the 105 sites.
- Correction values for temperature height differences between the cells and for sunny and shady side of hills.
- Topographic maps of the region processed from contour lines to polygon data

4.3 Results

The result of the temperature plot for July values is given in Figure 7. The correction factor for height was 0.6°C for 100 meter and the same for sun and shade. Tests run for the other monthly and yearly data showed that the same factors could be used for all average values.

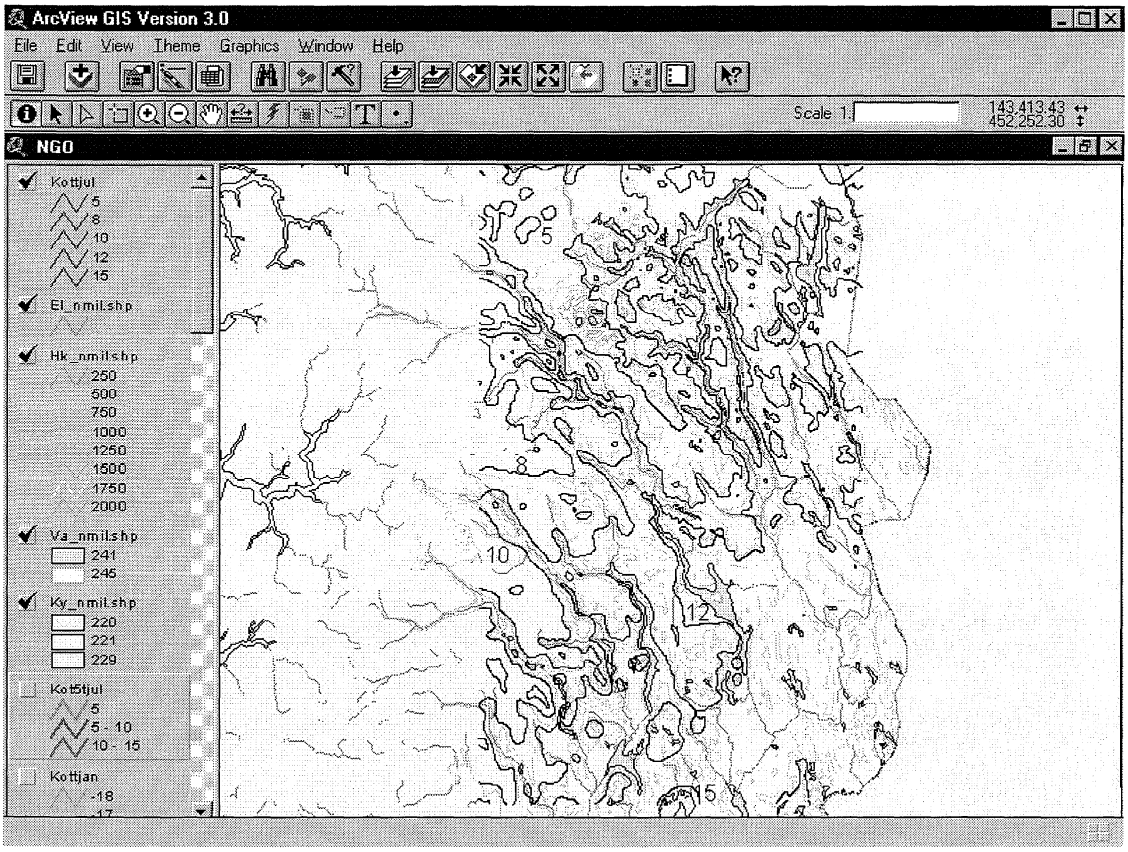

Fig. 7. Iso-line maps for the average July temperature distribution for a region of South-East Norway.

There are considerable differences in the amount of rain falling in different parts of Norway, it ranges from 3500 mm per year at places on the West coast to 300 mm in the upper valleys in East Norway. Within the modelling region the variation is 300 mm to 1200 mm per year. On a regional scale it turned out that we did not need to take into account the influence of hills and wind direction since we had sufficient meteorological rain observations in areas with rain shadows to form a reliable model for the amount of rain.

Scheffer's index uses the number of days with rain. The number of days with rain is not regularly reported for all meteorological sites in Norway. From the available number of days with rain data the model turned out to be less reliable than for the precipitation model. However by comparing the data sets where both rain amount and days with rain were available it turned up that number of days with rain was nearly independent of the amount with rain. An average value for days with rain can therefore be used for the whole region and the variation in Scheffer's index in the region will be entirely dependent of the variation in temperature.

For East Norway the input data for calculating the Scheffer's index will then be the monthly average values for temperature in each cell and a monthly average number of days with precipitation for each month used in all cells.

5 Conclusions

This study has shown that it is currently possible to model the temperature, precipitation and the Scheffer's index on a regional scale even in areas with large variations in topography as in Norway. The model could easily be adopted to other areas with smoother topography. In even rougher terrain such as in Western Norway greater concern must be given to local variations in precipitation parameters.

Providing information on days with precipitation and Scheffer's index does not seem to reflect the variation in rotting hazard in Eastern Norway. The duration and amount of wetting seems to play a more important roll. Even if a more precise equation could be formed, it would not solve the importance of the local influence to a building and the design of the building itself.

In the Lillehammer area the variation in Scheffer's index between two measuring sites 0.5km apart could be between 6 to 20%, and on the micro scale on a building even more. The WETCORR instrument is shown to give reliable data for time with rain with an open exposed sensor. The temperature sensor on the WETCORR sensor will also give information about the type of precipitation like rain or snow.

On the micro scale the WETCORR sensors are reacting to every type of moisture formed on the surface. The various events like rain dew or snow have different current characteristics and can be separated by interpretation of the continuous current record. Hygroscopic particles will form a moisture film on building substrate. On more susceptible materials than resinous pine this will increase the hazard for rotting or surface discoloration from mildew. On other materials, such as metals it would also increase the corrosion hazard.

Investigations of Mass and Energy Flow in the Existing Building Stock

H. Kloft and J.-D. Wörner
Institute for Structural Analysis, Darmstadt University of Technology,
Darmstadt, Germany

Summary

The complexity and dimensions of interlacing of buildings with environmental effect – shortage of raw materials, waste removal problems, global warming effect etc. – requires a reduction of mass and energy flow in civil engineering in the future. One of the most important necessities for this is to preserve the existing building stock. Within the framework of investigations regarding "building material usage and the primary energy input for residential buildings constructed at different times", 20 residential buildings of varying ages (typical examples of solid-wall type of construction) were examined with regard to their building material and mass composition. In addition, the primary energy contents of the buildings concretized in the form of building materials - the so-called accumulated energy expended in the production of the building materials (PEI,) - was also determined. The purpose of the investigation is to obtain information regarding the composition of building materials in residential buildings dependent on their age, and thus gain knowledge for dealing with existing buildings. As results we have found characteristic values for the material composition and the primary energy inputs of buildings from different age groups.

A crucial finding, apart from the relationships and dependencies of building material masses and primary energy input, is the dependency of used building materials and construction methods in the case of residential buildings of earlier building age groups on their age group. It becomes apparent that a change of the used building materials as a rule concurs with a change of the constructive composition. As a conclusion from this finding one derives a *"Building Element Catalogue to Register and Assess Existing Residential Buildings".* The compiled constructions extend over a time span from 1890 to 1970 and concentrate mainly on building construction in urban multi-storey residential buildings.

To shown the influence of the period of use we have investigated three single family houses: A house built in accordance with the German thermal protection ordinance (WSVO), a low-energy house (NE-H) and a so-called passive-solar house (P-H). As results of analyses the mass flow and the cumulative total energy necessary for the production, maintenance and operating of the three buildings over a period of 80 years are presented.
Keywords: mass and energy flow, material composition, primary energy input

1 Composition of Building Materials of Buildings Constructed at Different Times

Fig. 1 shows the total masses of the used building materials of all examined residential buildings related to their gross cubic content, represented as columns. A mean value of 0.528 Mg/m³ gross cubic content is obtained for all examined buildings. It is apparent that single family houses (mean value 0.592 Mg/m³ gross cubic content) tend to be heavier due to their higher proportion of building materials; the used building materials here normally enclose a smaller volume than for residential buildings for several families (with a mean value of 0.479 Mg/m³ gross cubic content).

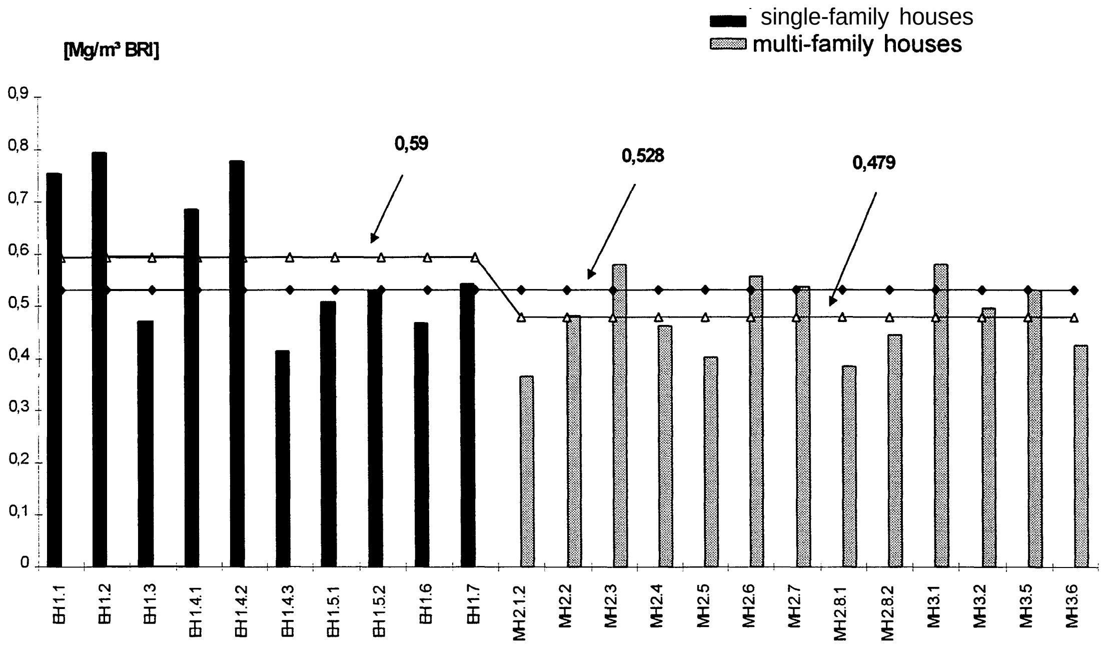

Fig. 1 Building Material Masses of the Investigated Buildings in Mg/m³ Gross Cubic Content [1]

The breakdown of the building material masses into the individual building material groups in fig. 2 shows the dominance of the mineral portion in examined buildings.

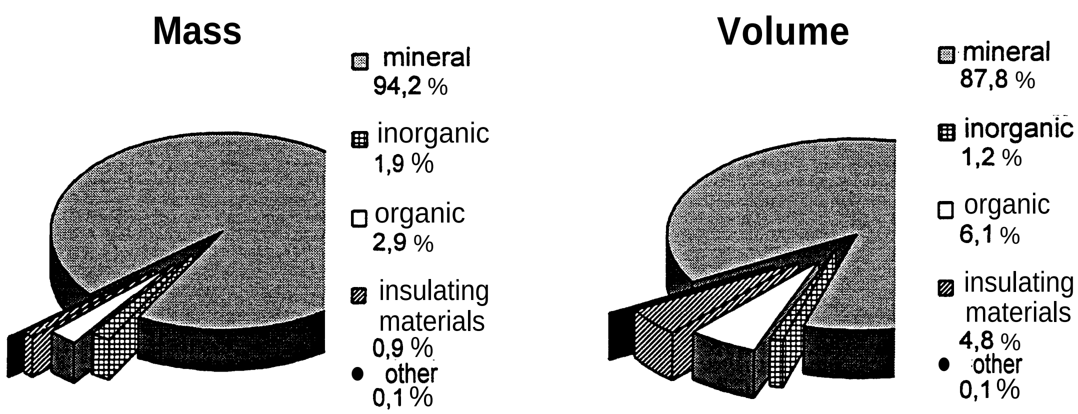

Fig. 2 Classification of the Building Material Masses in the Building Age Groups Averaged into Mass and Volume Percentages [1]

It can be recognised that the portion of the organic materials and the insulating materi-als have a greater weighting in the percentage by volume. This can be put down to the fact that these materials, in comparison to the mineral portion, have a lower specific weight at the same volume.

Figure 3 shows the usage of building materials in residential buildings as changing with time as a mass percentage distribution. It can be seen that the composition of the building materials changes from one age group to the next. Whereas the concrete portion has increased since the mid 1920's, the portion of timber as an organic building material has decreased to under 5 %. Although the buildings of the age groups from 19 18 to the present day are mainly examples of the solid-wall type of construction, the portion of block and brickwork walling decreases in this presentation. This illustrates the fact that the increased use of concrete is not only at the expense of the building material timber but also block and brickwork walling. The building materials clay and slag, which were still often used at the beginning of this century in timber beam ceiling constructions, have almost completely disappeared since World War II. In comparison, a continual increase in the use of inorganic materials such as glass and steel as well as insulation materials can be observed. The proportion of the collective group mortar/plaster/gypsum remains generally stable.

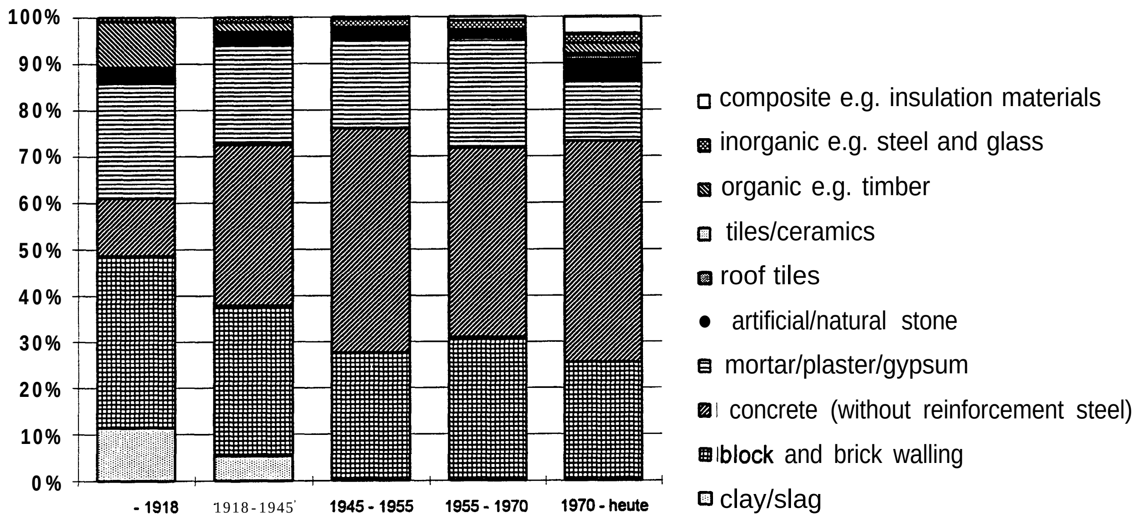

Fig. 3 Usage of Building Materials in Buildings of Various Age Groups as a Mass Percentage Distribution [1]

Fig. 4 represents the distribution of building material masses in loadbearing structure and finishes. The illustration shows that more than 80 % of the building material masses of the examined residential buildings can be apportioned to the loadbearing structure, and less than 20 % on the finishes. A displacement of the building material masses from the loadbearing construction to finishes is recognisable in the younger building groups. This emphasises the increased use of building materials in the area of finishes due to the increasing requirements made for thermal and sound insulation. It is also of interest to note that for buildings constructed prior to 1918 the internal finishes also have a greater weighting. This tendency is accounted for by the fact that one then constructed the intermediate floors using timber beams, and the spaces between these beams were filled with sand, clay and slag. The use of timber and clay/slag in the building group prior to 19 18 is also documented in figure 3.

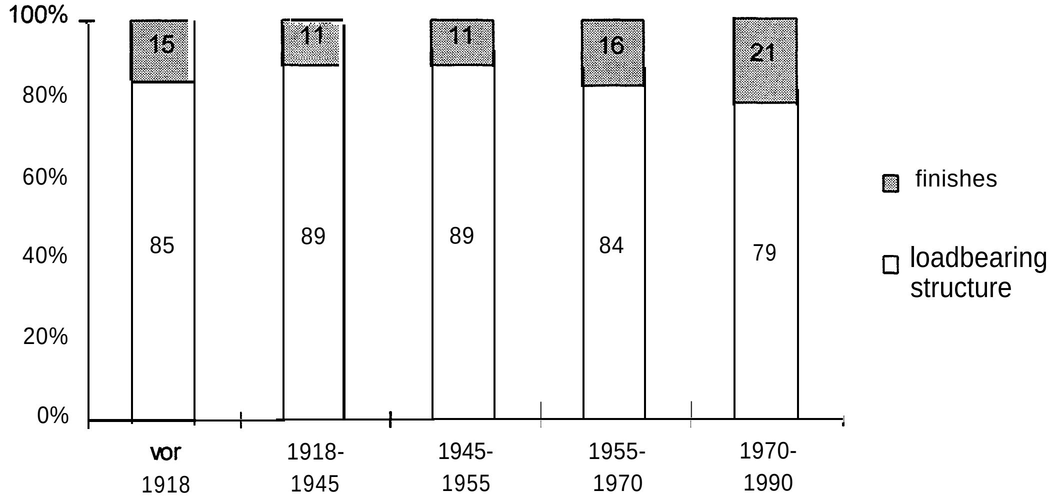

Fig. 4 Distribution of Building Material Masses in Loadbearing Structure and Finishes [1]

The average proportion of the individual building element groups in the total mass of all examined residential buildings, given in fig. 5, shows the dominance of external walls and floor/ceiling construction each with a value of 3 1 % for multi-family houses, followed by internal walls with 21 %. For single family houses the proportion for external walls with 39 % is much more characteristic, instead the floor/ceiling construction portion is barely 21 % and the internal walls with 14 % are of less influence. Taking the external and internal walls together, it becomes apparent that the proportion of the walls for single and multi-family housing in total are almost identical with just over 50 % of the total mass.

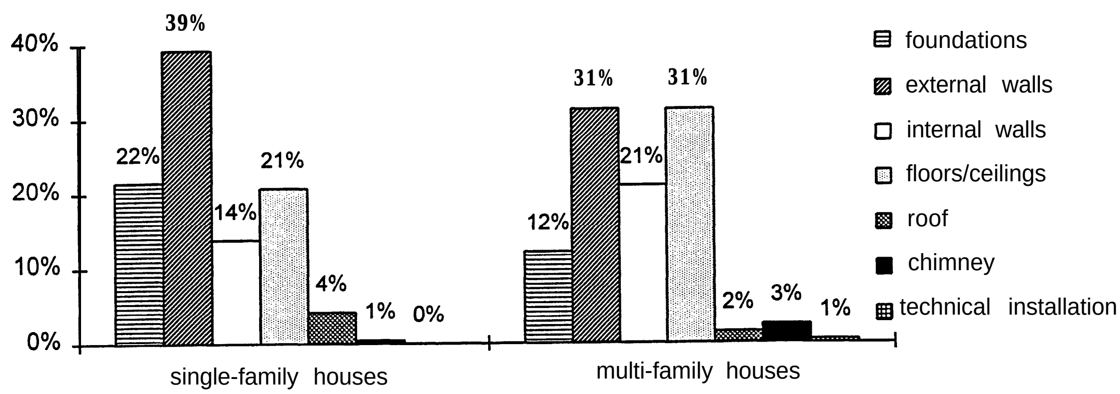

Fig. 5 The Average Proportion of the Building Element Groups in the Total Mass of the Examined Single Family and Multi-Family Houses [1]

Furthermore it can be seen that the building element groups foundations and roof are of greater weighting for single family houses. This shows that the discernible tendency of the higher average building material masses of single family houses, given in figure 4, is mainly to be found in the values for foundations and roof. This seems logical, as just in the foundations the elements foundations, floor slab and cellar walls are often dimensioned and built for constructional or static reasons, for example to act against lateral soil pressure. A dependency on an increasing number of storeys only becomes apparent after 5 - 6 storeys. The building material mass of the roof is however independent of the building height; it is determined by the built-over area and the roof shape. With increasing building height, the influence of the roof is thus clearly less.

2 Production Energy Input for Buildings

The examination of residential buildings with regard to the cumulative production energy input (PEI_H) carried out on 20 buildings has shown that the basic primary energy input values for the building materials are not decisive but rather the building material mass, defined by the specific material density. Figure 6 shows the total sums of the building material masses and the cumulative production energy input (PEI_H) related to the gross cubic content for give chosen residential buildings in a co-ordinate system. The buildings are 4 - 5 storey multi-family residential buildings, in each case a typical representative of solid-wall type construction for the given building age group. It can be seen that all five buildings vary around the value PEI_H/mass = 2 GJ/Mg. It can also be seen that the building in the age group 1945 - 1955 is not only the heaviest but also has the highest PEI_H value; nevertheless however its relationship PEI_H/mass is more favourable than for buildings of the following building age groups.

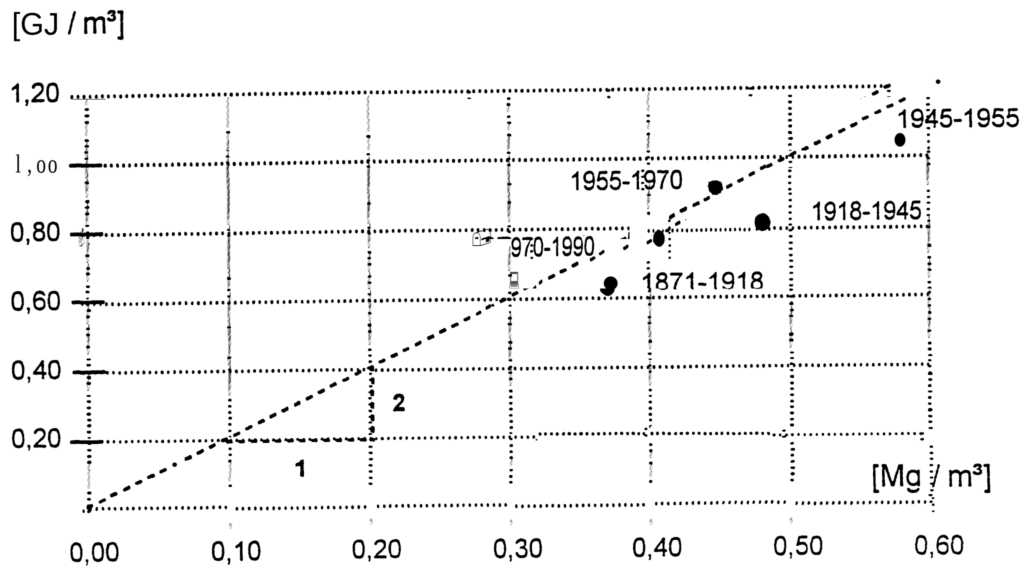

Fig. 6 Related Total Values of Building Material Mass and Primary Energy Input for the Five Multi-Family Houses [I]

Figure 7 shows the related building material masses and PEI_H for three multi-family houses, classified into building element groups in accordance with DIN 276.

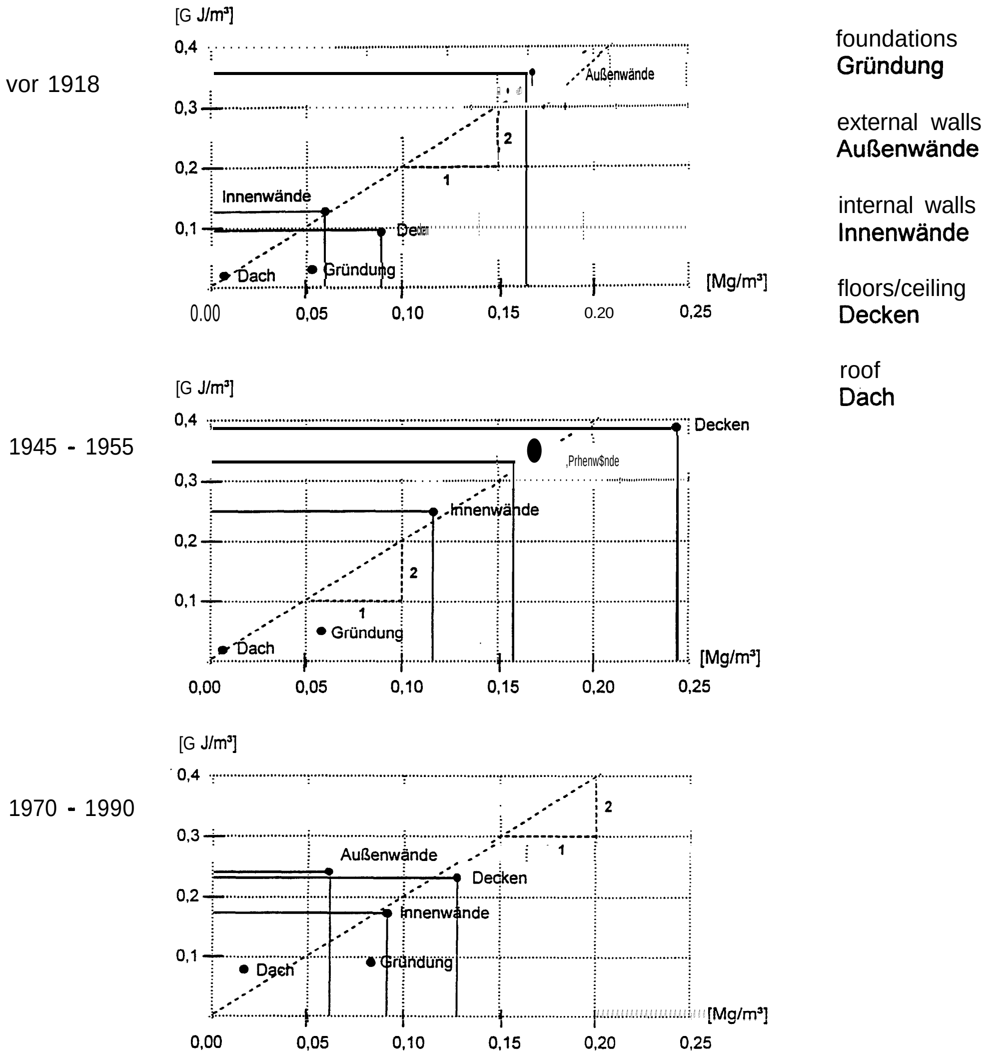

Fig. 7 Related Building Material Masses and Primary Energy Input for Three Multi-Family Houses [1]

Common for the examined buildings is the fact that the external walls and floor/ceiling construction are the dominant building element groups. For the building in the age group prior to 1918 it can be clearly observed that the external walls determine the size and level of the PEI_H value. If one examines the multi-family house constructed in the age group 1945 - 1955, a visible increase of the building element groups internal walls and floor/ceiling construction is noticeable compared to the building of the older age group. Not only have the absolute values increased mainly for the floor/ceiling constructions but also the level of PEI_H/mass has slightly increased. For the third building represented in figure 5.19 - in the youngest building age group from 1970 - 1990 - it is seen that the absolute values for the building element groups external walls and floor/ceiling construction have decreased again, and the individual building element groups are in closer proximity. It is noticeable that the PEI_H/mass level of the external walls has visibly increased. The building element group for foundations shows the lowest PEI_H with a value of approx. 1 GJ/Mg for all buildings.

3 Material and Energy Flow in Buildings During Their Use

In the following, the results of analyses of the material and energy flow in three single-family houses over a period of 80 years are presented [7]. A house built in accordance with the German thermal protection ordinance (WSVO), a low-energy house (NE-H) and a so-called passive-solar house (P-H) have been used as examples. Fig. 8 shows the cumulative building material masses of the three single-family houses in comparison. The stepped course of the curves result from the fact that individual building elements have to be replaced when their useful life has ended.

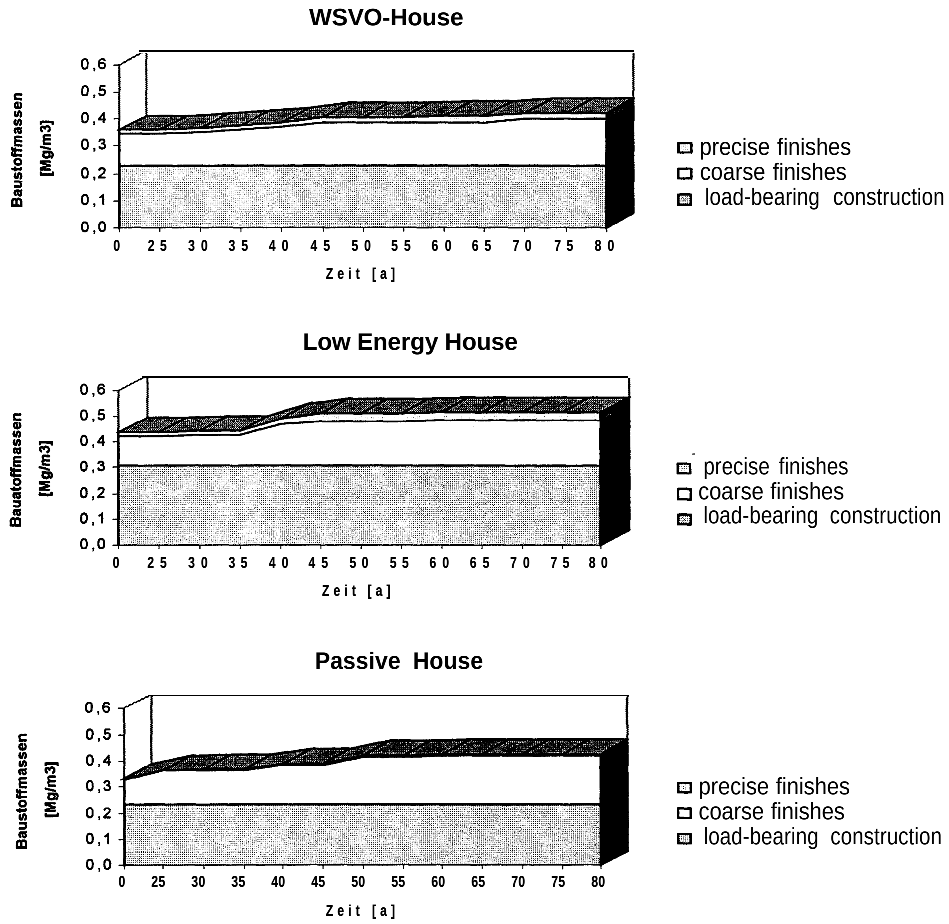

Fig. 8 Cumulative Building Material Masses of Three Single-Family Houses Over a Period of Use of 80 Years [2].

It can be seen that the finishes gain in importance within increasing length of use. In the case of the passive house, for example, the building material masses of the coarse and precise finishes have almost doubled after a period of use of 80 years due to maintenance measures. Fig. 9 shows the cumulative total energy necessary for the production, maintenance and operating of the three buildings. It becomes clear that the production, maintenance and operating of the three buildings. It becomes clear that the primary energy consumption for heating and the production of hot water is a multiple of the energy input for the production and maintenance of building materials in the case of a house built in accordance with the German. thermal protection ordinance. Even though the primary energy expended in production (PEI_H) for the passive house is almost double that of the building in accordance with this thermal protection ordinance, in the period of use the saving of energy clearly outweighs in the total audit.

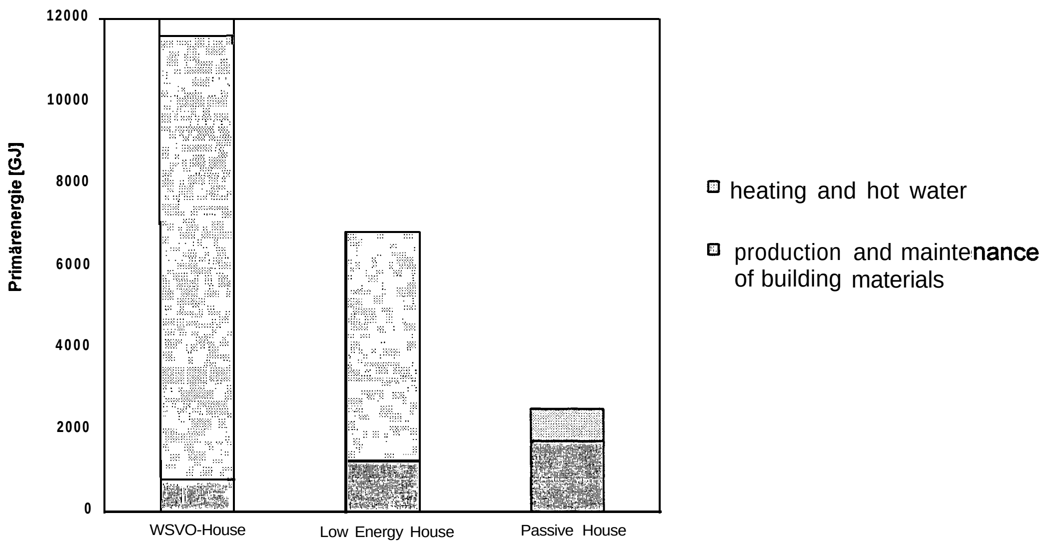

Fig. 9 Cumulative Total Energy Expenditure for Three Single-Family Houses Over a Period of Use of 80 Years [2]

4 Conclusions

In the future, the conservation and energetic restoration of the building stock will play an important role with regard to the reduction of material and energy flows in the building and construction industry. As shown in figure 4, more than 80 % of the building material masses in existing residential buildings can be apportioned to the loadbearing structure elements, and less than 20 % to the finishes. As normally the loadbearing construction of a building can be retained when larger alteration works are carried out, the preservation of existing buildings as well as the reactivation of empty buildings firstly contributes to the avoidance of residual building mass and disposal site volume, and secondly saves building material and energy resources.

Abstract
The historical building renewal requires procedures and methods to control degradation and obsolescence, in order to program the material and building system maintenance and to guarantee high quality interventions. For a fast reliable of constructed facilities, the individuation of variables affecting the building degradation and the study of their behaviour with time is the fundamental step [1]. The paper describes the use of diagnostic activities, based on the in situ alteration analysis, in the case of plaster surface renewal. The management information system connects data coming from different analytic methods in order to draw the life-cycle of the outside building finishing. To allow programmed maintenance operations, the identification of the contained alterations must be associated with the hypothesis of their development during the time. The simulation of degradation-induced phenomenon reduces doubts in the selection of intervention choices, allowing to program the maintenance. In addition, economical benefits and advantages for the maintenance management are possible too. The approach aim is to encourage the prompt intervention operations, restoring the initial bulding performance.
Keywords: plaster alterations, historical building life-cycle, maintenance program.

1 Introduction

So far the plaster degradation has not been considered as a progressive process and the produced damages never have been seen as product of a damage evolution. However, the consequences of the prolonged presence of degradation causes and the interaction with additional causes, able to increase significantly the damages, must be taken in account. The damage observed on the plaster surface is produced by the continuous action of agents coming from the environment (external agents) and the substrate (internal agents). In fact, the plaster is constituted of a number of superimposed mortar layers, that bond the wall surface regularising its discontinuities, so to give a homogeneous external flat surface with the function to protect the wall from environment factors [2,3]. Therefore, this component is equivalent to a filter, that interposed between wall and environment modifies the exchanges and suffers the degradation events. The included alterations are the effect of disturber phenomena that find their origin and their evolution in the environment, in the wall, and in the plaster layers.

In the building renewal, the acquisition step is of fundamental importance to select the operations required to achieve high quality results. Frequently, poor results are obtained because the analysis has been performed by inadequate methods. However, in addition to suitable analytical methods of investigation (destructive and non destructive tests), a complete set of rules and techniques always is required to assure efficacy and efficiency to the acquisition step. In fact, only the organisation of the complex sequences of analysis results and general information (i.e., building age, technologies used, environmental context, etc.) can allow the formulation of a right diagnostic hypothesis.

In the present paper, analysing the problem of the plaster surface renewal, it has been shown as diagnostic operations [4] can be developed on the basis of in situ observations of latent and visible surface damages.

2 Methodology section

The development of a specific lexis for the different alterations (visible and latent damages) that can be present on the plaster surface is required to give a rigorous organisation to the damage identification. Such identification is important to develop a correlation between plaster morphologic characteristics and specific alterations involved. The use of a lexis allows to perform two important objectives: first, it gives a common terminology to operators of this field of activity, and, second, it directs the operator among the several alteration causes. The proposed lexis is a re-elaboration of a standard terminology [5]. The three fundamental alterations classes and the specific alterations associated to each class are the following:

Deformation: change of the original geometric characteristics of the plaster surface and continuity parameters.

1. Alveolization;
2. desegregation;
3. separation;
4. erosion;
5. breaking;
6. lack;
7. swelling;
8. pulverisation.

Foreign material comparison: presence of foreign materials, stacked to the below surface, modifying the plaster surface uniformity.

9. Efflorescence;
10. coherent and incoherent surface deposits.

Chromatic heterogeneity: alterations of the chromatic uniformity of plaster surface.

11. Change of the original colour;
12. biological coat;
13. spot.

The degradation process can progressively increase with time. Such an increase can be due to the continuous presence of degradation causes, but also to the presence of additional causes, produced during the damage development [6]. In particular, the initial situation, characterised by a decrease of the performance levels relative exclusively to some specific properties, can be followed by a reduction in the performance levels relative to a different set of properties, with consequent changes in the initial conditions [7]. The prevision of the degradation phenomenon progress during the plaster life-cycle allows to perform a programmed maintenance of the surfaces so to reproduce their initial characteristics [8]. Only a suitable analysis and identification of the damages appeared with increasing of the degradation can assure efficacy and efficiency to the renewal. For this reason, all possible alterations must be organised in an evolution scheme where they are located in a logic sequence. Figure 1 shows the latent alterations that can be revealed during a periodic control by not destructive methods (e.g., thermography). Such alterations assume a recognisable 'appearance only with the increasing of degradation.

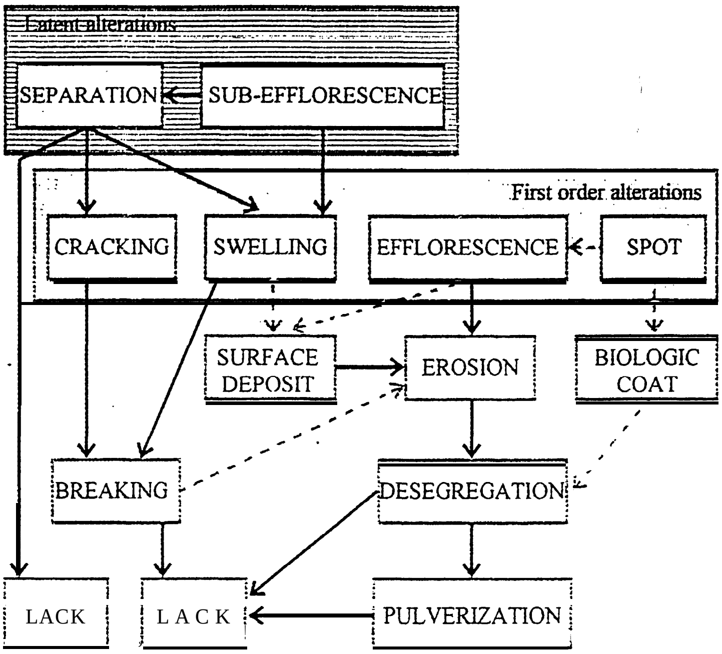

Figure 1 - The evolution scheme of alterations.

If the first order visible signs (read at initial time) are not totally solved by the renewal operations, they inevitably further develop. Consequently, higher order alterations, that cause processes able to transmit the degradation to the support wall, can result. In fact, the degradation progress leads to particular alterations, which are characterised by a more serious plaster and wall damage. The behaviour of the damage growth is influenced by several factors: plaster age, environment (i.e., building orientation and height, climatic conditions, air pollution, etc.), nature of the support and plaster materials, fabrication technology used, etc.. On the basis of all these factors, the degradation direction for both the support and plaster components can be statistically predicted for the particular environment present. However, when the plaster surface of the façade is damaged in several points, it becomes possible to formulate the hypothesis on the dynamic process characterising the degradation. Such hypothesis allows to perform renewal operations before that damages become excessively serious in some points of the façade.

In Figure 1, the continuous lines represent the visible signs included in the degradation ways started from one of the possible alterations. In addition, it has been observed that the production of some -particular alterations produces the favourable conditions for the development of new alterations. In this-case, such new alterations are produced only because ofmorphologic and physic-chemical surface modifications of the initial damage state. For example, the plaster surface swelling, can promote the surface deposit production and/or thekfflorescence. Also the efflorescence, producing micro-discontinuities on the plaster surface, easily accepts surface deposits.

Among the diagnostic systems for the study of latent damages [9,10], the thermographic analysis [11] is a very important technique that allows to obtain information on the full' plaster surface. The thermographic analysis is performed by a camera-video having a semiconductor sensor sensible to the infrared radiation. The study of the alteration processes requires the determination of microstructural and physic-chemical characteristics of altered and intact materials, and their comparison. Also in the case of plaster separations, the latent alterations can be revealed by a thermographic investigation. In particular, the presence of regions characterised by higher isothermal levels is indicative of plaster separation phenomena. The higher emissivity of regions where a separation is present is due to the higher wall ability to follow the environment temperature variations. The capillary phenomena, which progress produces damp spot and separation, are characterised by isothermal levels lower than the façade. The thermography, showing the real boundaries of a only partially visible phenomena, allows to obtain a damp distribution map before to have soluble salt diffusion processes, spot formation, and plaster separation. The analytical method can involve the microscopical investigation of samples (altered/intact materials) to reveal the morphology, colour, and consistency differences. The altered plaster/substrate interface has to be analysed to individuate the presence of compounds as sulphates, chlorides, nitrates, etc. (i.e., sub-efflorescence). The analytical investigations are performed by chemical methods, x-ray diffractometry, and IR spectroscopy. To value the phenomenon diffusion and to know the functionality loss of the plaster is required to perform the same analytical investigations on the full plaster section. Also a physical characterization of the plaster can give useful information.

The breaking is revealed by the presence of a large number of widespread micro-cracks or a low number of large cracks. Usually, the breaking can develop lack, because it can be originated at substrate-plaster interface. The breaking starts in the interior material or between the plaster layers (because of fabrication defects) and propagates up to surface, producing a partial plaster separation. When the process involves several plaster layers, the size distribution analysis of the inert contained in the different plaster layers allows to establish the presence of fabrication defects. When the plaster easily detaches from the substrate, the plaster-substrate interface has to be analysed to value the presence of new compounds that, producing a pressure on the plaster, cause the cracking.

3 Discussion

The Maria SS. Dell'Addolorata church, inserted in the S. Sofia conventual complex, was fabricated in the IX Century and it has undergone several changes and additions principally during the XIX Century. The main façade (see Figure 2) contains a stone-made base surmounted by pilasters with Corinthian capitals and by a bas-relief medallion in the middle. Geometrical figures representing bricks are present on the plaster surface contained between the pilasters. The individuation of the alteration evolutive process is possible on the basis of an analysis of alterations contained in the façade, shown in Figure 3.

Different damage levels can be observed in the building façade (Figure 3). The separation is the most frequent damage, and, therefore, the following evolution ways are possible:

- separation-lack;
- separation-cracking-breaking-lack;
- separation-swelling-breaking-lack.

The presence of a scarcely visible erosion alteration suggests the following additional evolution way:

- erosion-desegregation-pulverisation.

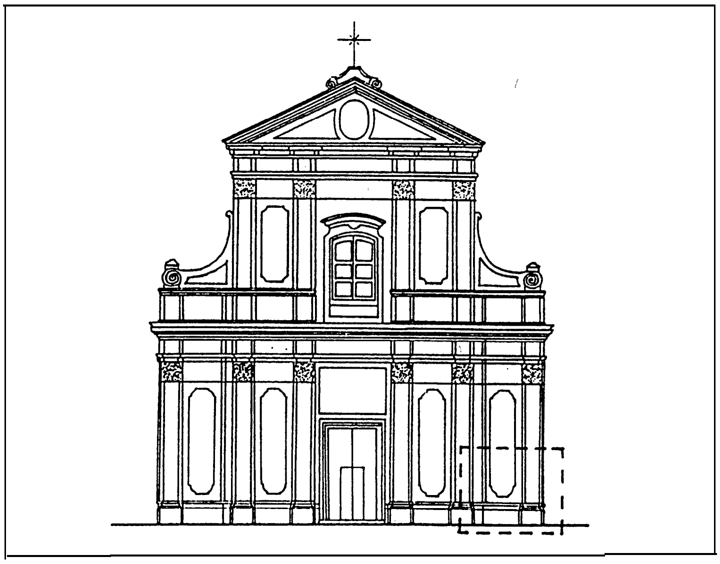

Figure 2 - Maria SS. Dell'Addolorata church Est-façade with the indication of the region containing the damages in Figures 4÷6.

Figure 3 - Maria SS. Dell'Addolorata church main façade.

The erosion can start from the presence of efflorescence or from the formation of coherent surface deposits, frequently, revealed during the investigation. The separation is the most evident damage and it frequently is present in the base region, where the contact is between materials characterised by different physical properties. In fact, as visible in Figure 4, the top of the base is not sensible to alteration phenomena, instead, the above plaster is almost totally lost.

Figure 4 **-** Alteration phenomena present at interface between base top and plastered wall.

It must be observed that, usually, the presence of a contact region between materials with significative porosity differences inevitably produces a large alteration of the higher porosity region. Such a behaviour is in accordance with the damages shown in Figure 4.

4 Conclusions

Starting from the analysis of the plaster surface alterations, it is possible to develop a diagnostic project including the investigations required for a complete phenomenon knowledge. Analytical investigations carefully performed allow the individuation of the causes required to the renewal operations. In addition, the individuation of the degradation evolution ways is required for an adequate maintenance programming [12,131. In the presents case, such approach allows the operations required to avoid the full plaster surface loss, so to reduce as much as possible the substrate damages. In the case of historical buildings, the possibility to foresee the plaster life-cycle reduces the material loss avoiding both modifications in the original nature (materials and shape) and application of the new plaster. In particular, the use of new plasters always has compatibility problems with the existing plaster and substrate performances [14].

Environmental assessment method adapted to buildings

M. Erlandsson
Ragn-Sells Miljokonsult, Sollentuna, Sweden

Abstract
This paper suggests an impact evaluation system for buildings called the Safeguard Assessment Method adapted to Buildings, SAM(B) The evaluation system corresponds to the step in a Life Cycle Assessment (LCA) called Impact Assessment. This means that the structure follows a LCA, suggested by ISO.

The assessment of buildings are divided in three themes; energy use (during service life), material flow and site specific values. Both energy use and material flow describes effects caused by the building and its utilisation. For a building the reverse is also relevant - the effect from emissions realised by anthropogene or natural sources. The reverse is taken into account in the theme "site specific values". For the moment only evaluation factors related to indoor air quality (IAQ) are introduced.

The evaluation system is based on the outcome of the inventory analysis from an LCA, except in the case of the site specific values which are based on in situ measurings. The suggested evaluation method in this paper is based on three safeguards. The safeguards are areas of protection, and here regarded as end points, which means that no further agglomeration should be performed. The safeguards are

- human health
- ecological systems
- resource efficiency.

Since the SAM(B) is still under development the only safeguard described in quantitative terms in this paper is related to the safeguard called human health. The evaluation is based on the concept "distance to target", where the target is equal to a "long time low risk concentration" of hazardous substances or comfort factors. Then a correction term is used to give an adequate evaluation of health aspects with serious risks compared to suffering and well-being in general. Preliminary figures for **17** emissions to air is given in Table 1.
Keywords: buildings, impact assessment, indoor air quality, life cycle assessment, safeguards, evaluation.

1. Introduction

Life cycle assessment (LCA) is a common tool for evaluation of the environmental impact from products and services. The result of an LCA study can for instance depend on:

- the aim of the study
- data quality
- system boundaries
- choice of impact valuation method.

The three topics given above are discussed in Erlandsson [1] for products assessment in general. In that report a development of LCA is described and called Life-Time Assessment (LTA). The LTA-method gives a solution to the problem with open loop recycling, one of the most critical points in the life cycle inventory part of an LCA. The LTA-method has then been further developed. How the LTA-method should be applied on assessment of buildings has been suggested in Erlandsson [2]. In this paper only the last topic given above - the choice of impact evaluation method - is discussed. A concept for an evaluation method (for buildings) is introduced.

2. The Safeguard Assessment Method, SAM

A general problem in developing of LCA to a user-friendly tool, is that it will be dependent on a reliable impact Assessment method. An evaluation method adapted to buildings must be extended (compared to an ordinary product-LCA for consumers products) to include adequate environmental themes valid for a building. Such topics are for instance contaminated soil, indoor air quality, possibilities for conversion, local environment and maintenance, choice of energy system, flexibility and water consuming. This paper presents a first conceptual approach for environmental evaluation of three areas of protection. These areas are called safeguards and the method is called **- the Safeguard Assessment Method, SAM.** Such safeguards as given in “Code of Practice“ by SETAC [3], are human health, ecological health and resources. In this paper however, these safeguards have been modified. The major remark is that the term health often includes more than only pure health aspects, such as general well-being. The safeguards discussed here are:

- human health
- ecological systems
- resource efficiency

An other difference between the original SETAC version and the safeguards in the SAM is that resource depletion is regarded as a monetary value and not treated at all as an environmental matter. The term resource efficiency is introduced instead and includes environmental issues regarding raw material extraction. It is often found that impact evaluation methods need to take into account special effects that are not of general kind, such as local environment. A special subcategory is here introduced for the safeguard human health, called comfort. This version of the SAM-method is therefore called **SAM(B), the Safeguard Assessment Method adapted to Buildings.**

The three safeguards are (for the moment) regarded as end-points, which in this case mean, that no agglomeration between safeguards should be made. However, this may of course be the practical case for internal use priority purpose, in a screening material selection process, as suggested in the EPS-system [4]. The idea of using safeguard is found in the EPS method (including five safeguards) and agglomerated by using a concept of “willingness to pay“. However, the safeguard in the EPS system is not used in practice, since the index in literature only is given as a single ranking index between different released emissions and use of resources.

3. The structure of SAM(B)

The environmental impact of buildings is often divided in a number of categories [5, 6, 7]. Two common categories are material flow and energy use. A third subcriteria introduced here is “Site specific values” and takes into account environmental themes that are equal to the difference between SAM vs. SAM(B). Material flow can be described as activities related to the building manufacturing process, construction, operation and service (heating energy excluded), maintenance, rebuilding, final demolition. Energy use for heating is here treated separately. In Sweden it is possible to buy electricity of different origin. The choice of electricity deliverer is therefore relevant for buildings with a high potential use of electricity. The environmental profile can easily change over time due to the present deliverer’s energy mix, and its environmental backpack.

Both energy use and material flow describe effects caused by the building and its utilisation. The reverse process will is also be relevant for a building - the effect from emissions realised by anthropogene or natural sources. Example of such site specific issues (that can imply great impact for the building environment) are taken into account in the building sub-category Comfort. e.g.;

- contaminated soil
- radon from ground or from building materials
- noise
- contaminated water
- indoor temperature
- ventilation
- moisture and microbiological activities

The environmental impacts given above are all related to the safeguard human health, why SAM(B) for the moment can use the standard version of the other two safeguards.

Files Edit Insert Tools Show Window V X

Environmental theme for a building	Safe guards			Single score index (not recom. for public use)
	Human health	Ecological system	Resource efficiency	
Energy use	2 B	A B	IV B	Σ horizontal
Material flow	3 B	C B	III B	Σ horizontal
Site specific values	1 B	B B	VI B	Σ horizontal
Sum for the building:	Σ6 B	ΣF B	ΣXIII B	Σ vertical = Σ horizontal

Figure 1 A hypothetical example of the interface of an assessment of a building. (B in the figure indicates that a bench marking value can be found. Please note that at this point only site specific values have been established for the safeguard human health, why the figure indicates a future development).

4. The safeguards

The practical calculation of the impact assessment is here divided into two steps:

0. Inventory parameters from the inventory analysis
1. Recalculation of inventory parameters into (potential) effect categories as given in Table 1 to 3, for each building theme.
2. Calculation of the sum for each safeguard for the building.

Table 1 The structure to evaluate the safeguard human health

Safeguard,	divided in	Indicator	Effect category
human health	1. shortened life 2. comfort	1. low risk level 2. acceptable comfort level	• genotoxicity • toxic • asthmatic, allergenic and hyper sensitive • heart and vascular disorder • decease carrier • rheumatism • reduced lung function • reduced immune defence system • effect on the central nervous system (CNS) • noise • temperature • moisture level • smell (odour)

In the safeguard human health, it is possible to include aspects regarding work environment. In SAM this is missing, as well as effects by smoking and accidents. Smoking is included as smoking effect from the surrounding environment/people. It is noticed that smoking is one of the most important sources that effects the safeguard Human health today. In an evaluation method adapted to a person, SAM(P), it would be most adequate to include smoking, as well as accidents or work environment. As mentioned earlier the safeguard human health is here divided into two issues. The first one takes into account for shortened life, and the second relates to non mortal issues, here called comfort.

Table 2 The structure to evaluate the safeguard ecological systems

Safeguard	Indicator	Effect category
ecological systems	• biodiversity of fauna (and flora)	• acidification • eutrophication • ozone depletion • global warming • photochemical ozone • eco-toxicology

Biodiversity is the only indicator suggested for the safeguard ecological systems. Because of lack of data for flora the indicator biodiversity only deals with fauna. The evaluation can be made as a world wide assessment or as is done here, for a country.

Table 3 The structure to evaluate the safeguard Resource efficiency

Safeguard,	**divided in**	**Indicator**	**Effect category**
Resource efficiency	1. occupation of ground 2. substitutable	time delay for same amount of biodiversity and production space 1. environmental impact to "produce" a new material source.	• biological productivity • agglomerated effect categories effects regarding "reproduction" of raw materials

The most common way of assessing resources as areas of protection is to take into account the scarcity factor one way or other (e.g. CML and UMIP). The term "scarcity" is changing from time to time, caused by new methods of extraction, prospecting methods, market price of raw materials etc. One could ask if the scarcity is best taken into account in the society in a quite natural way by using monetary terms? Since the reserve/scarcity to be used is defined by monetary terms, resource depletion is here regarded as an non environmental issue. What is not included in a ordinary LCA is the environmental impact to recreate a resource or substitute a fossil fuel. Steen [S] has in the development of the EPS-system given figures for such evaluation. This way of treating the resource use is most adequate for the safeguard resource efficiency. Another aspect not taken into account for in a traditional LCA is the local effect of resource extraction. A method to assess occupation of ground and the time delay factor before it is as productive (measured in biodiversity) as before is discussed in an assessment method suggested by Erlandsson [9]. The assessment between the two indicators suggested for the safeguard resource efficiency, is under evaluation.

5. Discussion of result from SAM(B)

The development of SAM or SAM(B) is not yet finalised and a complete evaluation method does not exist. Since only the safeguard human health, is considered for in all three environmental themes for a building, only a specific methodology for this safeguard is given in this paper.

The basic idea how to assess the safeguard human health is partly inspired by a concept of evaluation of emissions (in general) introduced by Ahbe et al [10]. In this concept a critical level is defined and the evaluation is then made by the concept "distance to target". The method suggested here is based on a "long time low risk concentration" of hazardous substances or comfort factors. This kind of low risk levels can be found by WHO, but in this paper a Swedish work has been used [1 1]. In the equation given here the concept "distance to target" is used and then taken into account for a correction factor. The correction factor is used to give an adequate evaluation of health aspects with serious risk (fatal outcome), compared to suffering and well-being in general. All environmental impacts with fatal outcome has a correction factor equal to 1, and figures given for well-being has been reduced by a factor of 75. As comparison one could say that a lifetime of 75 years reduced by 1/75 is equal to one year.

The equation for evaluation of the safeguard human health can be described as the quotient:

$$\frac{\text{normal background concentration}}{\text{long-time low risk level times a correction factor}}$$

Note that the normal background concentration makes the index "more site specific" than is common in an ordinary LCA. This use of normal background concentration should be made by with caution. The justification of admitting this factor is that a historical site specific background has influenced life and both human, flora and fauna should have time to adapt to that situation. Another case is radiation where one could say that the natural background already is too high. By this evaluation system high background concentration is a part of "natural death" or effecting the biodiversity etc. In practise this means that we will accept more people suffering from natural radiation than from an extra exposure of toxic chemicals (in Sweden). The calculation performed so far is preliminary and given below in Table 1.

Table 1 Preliminary figures regarding human health valid for evaluation of emissions to air [11, 12 13, 14,15,16]

Substance	**Evaluation**	**Comments**
Sulphur dioxide	0,002	
Nitrogen oxides	0,007	
Particular matter (general)	0,002	
Ozone	0,0002	
Carbon monoxide	0,003	
Benzo(a)pyrene	7	
Formaldehyde	0,120	To use for indoor air quality, IAQ (= site specific value)
Toluene	0,023	
Xylene	0,041	
Benzene	6,2	
Ethylene	264	Based on background figures for only one site
1,3-Butadiene	41	
Styrene	0,003	
Dichloromethane	0,0005	
Trichloroethylene	0,0062	
Tetrachloroethylen	0,051	
Radon	0,54 (Bq)	To use for IAQ

A comparison of values given in Table 1, with an evaluation based on only a critical background level, the evaluation method given here makes in principally ozone and carbon monoxide "more hazardous", and the reverse for benzene, ethylene, B(a)P and 1,3-butadiene.

A future development of SAM(B) will hopefully be founded and published elsewhere.

Wood-Assess – Systems and Methods for Assessing the Conservation State of Wooden Cultural Buildings

S.E. Haagenrud and J.F. Henriksen
Norwegian Institute for Air Research, Kjeller, Norway
J. Veit
Deutsches Zentrum für Handwerk und Denkmalpflege, Fulda, Germany
B. Eriksson
Centre of Built Environment, Royal Institute of Technology, Gävle, Sweden

Abstract
Europe's rich culture in wooden buildings are rapidly degrading due to environmental impact, wrong conservation techniques, and lack of resources and technological tools for appropriate conservation. These issues are addressed in the EU -project ENV4-CT95-01 10 Wood-Assess, and this paper summarises objectives, strategies, work-tasks and some main results from the recently finalised project. It's main objectives have been to develop and validate methods and technologies for proper assessment of the conservation state and for mapping and assessing environmental risk factors and -areas to wooden buildings on macro, local and micro-scale. The systems and methods have been validated by assessing chosen buildings in Germany, Sweden, Norway and Poland. Main work-tasks have been the development of an assessment protocol and a field inspection system, of the WETCORR method for continuos monitoring of temperature and moisture in the micro-environment on and within wood, and of a system for mapping the rotting index for wood on various geographical levels by the use of existing climatic data, standards and the WETCORR measurements. The assessment system, which allows for maintenance management is available in a PC-based geographical information system, GISWood.
Keywords: wooden buildings, condition survey, assessment protocol, mapping environmental risk factors and -areas, geographical information systems (GIS).

1. Introduction

Europe's rich culture in wooden buildings are rapidly degrading due to environmental impact, wrong conservation techniques, and lack of resources and technological tools for appropriate conservation.

There are 2.4 million timber-framed buildings in Germany. Most of them erected before 1870 (79%). Norway has 2500, and Sweden 800 wooden buildings that have been listed for conservation. To this must be added the logged-timber buildings in Upper-Bavaria and the Black Forest, and also the "Umgebinde" buildings in eastern part of Germany, and in Poland and the Czech Republic. Also in central and southern part of Europe there are a lot of timber- framed houses.

Wood is also an environmental friendly, but scarce, material which today should have a potentially much wider use. In that respect better systems for its protection should be developed.

The Wood-Assess project pursues pooling of European resources to develop methods and technologies for proper -assessment of the conservation state and for mapping and assessing environmental risk factors to wooden cultural buildings. This will facilitate a more sustainable management.

2. Model for degradation of wooden materials and objects

The degradation of outer parts of wooden buildings are influenced by a whole set of factors, see Figure 1, such as environmental degradation agents classified here according to IS0 6241 (1), quality of wood and the type of and quality of wood protective treatment, maintenance and so on.

The relationship between the environmental degradation agents and the observed effects are expressed as dose-response functions. Due to the very complicated nature of the degradation system and a lack of systematic scientific research, very few quantitative dose-response functions exist today. Scheffer's Climatic Risk Index (CRI),

$$CRI = \frac{\sum_{Jan.}^{Dec.}\left[(T - 2)\ (D - 3)\right]}{17} \qquad (1)$$

which describes the rotting tendency of wood as function of climatic parameters of temperature and moisture, is an example of such functions (2). A main objective of the project is to develop and validate such an index for the chosen locations.

Further, when looking at building elements and the whole building, factors such as constructive solutions, micro environment at the building, workmanship and the time aspect, i.e. the history of the building becomes essential.

Information on all these elements needs to be elaborated in a systematic way, as does also the methodology for carrying out the condition assessment survey including the field inspection.

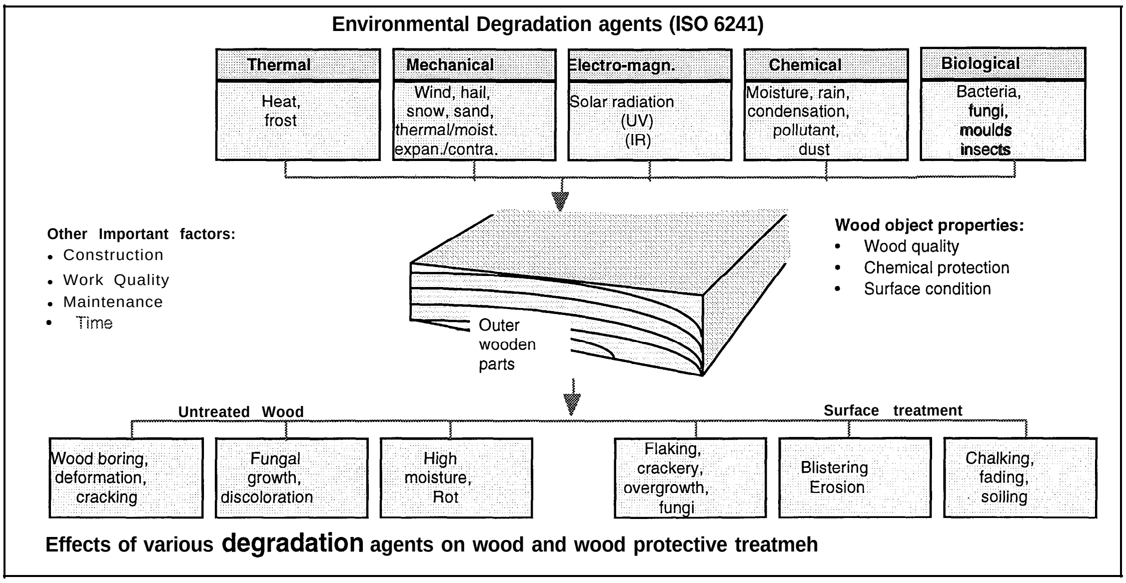

Fig 1 Degradation of wooden objects – model of degradation factors and their observed effects.

3. Project objectives and strategies

Objectives are to *develop and validate:*

1. *Systems and methods for assessing the conservation state for the outer wooden parts of cultural buildings, and their causes and effects.*
2. *Methods for measuring continuous surface time **of** wetness and resulting moisture content inside wood, biological and environmental damage to wood.*
3. *Methods **for** assessing and mapping environmental risk factors and areas **for wood** on meso- and micro- scale at some locations in Europe.*

The systems and methods are validated by assessing outer wooden parts of chosen buildings in Germany, Poland, Norway, and Sweden. Locations and types of houses are characterised as follows:

Germany:
Ebersbach – inland climate, originally agricultural and for many years industrial emission. *“Alte Mangel”* - German “Umgebindehaus” (logged construction in ground floor and timber frame above) built between 1767 and 1770.

Poland:
Swidnica – dry inland, heavy industrial pollution, object *“Peace church **of** the Holy Trinity”*, timber-frame construction built between 1656 and 1657.

Norway:
Maihaugen – House *“Hjeltarstua”* is situated on Skjåktunet at Maihaugen open air museum in the outskirts of Lillehammer. The house, which was built in 1763, is a log

house with log loft on the east part of the house. It was moved to Maihaugen around 1905.

Sweden:
Gävle – urban coastal, cold climate. House *"Berggrenska Gården"* is situated in the centre of the city. It was built in 18 13 and partly rebuilt in 1869,
Stockholm – urban, cold, climate. House "*Norrkulla gård*" is situated north-east of the centre of Stockholm at Waxholm. Cabin built of logs dovetailed at the corners, outer vertical boarding. Ground floor built between 1750 and 1800, and the second floor built after 1850.

4. Results

4.1 PC based assessment protocol and field inspection system

The Assessment protocol is synthesised from existing national guidelines and standards in the participating countries (3). The protocol is available in a PC-based geographical information system (GIS), see Figures 2 and 3.

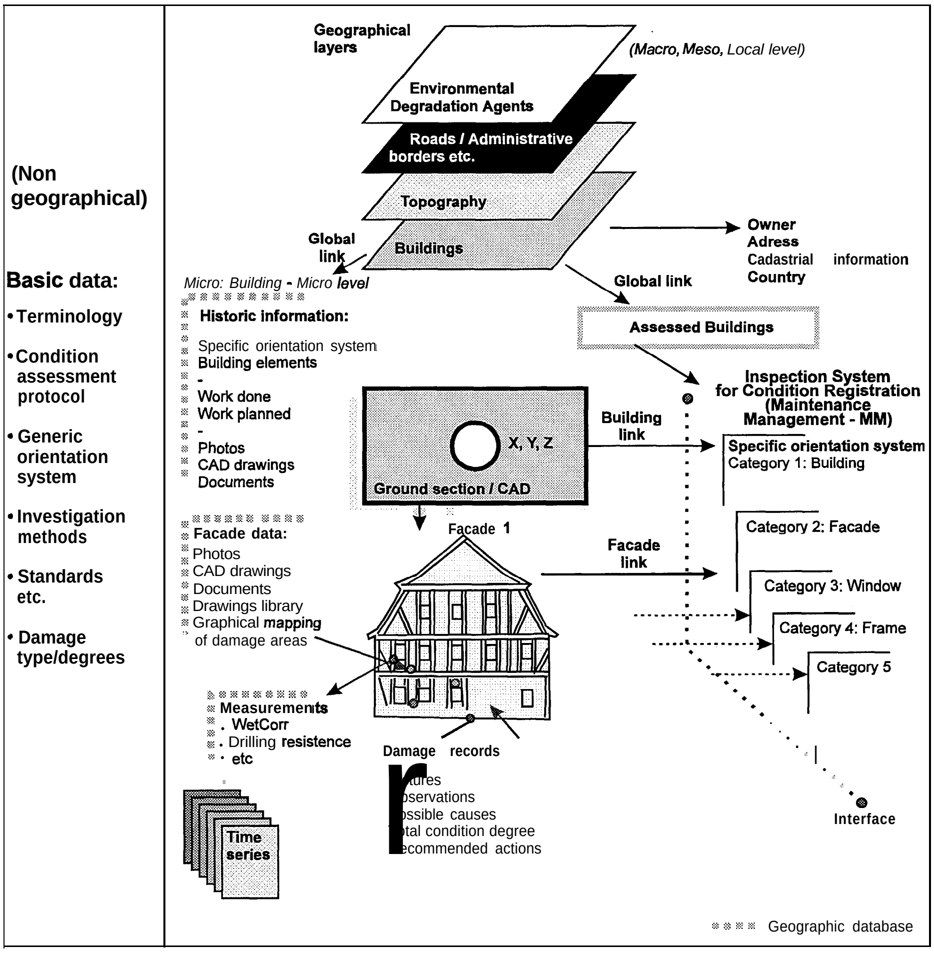

Fig 2 Schematic view of integration of information and information elements in GISWood.

Figure 2 shows a schematic view of levels of information and information elements in GISWood, such as

- Building orientation system;
- Description of purposes, phases and levels of investigation;
- Overview of investigation and measuring methods;
- Themes for environmental risk factors;
- Databases with types, degrees, causes and effects of damages (Pictures and texts);
- System for graphical mapping of damages.

This system will give the user a tool to handle and systematise data from the assessment of cultural wooden buildings. This ranges from needed basic background data and knowledge down to detailed measurement and inspection data. Different user levels are taken into account (3).

The Wood-Assess – GIS system is based on the standard ArcView 2.1 package, which is a part of the ARC/INFO GIS system, delivered by ESRI. ArcView is Windows based program running under MS-Windows 3.1, Windows 95 and Windows NT.

Figure 3 shows the assessment and categorisation of some damages at Hjeltarstua, Maihaugen, Norway as recorded by the inspection system, MMWood and exhibited in the GISWood system.

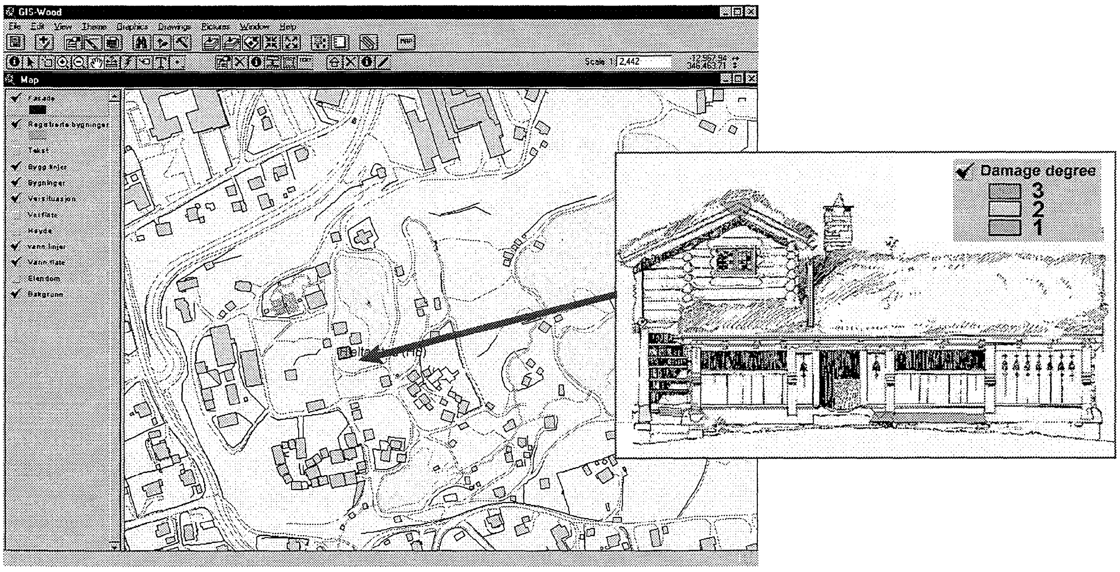

Fig 3 Damage assessment of Hjeltarstua at Maihaugen, Lillehammer exhibited in GISWood.

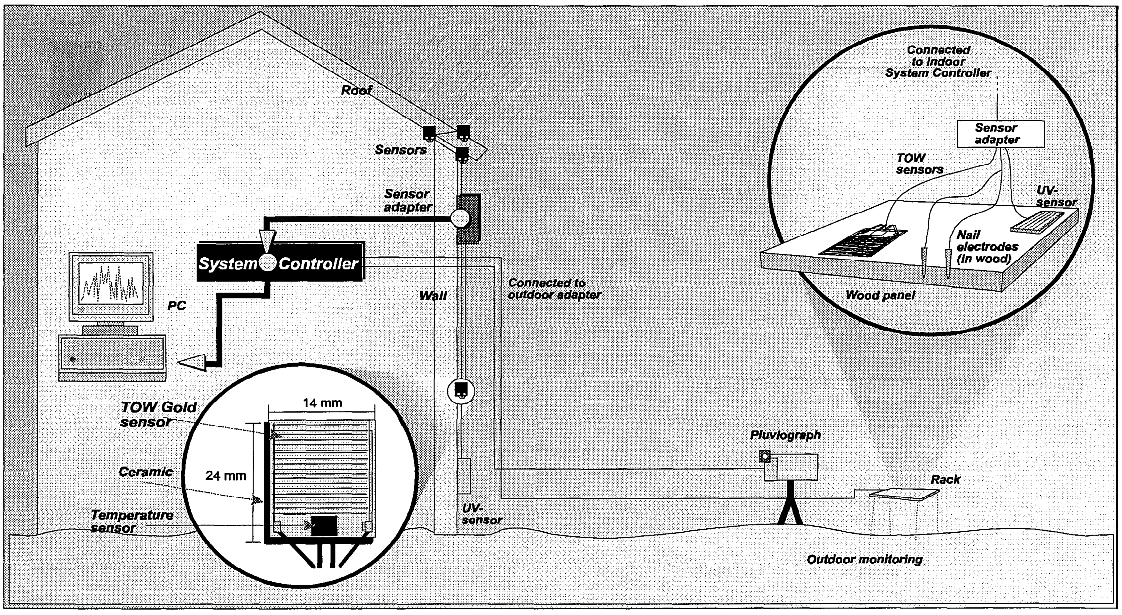
MMWood is a computer-based system developed in order to structure the work and the resulting information handling from inspections, and also as a tool easing the planning and execution of maintenance work.

The inspection is done by using a handheld computer with a bar-code reader and a digital camera for taking pictures. The bar-codes are defined in the assessment protocol, and consists of categories of elements of a wooden building, observations of symptoms linked to these elements, and a set of predefined questions ensuring the proper registration of relevant information.

4.2 Measuring moisture and temperature on and within wood

Measurement methods for moisture and temperature in the micro environments are based on the NILU WETCORR measuring device (4). The existing gold sensor measures surface moisture and -time of wetness, while nail electrodes is developed into a new sensor application, WETCORR INWOOD, for continuously measuring the uptake and distribution of moisture within wood. This has been performed both in laboratory measurements in climate chambers and in field at the chosen locations (5). The monitoring set-up in field is shown in Figure 4 , and the results are described by Eriksson (5).



a) b)

Fig 4 a) WETCORR instrument with gold (Au) sensors for monitoring Time of Wetness (TOW) and temperatures, and sensor for measuring critical UV-radiation, at various places on buildings. b) Climatic Risk Index assessment at location of house. Pluviograph for precipitation and Wood sample with Au sensor for surface TOW and nail electrodes for moisture inside wood (INWOOD), and sensor for critical UV-radiation.

4.3 Assessing and mapping environmental risk factors

There are great differences in temperatures and precipitation regimes in Europe. This results in equally great differences in potential wood decay rates.

The assessment of Environmental risk factors were assessed by calculating Scheffer's climatic index for potential wood decay from existing meteorological monthly data for temperature and duration of precipitation at the chosen locations, and on measurements of selected climatic variables at one site on each location, see Fig 4. By comparison with the WETCORR data for wetness duration and temperature, this climatic risk factors can be transformed to a WETCORR based Climatic Risk Factor (6).

This formula will be specific for each type of wood, and opens up the possibility of continuous moisture characterisation of various types of wood. To map the CRI in the micro environment on the building, WETCORR measurements are performed on the critical points of the assessed buildings. By comparison of these data with the open exposure data, relationship between the local incoming climatic moisture and the resulting micro-climatic moisture on and within wood parts of the buildings is obtained. This will be major new methodologies and tools for assessing the climatic risk factors for wood preservation on meso-, local- and micro scale in Europe, which can have broader implications also for the building sector in its implementation of the Construction Products Directive (7).

5. Conclusions

Common guidelines for documentation and assessment of condition state of outer wooden buildings have been developed, based on documentation and evaluation of damage causes, effects, consequences, risks and possible remedial actions. The assessment protocol also contains modules for assessing the environmental risk factors and is available on a PCIGIS based platform.

Ecological aspects of using concretes with large-tonnage waste

B. V. Gusev, L. A. Malinina, T. P. Shcheblykina
State Research Centre (SRC) “Construction” of the Russian Federation,
Research Institute of Concrete and Reinforced Concrete [NIIZhB], Moscow, Russia

Abstract

Great attention is currently being paid to destructive effects of industrial activity that in certain countries has been known to disturb the balance of nature. Construction ecology deals with the utilization of large-tonnage waste accumulated in industrial disposal areas. Large-tonnage waste (LTW) occupies vast territories of land, increases man-made environmental effects, and thus adversely affects human health in general. The construction materials industry holds a unique pACLe within this context. The use of LTW in the construction industry can solve the three-pronged problem of reducing the cost of construction materials, saving natural raw materials, and protecting the environment. LTW contains many harmful impurities including heavy metal compounds. So, waste can be utilized to advantage only if both the technological and ecological-health properties of waste and building materials are taken into account. The authors of the paper jointly with the Research Institute for Ecology of Man and Health of the Environment (RIEM&HE) have determined the ecological-health properties and characterized the level of danger of man-made waste and of hardened cement paste based on low-clinker binders and various concretes containing acid ash. The study has shown that the toxicological problem of man-made wastes and of construction materials on their basis does exist. However, in spite of the fact that individual waste materials may be harmful, man-made waste combined with traditional construction materials can be used to manufacture ecologically benign materials. This is because hardened cement paste and concrete can fix harmful ingredients in place both by drawing them into hardening process and by making them part of the structure of hardened cement paste.
Keywords: concrete, large-tonnage waste, heavy metals, toxicity, ecology.

1 Introduction

Great attention is currently being paid all over the world to destructive effects of industry that disturb the balance of nature [1]. Modern ecology has split into a considerable number of specific areas. What is known in Russia as "construction ecology” deals in particular with the utilization of large-tonnage waste (LTW) that has accumulated at dumps occupying huge land areas. This in turn has increased the man-made environment loads that consequently produce a considerable adverse effect on human health.

The construction materials industry holds a unique pACLe within this context. The use of LTW in the construction industry as valuable secondary mineral raw materials can solve the three-pronged problem of reducing the cost of construction materials, saving natural raw materials, and protecting the environment.

Large-tonnage waste can be used most efficiently in the production of the binders that do not need much energy to manufacture, of aggregates, and of various types of concrete since in this case the best cost effectiveness can be ensured and competitive materials can be produced.

High technological compatibility between man-made waste and natural materials, including Portland cement, is due to the affinity of the elementary composition which mainly consists of oxides, including SiO_2, Al_2O_3, Fe_2O_3, and CaO and, in small quantities, MgO, SO_3, MnO, Na_2O, and K_2O. The difference between man-made waste and natural raw materials lies only in quantities of these oxides.

Together with basic oxides, natural and man-made raw materials contain small amounts of impurities that can be divided conventionally into technologically harmful and ecologically harmful agents. The content of the technologically harmful impurities that adversely affect the engineering properties of concretes, binders and aggregates and reduce their durability is quoted in all specifications.

Ecologically harmful impurities are toxic elements and these include primarily the compounds of heavy metals, such as Pb, Ca, Co, As, Cu, Zn, Ni, Cr and Mg; and toxic substances and carcinogens which were not considered harmful in the past. In Russia, it is only in the last few years that radioactivity of man-made waste that is being checked due to the publication of GOST 30108-94.

Table 1 lists typical ranges of contents of heavy metals derived from ashes of cogeneration plants (CGP) in Russia. The data were reported by the Resource Research Institute. Table 1 shows that contents of individual elements in ash can vary by an order of magnitude from **3** to 10.

Table1 Content of heavy metals in ashes of coals from main deposits in Russia.

Element	Cd	co	cu	Ni	Pb	Zn
Content g/ton	**2.5-24**	**30-85**	**25-246**	33-194	**64-224**	**87-267**

It can be seen then that wastes can be utilized to advantage only when, in addition to technological properties and performance in construction, the ecological-health properties of the waste and of building materials they are part of are taken into account. Thus secondary pollution can be avoided and ecologically clean dwellings can be built.

The most important industrial waste for construction is the waste of power plants, of the metallurgical industry, and of the chemical industry. These include wastes such as ash and ash-slag mixes, metallurgical slag and sludge, and sulphate-bearing production waste.

The distinctive characteristic of metallurgical and power plant wastes is their capacity for sulphate, alkali and other types of chemical activation of waste from other industries, including sulphate-bearing materials, both natural and man-made. We applied this principle to develop a new type of a low-clinker composite binder based on sulphate-bearing materials of natural or man-made origin (e.g. phosphogypsum-dihydrate) and on acid ash from cogeneration plants, which mutually activate hardening. This binder was developed with a Portland cement content of up to 30% by weight. The binder is hydraulic, water-resistant and has a normal setting time. The strength of hardened cement paste varies from 15 to 45 MPa. Fine-aggregate concretes made with this binder and ash-slag mixes as fine aggregates are equivalent to the concrete strength grades of B7.5 to B20, Portland cement content being 50 to 100 kg/m^3.

In collaboration with the Research Institute for Ecology of Man and Health of the Environment we have determined the EH properties and the level of danger of man-made waste and hardened cement paste with low-clinker binders and various concretes containing up to 600 kg/m^3 of acid ash.

2 Investigation procedure

We used accelerated methods developed by the Research Institute for Ecology of Man and Health of the Environment [2] to evaluate the EH properties. The principal stage of this test procedure is a biological-chemical analysis of multicomponent industrial waste. Along with the chemical analysis, the level of biological activity of waste specimens was investigated. The presence of mobile forms of heavy metals in the wastes served as an indication of the biological activity. The quantities of heavy metals vary over a wide range depending on the acid-base equilibrium in the environment of the waste. So the content of heavy metals was determined in tap water (pH 7.0 to 7.2) and in an acetate-ammonium buffer solution (pH 4.8). The analysis and comparison of heavy metal contents in these extracts enabled us to predict the level of danger of a particular waste material.

The buffer extract can simulate the acidity of soils and the effects of acid rains thus making it possible to evaluate adverse effects of wastes when they enter the soil or are affected by an acid rain. The comparison between the heavy metal contents in the water and in the buffer extracts of the waste and their allowable concentration limit (ACL) for soil and water ponds permits the evaluation of the level of potential danger of the waste for the environment.

Together with the biological-chemical analysis, criteria were developed and a method for evaluating the danger of metal-contaning waste by accelerated biotests (a biotest for germinating seeds and biotesting by means of water organisms of infusoria and daphnia) was substantiated by experiments.

The terms “ecologically clean materials” and “ecologically clean dwellings” have become quite common in the last few years. The basic governing documents currently in use for the ecological-health (EH) evaluation of a material or a medium are allowable concentration limits (ACL) of contaminants for various media. It can be said with assurance that a construction material is ecologically clean if the release of ecologically harmful substances from the material does not exceed the ACL for free air, soil and water ponds.

The procedure for investigating specimens of hardened cement paste based on low-clinker binders is as follows. The migration of substances from the material to the air was tested in special accumulating chambers. Specimens of the material having the same composition were placed in the chamber for 24 hours and then air samples were taken. Air was sampled again in the chamber after 10 and 30 days, and changes in the migration of harmful substances into the air were determined. For comparison, the same tests were made for specimens of construction materials that did not contain any wastes (control specimens).

The investigations in the chambers were conducted at temperatures of 20^0C and 40^0C. Various air flows varying from 0.02 m/s (indoor service conditions) to 1.5 to 5 m/s (street conditions) were simulated to produce the effect of wind erosion on the material under study and to take air samples to check for accumulated dust. The dust was then subjected to chemical analysis to determine the content of harmful ingredients.

Since the density of hardened cement paste and of concrete specimens is very high and the migration of chemical substances to the air is relatively low, the during the EH investigations we were able to study the degree of migration of chemical substances from building materials under the action of real-life situations such as acid rains (for certain types of buildings), seasonal temperature differences, or deterioration of a material. The best way to simulate such conditions is the investigation of water extracts from construction material specimens that have insignificant spallings from surface, thus simulating some damage to the material.

Water extracts from construction materials should be also tested where they may be in contact with water that can dissolve their components, including the compounds in the waste used in a material, which thus can get into ground water.

To study the migration of harmful substances to water, specimens of construction materials should be placed in tanks filled with distilled water. The ratio of the volume of the material to that of water depends on the intended use of the material. When the contact with water is of short duration and not permanent (e.g. walls of houses or roofs), this ratio is 1: 10. If construction materials are used in long-term and permanent contact with water (e.g. foundation blocks, road slabs, piles, and elements of hydraulic structures), the ratio is increased to 1:2 or 1:3.

Water extracts were tested in 1, 3, 7, 10, 20, and 30 days of water immersion in a bath of 20^0C and 40^0C characteristic temperature of dwellings in summer.

3 Results and discussion.

The EH properties of the following materials were investigated:

- ash of two cogeneration plants (i.e., from their dumps);
- phosphogypsum-dihydrate from the Voskresensk cement factory (i.e., from its dump);
- Portland cement;
- hardened cement paste (FGC-70, FGC-30, AGCB, see below);
- concretes containing ash (i.e., normal-weight concrete, fine-aggregate concrete, and lightweight concrete);

The first type of the hardened cement paste specimens (FGC-70 and FGC-30) contained fine cements containing 70% and 30% ash and 30% and 70% Portland cement, respectively. The second type of the specimens (AGCB) was based on fine ash-gypsum-cement binder that contained 40% ash, 40% phosphogypsum-dihydrate, and 20% Portland cement.

The total content of heavy metals was found by mass spectrometry. The content of the metals in mobile form in water and in acetate-ammonium extracts was determined by the atom-adsorption method and by the spectrophotometric method.

The research results are given in Table 2. One can see from this Table that the wastes had in their composition harmful ingredients such as Cd, Co, Cu, As, Cr, Zn, etc. The total content of these elements in some wastes considerably exceeded the allowable concentration limit (ACL) for soil. So, these wastes could be classified as potentially dangerous. The analysis of the content of water-soluble forms of heavy metals found their largest quantity in phosphogypsum (Cu, Ni, Zn) and in the ash from the Severodvinsk cogeneration plant. So we could say that these wastes were biologically active.

Table 2 Content of heavy metals (gross and flowing forms) in various types of waste

Waste type	Content of elements	Cd	Co	Cu	As	Ni	Pb	Cr	Zn
Dsposal ash CGP-22	total, mg/kg	2	19.6	14.5	16.5	-	9	180.3	16.4
	water extract mg/l	0.001	0.01	0.01	.015	0.01	0.01	0.01	0.01
	extract in buffer solution, mg/l	0.001	0.01	0.12	0.091	0.01	0.01	0.18	0.46
Ash from Severodvinsk CGP Sample 1	total, mg/kg	2.9	59.4	87	59	213	2.3	704	115.5
	water extract mg/l	0.001	0.01	0.01	0.04	0.01	0.01	0.01	0.01
	extract in buffer solution, mg/l	0.001	0.06	0.31	0.6	0.19	0.01	0.3	0.3
Ash from Severodvinsk CGP Sample 2	total, mg/kg	1.5	10	40	-	40	5	9	16
	water extract mg/l	0.03	0.05	0.04	-	0.06	0.1	0.02	0.03
	extract in buffer solution, mg/l	0.6	1.0	2.8	-	4	-	1.4	3
Phosphogypsum dihydrate from Voskresensk factory	total, mg/kg	2	227	126	-	7.5	2	7.1	185
	water extract mg/l	0.001	0.01	1.37	.0004	0.13	0.01	0.01	1.24
	extract in buffer solution, mg/l	0.001	0.03	1.3	.0004	0.16	0.01	0.01	1.35
Portland cement without admixtures	total, mg/kg	2	7.4	16	2	11.3	2	119	35
	water extract mg/l	0.001	0.01	0.01	.0004	0.01	0.01	0.01	0.01
	extract in buffer solution, mg/l	0.001	0.01	0.02	.0004	0.01	0.01	0.32	0.01
Allowable content limit in soil (ACLs), mg/kg		0.5	50	33	2	20	32	90	55
Allowable content limit for water ponds (ACLwp), mg/l		0.001	0.1	1.0	0.05	0.1	0.03	0.5	1.0

Table 2 shows that the quantity of mobile forms of metals in the buffer solutions increased significantly for all wastes as compared with the water extract. In some cases it substantially exceeded ACL for water ponds.

The Laboratory for Industrial Waste at the RIEM&HE (Moscow, Russia) have investigated the wastes and established their level of danger. It was found that the waste under study fell into the category of highly dangerous materials. These findings are rather doubtful. The level of danger thus established puts these wastes in the same group with really harmful waste such as galvanic sludge. It means that the experimental procedure when used regardless of the actual application of waste should be adapted to the specific use of waste in the production of building materials.

We should emphasize that it is very important to determine correctly the level of danger of a particular material. Groundless overrating or underrating of the danger level of industrial waste can only have negative consequences. The former will complicate application and reduce the quantities of waste in the production of construction materials while the latter will be evidently dangerous for human health.

The results of studying the EH properties of hardened cement paste specimens containing the fine low-clinker binders FGC-70 and AGCB that emit harmful substances to free air are shown in the diagram (Fig. 1) in terms of ACL units.

$$C_i \text{ (in ACL units)} = C_i / ACL$$

where C_i is the concentration of the i-th element released from the specimen to the environment.

It is evident from these results that the EH properties of hardened cement paste with AGCB differ considerably from those of the cement paste with FGC-70. In the case of the AGCB hardened cement paste, the release of heavy metal compounds into the air is substantially lower than the ACL (see Fig. 1).

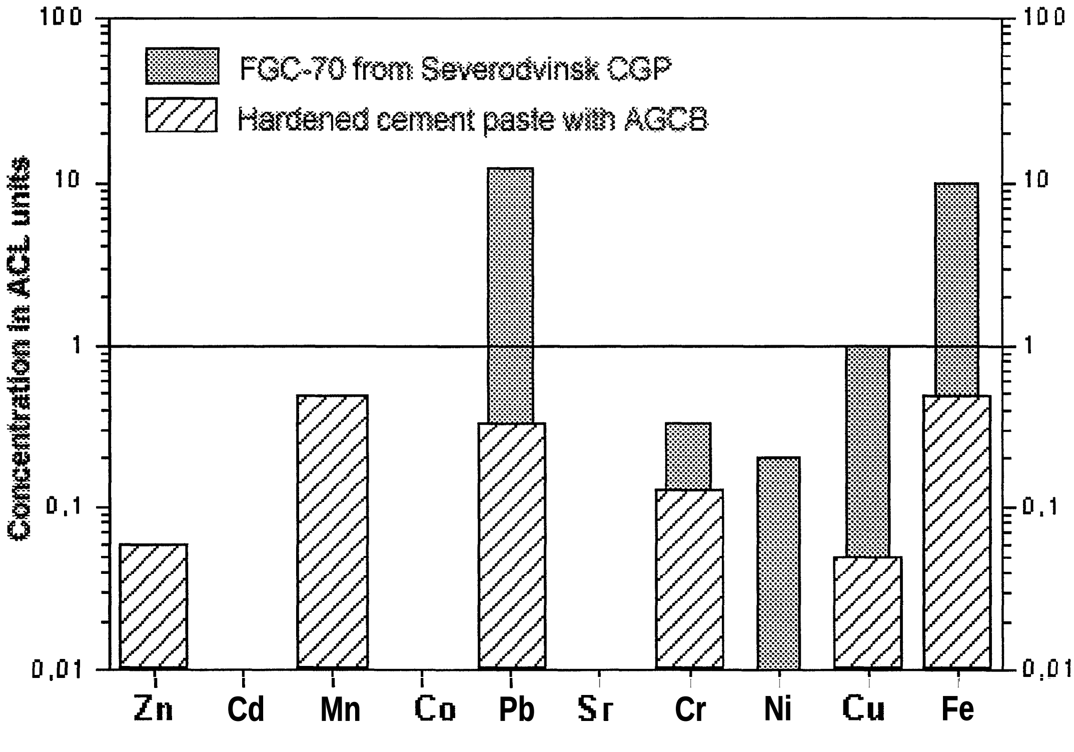

Fig. **1**

In addition, the research results showed that water extracts from ash-gypsum-hardened cement paste did not contain any water-soluble compounds of Cu, Zn, Ni, and

Mg which were found in water extracts from phospho-gypsum. This points to the fact that hardened cement paste can “absorb” harmful ingredients present in industrial waste.

Ecological-health properties of various concretes (i.e., normal-weight concrete, fine-aggregate concrete, and lightweight concrete) that contained disposal ash from the CGP-22 were studied. The investigations demonstrated that specimens of normal-weight concrete (ash content 350 kg/m^3), of fine-aggregate concrete (ash content 500 kg/m^3), and of lightweight concrete (ash content 350 kg/m^3) do not emit harmful ingredients to the air and water. Thus, it may be said that these materials are essentially clean ecologically.

Conclusion

On the strength of the above data obtained we can draw the following conclusions:

- The problem of toxicity of man-made wastes and of their products does exist and the research results confirm it.
- Man-made waste combined with traditional construction materials can be used to manufacture ecologically benign materials. This is because hardened cement paste and concrete can fix harmful ingredients in place both by drawing them into hardening process and by making them part of the structure of hardened cement paste.
- The regulations currently in use do not contain any approved single procedure for evaluating EH properties of man-made wastes and the construction materials derived from them;
- It is essential that approximate methods should be developed to evaluate the EH properties of man-made waste and of construction materials;
- These methods need to be related to the peculiarities of using industrial waste in the construction industry and the subsequent service conditions in which the materials will be placed.

Experimental program to evaluate building components service life: an application

P.N. Maggi, F. Ravetta, F. Re Cecconi
DISET - Polytechnic of Milan - Milan - Italy

Abstract

The knowledge of the service life of building materials and components is a basic requisite in order to correctly compare global costs (manufacturing cost, maintenance cost, recycling or demolishing cost) of different building components. It is also recognized that the best way to obtain the actual service life of materials and components is to analyze statistical data from existing buildings, but the observation of existing buildings requires a lot of both economical and human resources that are not easily found. This paper intends to give a contribution in the field of building materials durability showing principal intermediary results obtained from ongoing research by the Polytechnic of Milan. This project is in association with an Italian industry leader in coil coated steel sheet manufacturing. The results presented in this paper are part of one of the first test application of a methodology elaborated at the DISET - Polytechnic of Milan to evaluate building components service life. In particular, results will be presented from surveys on existing buildings built from 1985 to 1996 and from three years atmospheric environmental exposure tests conducted both in Italy and in Holland.

Being results obtained from a test application they have been useful to tune the methodology and to gain knowledge in the field of coil coated steel sheet durability.

Keywords: Building products, coil coated steel sheet, exposure test, service life, survey.

1 Introduction

The solution of the problem of sustainable development in building sector passes through the individuation of some priorities in the choice of the materials to be used in the design and the production of building components. The choice of these materials must take into account their compatibility with the global equilibrium of use of natural resources. This compatibility can be expressed as the global cost (manufacturing cost, maintenance cost, recycling or demolishing cost) of the material itself. Therefore only materials for which this compatibility is recognised, i.e. those materials which minimise the global cost function, should be taken into account for an environmental conscious building process. The architects and the maintenance managers could make the right choice, i.e. reduce the environmental impact of the building, only if they could evaluate this global cost. It is recognised that the right value of the service life and the reliability of this value are a basic requisite in order to correctly compare global cost.
At the DISET - Polytechnic of Milan researches on these subjects started more than ten years ago and, at the present time, have produced a methodology to evaluate reliability of a certain value of service life by the functional analysis (the paper "*Functional analysis as a method to design new building components*" presented in this congress shows some of the results achieved in this field) and a methodology to evaluate building components service life (the paper "*Methodology and experimental program to evaluate building components service life*" presented in this congress explains the methodology and shows first experimental results). This paper presents some of the results achieved in the first phase of the research on building components service life.

2 The methodology

The goal chosen for the research at the DISET was to evaluate the durability of a set of seventeen building components for exterior wall without considering, in the first time, the connection between components. The methodology, although defined in its main characters, is still subjected to little changes according to what comes out from the ongoing experimental program and from the studies of our research group.
Some main steps can be found inside the proposed methodology. These steps, with the exception of minor changes due to the evolution of the research, seem to be definitive. One of these is the step that comes out with the evaluation of building products sensitivity that is essential in order to evaluate building components service life according to our methodology. The step that describes how to compute building product is one of the most tested of the whole methodology and has been already presented in an Italian congress [1].
The evaluation of building components sensitivity, if they are imagined to be exposed directly to aging agents, can be made following these scheme:

- definition of the aging agents relevant for the building product under evaluation;
- collection of bibliographical information;
- computation of building product sensitivity;

2.1 Definition of the aging agents

One of the first results of the research was the definition of a set of aging agents to which the evaluation of building components behavior over time can be referred. It stands to reason that durability of building components changes according to the different environment (i.e. aging agents) in which they are used. Since it is possible that different building products are influenced in their behavior by different agents, the set defined has been used as a base point in order to create a subset of aging agents relevant for the specific product. Table 1 shows the set of agents, the ones relevant for coil coated steel sheet are highlighted by a "*x*". The set of agents here quoted has been defined joining indication of some Italian and foreign standards (English and American)[2][3][4].

	Set of aging agents	
Chemical agents	CO_x	x
	NO_x	x
	SO_x	x
	Sulfuric acid	
	Carbonic acid	
	salts	
	Cleaning products	
Weathering agents	Moisture	x
	Rain	x
	Snow	
	Ice	
	Hail	
	Water vapor	x
	Wind	x
	Air pollutants	x
	High temperature	
	Low temperature

	Continuous mechanical stresses	
Biological agents	Animals	
	Vegetable	

Table 1: The main set of agents and the ones considered for coil coated steel sheet

2.2 Collection of bibliographical information

Collecting data on behavior over time of building products that form the set of building components under analysis has been an essential step in the development of the research. The results of this phase have been stored in filling-cards in order to have an easy to read documents. Each filling-card describes one action, i.e. the consequence of one or more agents on the building product. The cards are divided in fields describing possible effects of the action and chemical or physical phenomena that lead to the effects. Unfortunately there aren't information or studies on every possible action on building products and on the consequences of these actions, especially for innovative products. As a consequence of this lack of information we felt necessary to gain further data through specific test programs and surveys on existing buildings. For this reason we joined an Italian industry leader in coil coated steel sheet manufacturing, La Magona d'Italia S.p.A., which kindly allowed us to publish results obtained from:

- quality control tests on new products conducted in their factory;
- atmospheric environmental exposure tests;
- survey on existing buildings built since 1985 with their coil coated steel sheet.

3 Atmospheric environmental exposure test results

Among the results obtained by the cooperation between DISET and La Magona d'Italia we can count those concerning atmospheric environmental exposure of coil coated steel sheet samples with different kind of coating. Samples with three different kind of coatings and painted with two different colors, light the first and dark the second, have been exposed for three years in two different places. The first exposure place is in Italy, in the nearby of the factory, the second is in Holland by the North Sea.
The three coatings differ for their resistance to the atmospheric agents, because of a different composition of the coating layer. In particular the manufacturer assures his products to have a color difference from the new ones less than 8 Celiab units (ECCA T3 [5]) and a chalking value (ASTM D659) higher than 6 after 10 years for the product called system 3000/90, after 15 years for the product called 5000/90 and after 20 years for the product called system 10000/90. The two different colors have been chosen in order to highlight eventual discoloration phenomena that are generally more emphasized on dark pigments. The following parameters were recorded:

- *D Gloss*: the gloss of a sample is measured by the amount of light reflected from a specimen in the specular direction. The shift value is reported as a percent value of the original gloss;
- *Scratch* or edge: rust penetration either through a cut on the coating layer or from the edge where the steel sheet is cut is measured. The value is reported as a percent value considering a penetration of 10mm as 100%;
- *6mm hole*: rust penetration from the edge of a 6 mm diameter hole is measured. The value is reported as a percent value considering a penetration of 10mm as 100%;
- *Bend 0-T*: this test comprises bending the sample through 180" over a period of l-2 seconds around various radii. The value reported is the percentage of defective surface;
- *Erichsen 6mm*: coil coated steel sheet are subjected to ball punch deformation. The value reported is the percentage of defective surface;
- *Dust retention:* The value is reported as a percentage considering the value 10 measured according to ASTM D3274 as 100% and the value 0 as 0%;
- *Chalking:* The value is reported as a percentage considering the value 10 measured according to ASTM D659 as 100% and the value 0 as 0%;

- *Blistering*: The value reported is the percentage of defective surface evaluated according to ASTM D714

Unfortunately it wasn't possible to report the same aging parameters both for the Italian samples and for the Dutch ones because the exposure tests in Italy began before the exposure tests in Holland and followed test methodologies based upon Italian standards, while in the Dutch tests the European Coil Coated Association standards were followed.

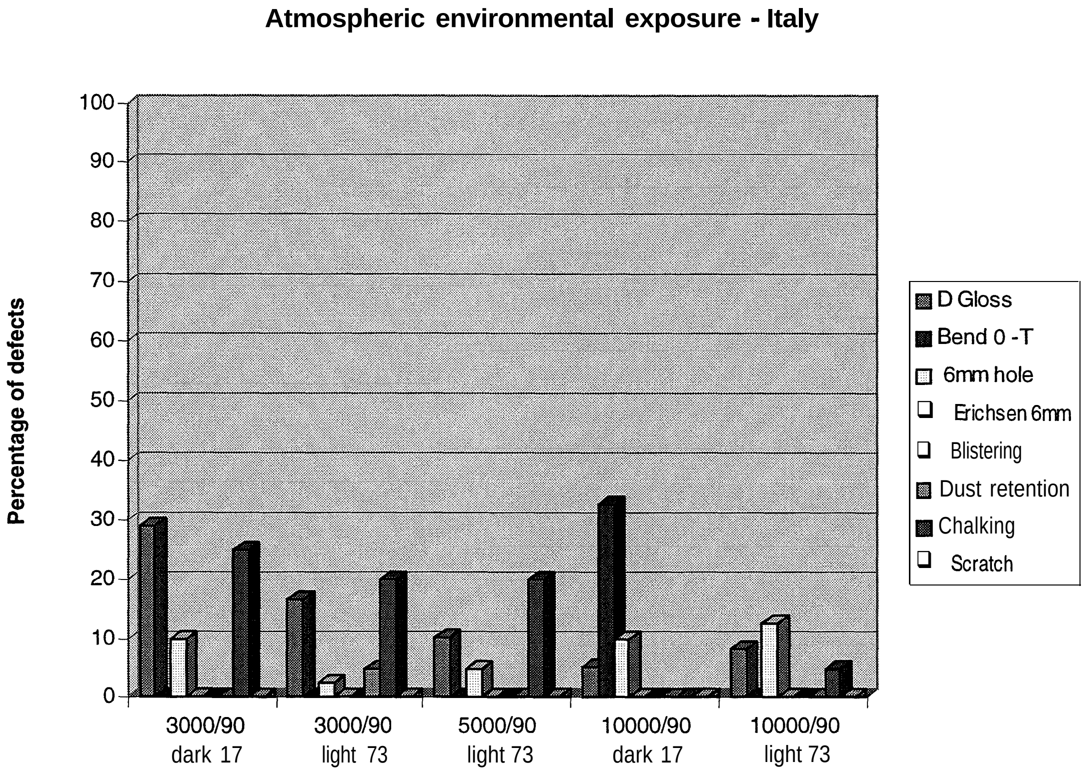

Figure 1: Results after 36 months of exposure in Italy

Examining the results after 36 months of exposure in Italy (Picture 1) we can see that the principal defects are a generalized loss of the initial gloss, some chalking and rust attack on the edge of the 6mm diameter hole. The loss of initial gloss detected in Italy is higher than the one measured for the samples exposed in Holland and is due to the high level of air pollution caused by dust. It is possible that this kind of pollution, maybe due to the presence of steel-plants in the nearby, faked the values measured, hiding the correlation between the loss of gloss and the color of the sample. This correlation can be seen in the values obtained for the samples exposed in Holland where there was less air pollution.

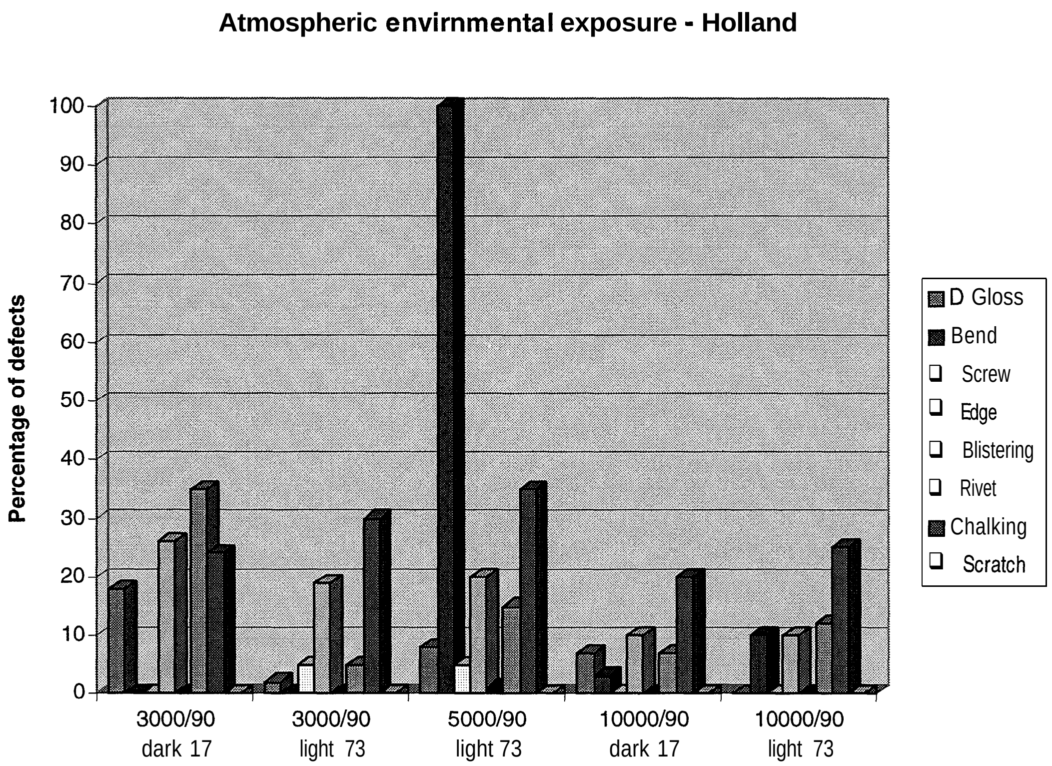

Figure 2: Results after 36 months of exposure in Holland

Results of the Dutch exposure (Figure 2) brightly show the effects of a marine environment through a high level of corrosion, on the cut edge and on the rivet, and a level of chalking higher than the one obtained after the exposure in Italy. In particular it was noticed that chalking happens with the same rate on all the samples, without correlation with the coating type.

Filling-cards of the degradation phenomena of coil coated steel sheet have been filled with the data obtained from this exposures. Anyway the application of the methodology drawn up by the research team at DISET and explained in the paper "*Methodology and experimental program to evaluate building components service life*" needed a deeper knowledge of degradation phenomena. For this reason survey were reputed necessary.

4 Results obtained from survey

Results obtained from the exposure tests in both locations were compared with the ones obtained from surveys on buildings built with the same coil coated steel sheet from 1985 to 1996. This comparison was made with the aim of obtaining an experimental validation of the mentioned filling-cards.

Relevant points were found for each building subject of survey. These points were characterized by particular exposure conditions, such as southerly exposure in places with a high sun radiation. Each point was recorded highlighting those particular aspects that may influence the natural aging of the building component, such as the distance from the sea, and reporting a brief description of the environment. The following parameters were recorded at intervals:

- color;
- gloss;
- chalking;
- dust retention,

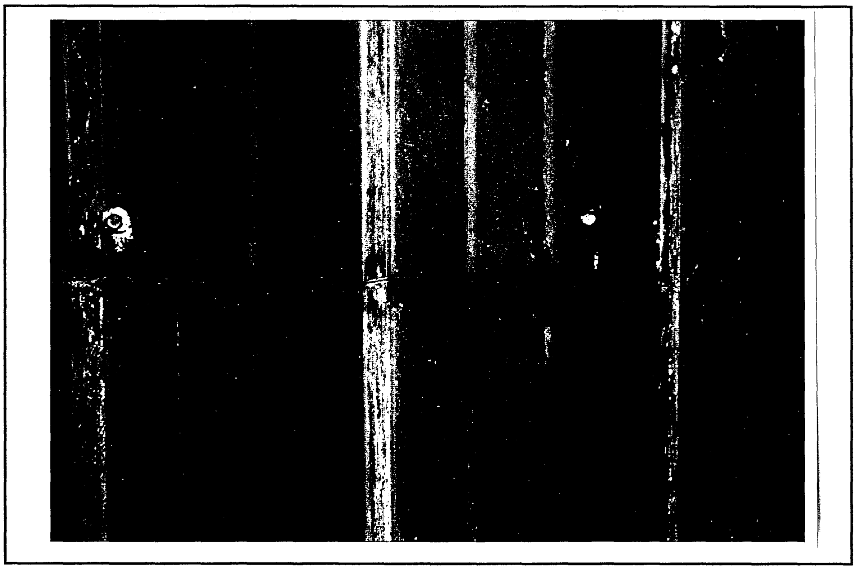

Figure 3: Particular of the external wall of a factory in Cremona (built in 1986)

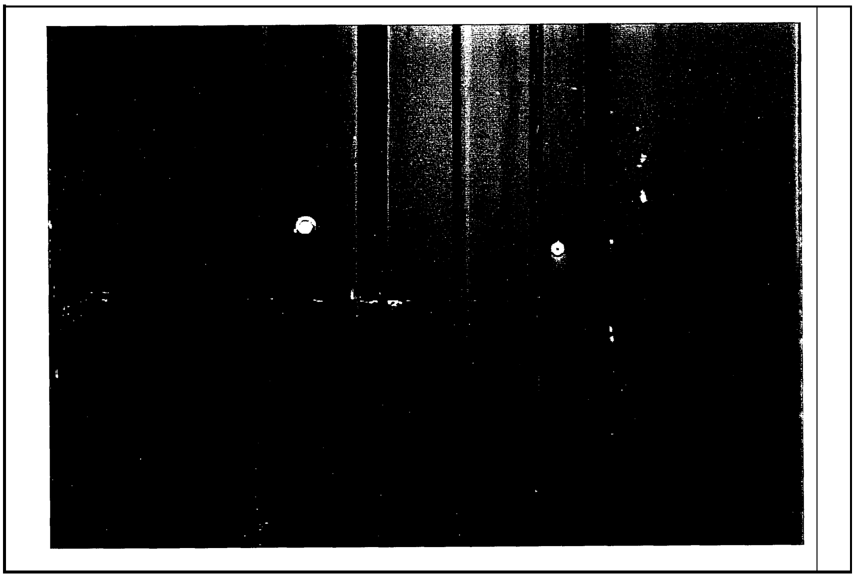

Figure 4: Particular of the external wall of a factory in Cremona (built in 1992)

Each point subject to survey is accompanied by a brief report, written on site, describing the maintenance state and highlighting, if any, external elements which may affect the maintenance state itself. Figure 3 and 4 shows two parts of a building, the first built in 1986 and the second built in 1992, subject of survey.
These surveys led to a substantial confirmation of data gained with the atmospheric environmental exposure tests, highlighting the action of sun radiation, which leads both to a discoloration even on light colored surfaces and, in association with other atmospheric agents, to chalking. The influence of air pollution and of particular kind of exposure (marine environment) is more evident in rust development. Anyway rust needs a propitious starting point such as a cutting edge or a screw hole to develop.

5 Conclusion

Data collection lead to two main conclusions:

- first of all it is necessary to proceed to a higher correlation among atmospheric environment exposure data. For this reason the Italian site is already changing its equipment in order to conform the parameters of analysis to the Dutch ones. This will allow the researchers to better understand the influence of different climate (a collection of climate and air quality data is already started);
- secondly it will be interesting to compare data obtained during surveys with the ones obtained from atmospheric environment exposure. This comparison, if related with the climate, pollution and environmental data of every site, will allow the researchers to set a quantitative relation between natural aging on site and atmospheric environmental exposure aging. This relation will lead to a quicker and more reliable evaluation of building components service life.

This experience stresses the necessity of atmospheric environmental exposure data and of surveys on existing buildings in order to obtain a better evaluation of building component service life. Only the knowledge of building components service life and of its reliability will allow everybody in the building process to make conscious choices in the direction of sustainable development. These conscious choices will turn out to be savings of natural resources which our planet is so poor of.

Building for Environmental and Economic Sustainability (BEES)

B. Lippiatt
Building and Fire Research Laboratory, National Institute of Standards and Technology, Gaithersburg, USA

Abstract
The BEES (Building for Environmental and Economic Sustainability) software implements a rational, systematic technique for balancing the environmental and economic performance of building products. The technique is based on consensus standards and designed to be practical, flexible, and transparent. The Windows-based decision support software, aimed at designers, builders, and product manufacturers, includes actual environmental and economic performance data for a number of building products.

BEES measures the environmental performance of building products by using the environmental life-cycle assessment approach specified in the latest versions of IS0 14000 draft standards. The approach is based on the belief that all stages in the life of a product generate environmental impacts and must therefore be analyzed. The stages include raw material acquisition, manufacture, transportation, installation, use, and recycling and waste management. Economic performance is measured using the American Society for Testing and Materials (ASTM) standard life-cycle cost method. The technique includes the costs over a given study period of initial investment, replacement, operation, maintenance and repair, and disposal. Environmental and economic performance are combined into an overall performance measure using the ASTM standard for Multi-Attribute Decision Analysis. For the entire BEES analysis, building products are defined and classified according to the ASTM standard classification for building elements known as UNIFORMATII.

The BEES methodology is being refined and expanded over the next three years under sponsorship of the U.S. Environmental Protection Agency's Environmentally Preferable Purchasing (EPP) Program. The EPP program is charged with carrying out Executive Order 12873, "Federal Acquisition, Recycling, and Waste Prevention," which directs Executive agencies to reduce the environmental burdens associated with the $200 billion in products and services they purchase each year, including building products. BEES is being further developed as a tool to assist the Federal procurement community in carrying out the mandate of Executive Order 12873.
Keywords: building products, economic performance, environmental performance, green buildings, life-cycle assessment, life-cycle costing, multiattribute decision analysis, sustainable development

1 Introduction

Buildings significantly alter the environment. According to Worldwatch Institute [1], building construction consumes 40 percent of the raw stone, gravel, and sand used globally each year, and 25 percent of the virgin wood. Buildings also account for 40 percent of the energy and 16 percent of the water used annually worldwide. In the United States, about as much construction and demolition waste is produced as municipal garbage. Unhealthy indoor air is found in 30 percent of new and renovated buildings worldwide.

Negative environmental impacts arise from these activities. For example, raw materials extraction can lead to resource depletion and biological diversity losses. Building product manufacture and transport consumes energy, generating emissions linked to global warming, acid rain, and smog. Landfill problems may arise from waste generation. Poor indoor air quality may lower worker productivity and adversely affect human health.

Thus, building-related contributions to environmental problems are large, and therefore important. Selecting environmentally preferable building products is one way to improve a building's environmental performance. However, while 93 percent of U.S. consumers worry about their home's environmental impact, only 18 percent are willing to pay more to reduce the impact, according to a survey of 3,600 consumers in nine U.S. metropolitan areas [2]. To be practical, then, environmental performance must be balanced against economic performance. Even the most environmentally conscious building designer or building product manufacturer will ultimately weigh environmental benefits against economic costs. To satisfy their customers, manufacturers and designers need to develop and select building products with an attractive balance of environmental and economic performance.

In this spirit, the U.S. National Institute of Standards and Technology (NIST) Green Buildings Program began the Building for Environmental and Economic Sustainability (BEES) project in 1994. The purpose of the BEES project is to develop and implement a systematic methodology for selecting environmentally and economically balanced building products. The methodology is based on consensus standards and is designed to be practical, flexible, and transparent. The BEES model is being implemented in publicly available decision-support software, complete with actual environmental and economic performance data for a number of building products. The intended result is a cost-effective reduction in building-related contributions to environmental problems.

In 1997, the U.S. Environmental Protection Agency Environmentally Preferable Purchasing (EPP) Program also began supporting the development of BEES. The EPP program is charged with carrying out Executive Order 12873 (10/93), "Federal Acquisition, Recycling, and Waste Prevention," which directs U.S. Executive agencies to reduce the environmental burdens associated with the $200 billion in products and services they purchase each year, including building products. Over the next several years, BEES will be further developed as a tool to assist the U.S. Federal procurement community in carrying out the mandate of Executive Order 12873.

This paper describes in general terms the current formulation of the BEES model for balancing the environmental and economic performance of building products, and illustrates its application in Windows-based decision support software.

2 Methodology

The BEES methodology takes a multidimensional, life-cycle approach. That is, it considers multiple environmental and economic impacts over the entire life of the building product. Considering multiple impacts is necessary because product selection decisions based on single environmental or economic impacts, such as recylability or first cost, could obscure other impacts that might cause equal or greater damage. Similarly, considering all life-cycle stages is necessary because decisions based on a single stage, such as the use stage, could obscure other stages that might cause equal or greater damage. In other words, a multidimensional, life-cycle approach is necessary for a comprehensive, balanced analysis.

Environmental performance is quantified using the evolving, multi-disciplinary approach known as life-cycle assessment (LCA). The BEES methodology follows guidance in the IS0 14040 series of draft standards for LCA. Economic performance is separately measured using the American Society for Testing and Materials (ASTM) standard life-cycle costing (LCC) approach (ASTM E 917). These two performance measures are then synthesized into an overall performance measure using the ASTM standard for Multi-Attribute Decision Analysis (ASTM E 1765). For the entire BEES analysis, building products are defined and classified according to UNIFORMAT II, the ASTM standard classification for building elements (ASTM E 1557). All underlying data and computational algorithms are reported and documented.

2.1 Environmental performance

Environmental life-cycle assessment is a “cradle-to-grave,” systems approach for assessing environmental performance. The approach is based on the belief that all stages in the life of a product generate environmental impacts and must therefore be analyzed, including raw materials acquisition, product manufacture, transportation, installation, operation and maintenance, and ultimately recycling and waste management.

The general LCA methodology involves four steps [3]. The *goal and scope definition* step spells out the purpose of the study and its breadth and depth. The *inventory analysis* step identifies and quantifies the environmental inputs and outputs associated with a product over its entire life-cycle. Environmental inputs include water, energy, land, and other resources; outputs include releases to air, land, and water. However, it is not these inputs and outputs, or *inventory* flows, that are of interest. More important are their consequences, or impacts on the environment. Thus, the next LCA step, *impact assessment,* characterizes these inventory flows in relation to a set of environmental impacts. For example, the impact assessment step might relate carbon dioxide emissions, a *flow*, to global warming, an *impact.* Finally, the *interpretation* step combines the environmental impacts in accordance with the goals of the LCA study. For a detailed discussion of these steps, see Lippiatt [4].

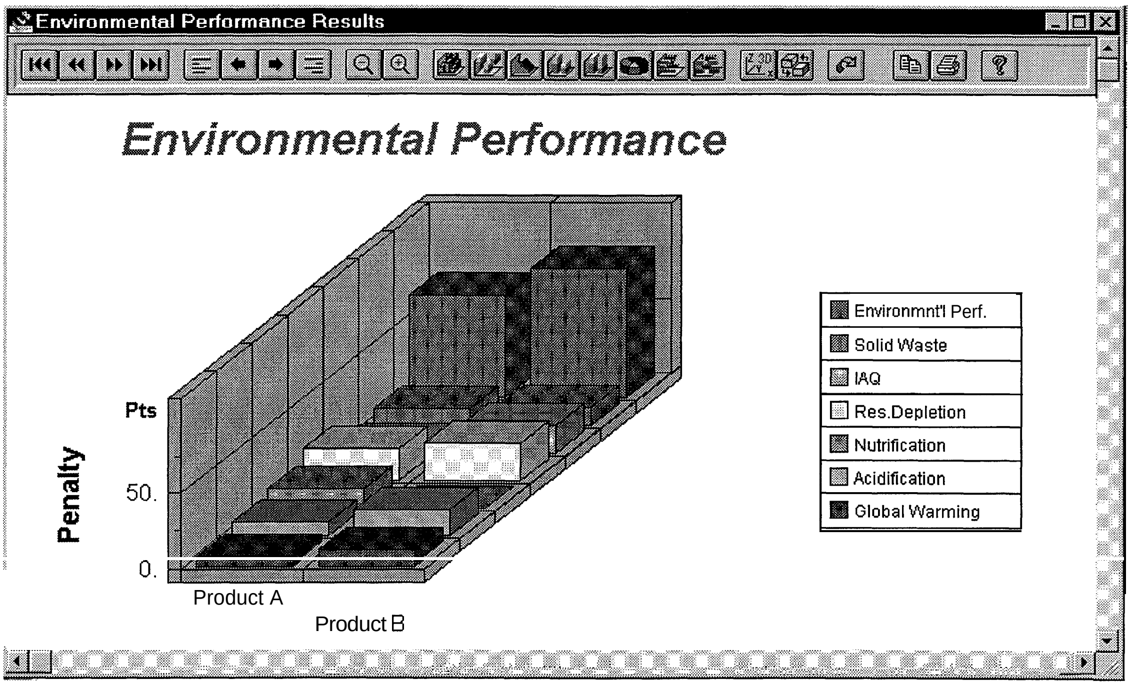

Figure 1. BEES Environmental Performance Results

The goal of the BEES LCA is to generate relative environmental scores for building product alternatives based on U.S. average data. LCA data collection is done under contract with Environmental Strategies and Solutions, Inc. (ESS) and Ecobalance, Inc., using the Ecobalance LCA database covering more than 6,000 industrial processes and gathered from actual site and literature searches from more than 15 countries. Where necessary, the data are adjusted to be representative of U.S. operations and conditions. In addition, ESS and Ecobalance gathered additional LCA data to fill data gaps for the BEES products. Assumptions made for each building product were verified through experts in the appropriate industry to assure the data are correctly incorporated in BEES.

The BEES model assesses six environmental impacts: Global Warming Potential, Acidification Potential, Nutrification Potential, Natural Resource Depletion, Indoor Air Quality, and Solid Waste. Because BEES uses U.S. average data, local impacts such as smog could not be included. Human health impacts are also excluded because the science is not yet sufficiently developed. However, if the BEES user has important knowledge about these or other potential environmental impacts, it should be brought into the interpretation of the BEES results.

Synthesizing the six impact category performance measures into a single, meaningful measure of overall environmental performance involves combining apples and oranges. BEES expresses global warming potential in carbon dioxide equivalents, acidification in hydrogen equivalents, nutrification in phosphate equivalents, natural resource depletion as a factor reflecting remaining years of use and reserve size, solid waste in volume to landfill, and indoor air quality as a dimensionless score. BEES combines these diverse measures of impact category performance into a meaningful measure of overall environmental performance using Multiattribute Decision Analysis (MADA), a technique for combining apples and oranges. The BEES system follows

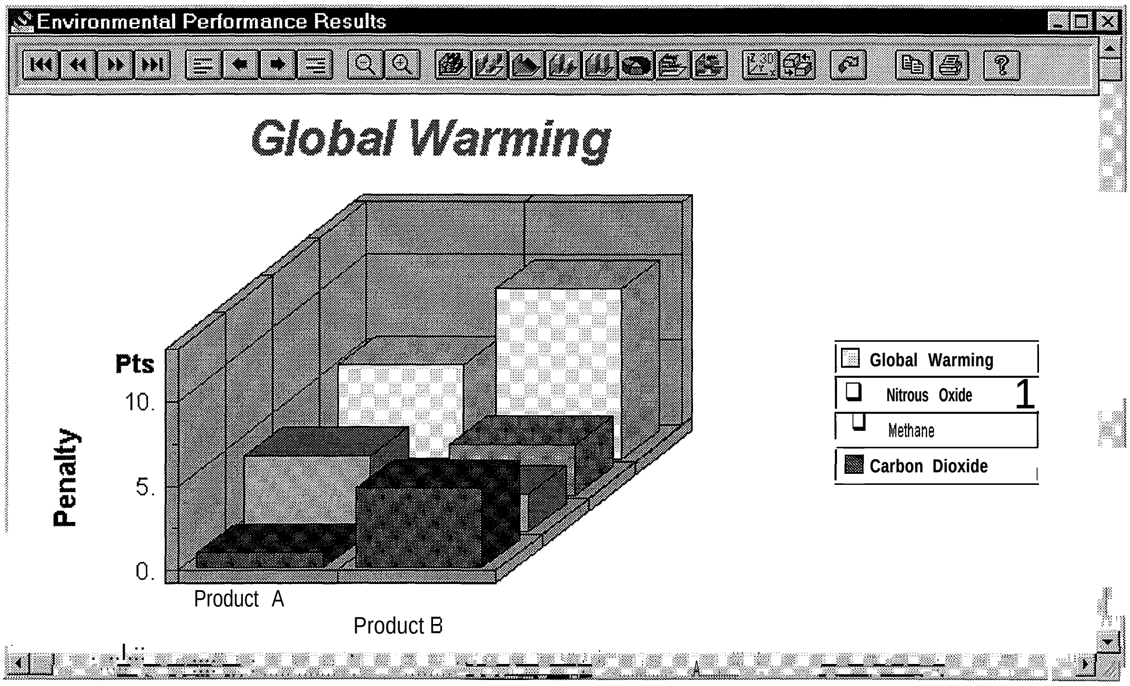

Figure 2. BEES Global Warming Performance Results

the ASTM standard for conducting MADA evaluations of building-related investments. [5]

MADA synthesizes the impact category performance measures by first placing them on a common scale, then weighting each impact category by its relative importance to environmental performance. (For a step-by-step example working through the numerical computations, see Lippiatt [4].) In the BEES software, the set of importance weights is chosen by the user. Two alternative weight sets are provided as guidance. These alternative weight sets are based on studies by the U.S. Environmental Protection Agency's Science Advisory Board and by Harvard University, and represent two different ways in which the United States, including its experts, values the environment. The BEES user may choose to use one of these weight sets unchanged, or as a starting point for developing their own set of weights.

Figure 1 illustrates the BEES graphical display of environmental performance results. The BEES environmental performance scores for Products A and B are displayed across the back row. This score is denominated in penalty points ranging from 0 to 100. As shown, Product B has worse environmental performance than Product A.

For each product, the environmental performance score is the sum of its weighted scores for the six environmental impacts, which are displayed in the remaining rows of the graph. Figure 1 illustrates the tradeoffs among environmental impacts that are often found in LCAs. Product B performs worse than Product A on global warming, acidification, resource depletion, and indoor air quality, better on nutrification, and about the same on solid waste.

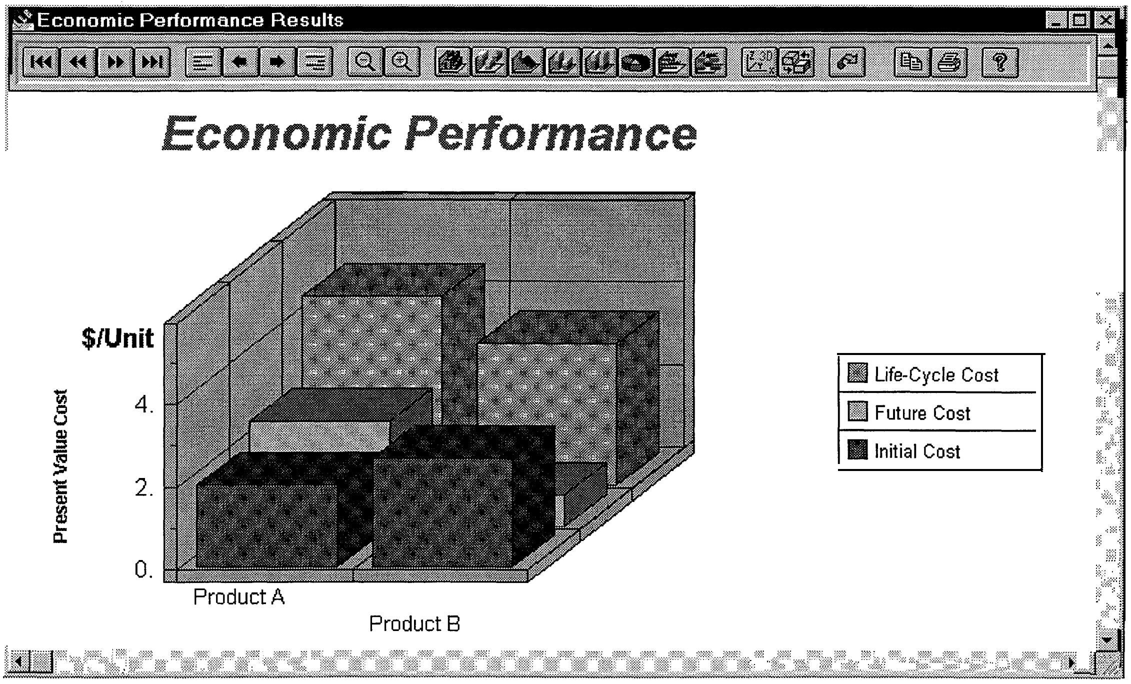

Figure 3. BEES Economic Performance Results

The BEES tool also displays detailed graphical results for each of the six environmental impacts. Figure 2 illustrates these results for the global warming impact. The global warming scores from Figure 1 for Products A and B are now displayed across the back row, with their breakdown among the contributing greenhouse gases in the remaining rows. As shown, the global warming score, which is almost twice as bad for Product B as Product A, is the sum of scores for carbon dioxide, methane, and nitrous oxide.

2.2 Economic performance

Measuring the economic performance of building products is more straightforward than measuring environmental performance. Published economic performance data are readily available, and there are well-established, standard methods for conducting economic performance evaluations. First-cost data are collected for the BEES tool from the R.S. Means publication, 1997 *Building Construction Cost Data,* and future-cost data are based on data published by Whitestone Research in *The Whitestone Building Maintenance and Repair Cost Reference 1997.* The most appropriate method for measuring the economic performance of building products is the life-cycle costing (LCC) method. BEES follows the American Society of Testing and Materials standard method for life-cycle costing of building-related investments [6].

BEES measures economic performance over a 50-year study period. The same 50-year period is used to evaluate all products, even if they have different useful lives. Evaluating products over a common time period is one of the strengths of the LCC method. It accounts for the fact that different products have different useful lives.

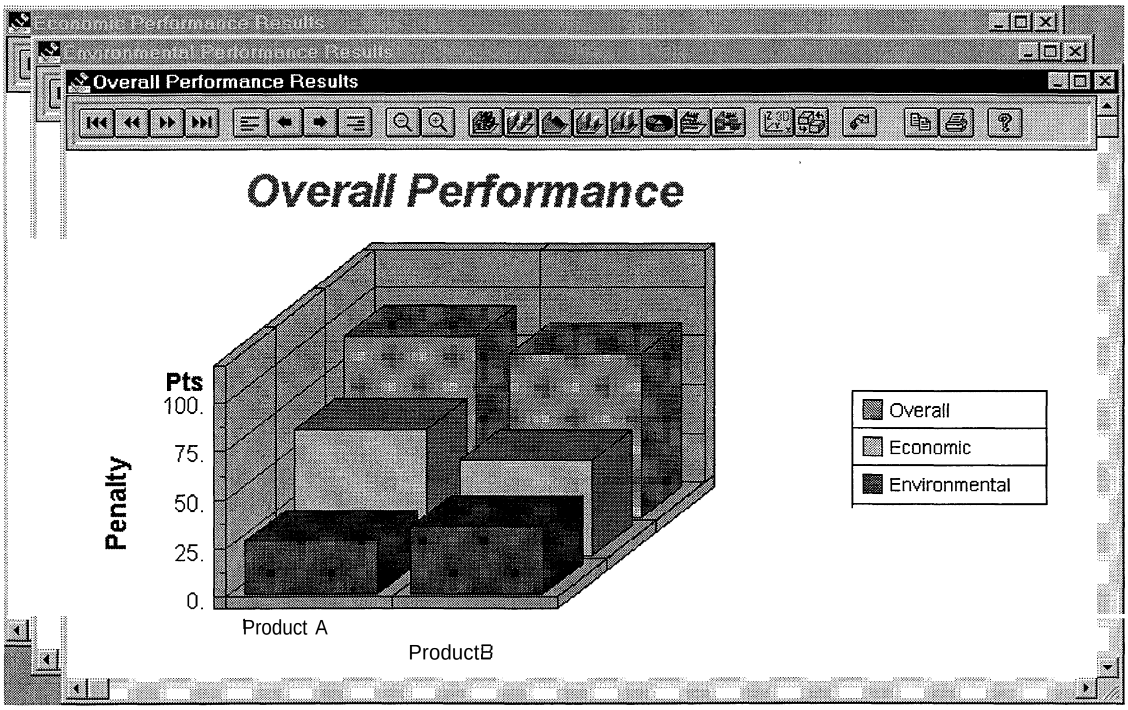

Figure 4. BEES Overall Performance Results

The LCC method sums over the study period all relevant costs associated with a product. Alternative products for the same function, say floor covering, can then be compared on the basis of their LCCs to determine which is the least-cost means of providing that function over the study period. Categories of cost typically include costs for purchase, installation, maintenance, repair, and replacement. The LCC method accounts for the time value of money by using a discount rate to convert all future costs to their equivalent present value.

Figure 3 illustrates the BEES graphical display of economic performance results for two product alternatives. The LCCs for Products A and B are displayed across the back row. As shown, Product A has a higher life-cycle cost than does Product B, even though its initial cost is lower, illustrating the importance of taking a life-cycle view.

2.3 Overall performance

BEES combines the environmental and economic performance results into a single overall performance score. To combine them, the results must first be placed on a common scale. The environmental performance score reflects *relative* environmental performance, or how much better or worse products perform with respect to one another. The life-cycle cost reflects *absolute* performance, irrespective of the set of alternatives under analysis. Before combining the two, the life-cycle cost is converted to the same, relative scale as the environmental score. Then the two performance scores are combined into a relative, overall score by assigning importance weights to environmental and economic performance. (For a step-by-step example working through the numerical computations, see Lippiatt [4].)

Figure 4 illustrates the BEES display of overall performance results. The environmental and economic performance scores from Figures 1 and 3 have been combined based on a 35 percent/65 percent environmental/economic importance weighting. The graph displays for each product its weighted environmental and economic performance scores and their sum, the overall performance score.

The BEES user specifies the importance weights used to combine environmental and economic performance scores and should test the sensitivity of the overall scores to different sets of weights.

3 Discussion and conclusions

Until now, green building decision making has been based on little structure and scientific data. There is a great deal of interesting green building information available, so in many respects we know what to *say* about green buildings. However, we have not organized and synthesized the scientific data so that we know what to *do* in a way that is both environmentally sound and cost effective.

The BEES tool satisfies this need by offering a unique blend of environmental science, decision science, and economics. It uses life-cycle concepts, is based on consensus standards, and is designed to be practical, flexible, and transparent. It is *practical* in its systematic packaging of detailed performance data in a manner that offers useful decision support. It is *flexible* in allowing tool users to customize judgments about key study parameters for which there is no consensus, such as the environmental impact category weights. Finally, it is *transparent* in providing the supporting performance data and computational algorithms.

The BEES tool will be expanded and refined over the next several years. Product technical performance will be added to the overall environmental/economic balance, and sensitivity analysis for testing the effect of changes in key study parameters will be automated. U.S. region specificity and greater flexibility in product specifications (e.g., useful lives) will also be incorporated. Finally, many more products will be added to the system so that entire building components and systems can be compared.

Development of the Lattice Model and its Application for the Shear Failure Mechanism

Fawzy Mohamed EL-BEHAIRY
Dept. of Civil Eng., Nagoya University, Japan
Tada-aki TANABE
Dr. of Eng., Professor, Dept. of Civil Eng., Nagoya University, Japan

Abstract

It is generally agreed that the truss analogy concept for shear resistance is easily applied to reinforced concrete structures. However, there exist several different truss models to analyze the shear resisting- mechanism in reinforced concrete beams. But in each model, there are still some problems to be investigated. For example, the Lattice Model, which is first proposed by Niwa et al. [10] and extended later by the authors in three dimensions [3,4], has several fundamental points to be clarified and other points to be modified. In this model the arch member is a very important concept, because after the yielding of shear reinforcement, the model can explain the increase in the shear capacity, while the simple truss model cannot, especially in the case of deep beams. The thickness of the arch element is determined by minimizing the total potential energy for the whole structure. But, any physical explanation for this minimization is not given, and once the value of the thickness of the arch element is determined in the elastic stage, this value is unchanged throughout the whole loading history. The thickness of the arch element may be changed during the loading stages, but its change is simply neglected. In this paper, we clarify this point in the first place and show the improved accuracy by performing the minimization at every loading stage.

In addition, the rational reasoning for the strain incompatibility through the width of a beam by separating the arch member and the truss member within one beam will be explained. It is found experimentally [8] that a two dimensional stress analysis is not adequate for reinforced concrete members. With these clarifications, the fundamental characteristics of the arch element mechanism for shear resistance are discussed, especially the strain values in the arch and diagonal elements in the same cross-section are not equal. The strains may not be uniform in the direction of member width. The third point to be clarified is the direction of most appropriate discretization for truss members. Finally, the application of the "Modified Lattice Model" to simulate the shear failure of reinforced concrete beams is carried out. The change of the stress states in each member inside the beam is investigated. This modified model can capture the shear behavior of concrete beams reasonably throughout the change of the shear resisting mechanism.

Key words: arch elements, modified lattice model, shear-resisting mechanism, subdiagonal element, and total potential energy.

1. Introduction

In this paper a new technique to modify the lattice model is shown. This new technique depends on the calculation of the minimum total potential energy of the structure at each step during the different loading stages. Adoption of the minimum total potential energy is studied fundamentally. The applicability of the modified model is examined by existing experimental data. Also the simulation of the shear failure mechanism for reinforced concrete beams is produced. According to the simulation and considering the objectivity of the post processing of the calculated results and the simple representation of the shear resisting mechanism, the modified lattice model can simulate the shear failure mode.

2. Outline of the modified lattice model

The chosen element discretization and structural geometry of the Modified Lattice Model is illustrated in Fig. 1. The reason behind this truss discretization will be explained in the following sections. The reinforced concrete beam has been simulated under bending and shear as simple truss components. The compressive stress in the upper part of the beam is resisted by concrete in the form of a horizontal strut with a cross-section area equal to the area of the upper rectangle in Fig. 2. The tensile stress in the lower part is taken by the bottom steel in the form of horizontal members in addition to the horizontal concrete fibers in the lower part with a cross section area equal to the lower rectangle area in Fig. 2. To resist the shear forces inside the beam, the truss model has diagonal concrete tension and compression members with the area as shown in Fig. 2, which can be fixed after the value of "t" is determined as it will be shown in section 3. In addition, there are vertical steel members, which represent the shear reinforcement in the web. Fig. 2 shows the cross section of a concrete beam modeled as a Modified Lattice Model.

In Fig. 1, the thick solid line represents the arch element which is assumed to be a flat and slender one connecting the nodes at both ends of the beam with an area as shown in Fig. 2. In this analysis, the arch element and the diagonal elements are separated and each one of them has its stress and strain distribution. The reason for this element separation is that the structural action is normally a combination of series and parallel couplings of the cracking zones and the uncracked (elastic) zones. In the Modified Lattice Model, we simulated these zones with continuous pairs of tension and compression members. Many codes [1] assume two dimensional stress fields; but if the member section is wide enough, the stress may not be uniform in the direction of member width. So, in this model we separate the arch element and the diagonal element, and each one of them has its stress and strain distribution. The

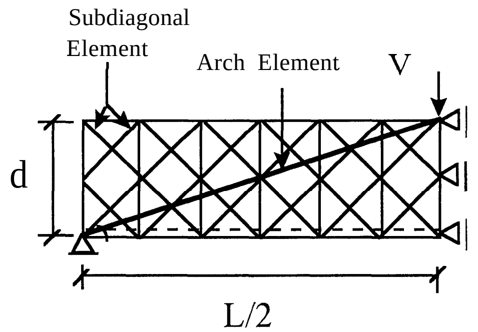

Fig. 1 Modified Lattice Model
Of Concrete Beam

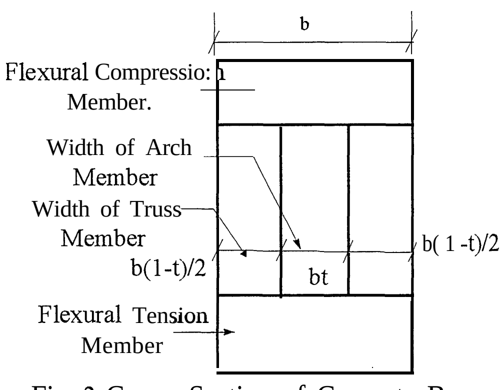

Fig. 2 Cross -Section of Concrete Beam
In Modified Lattice Model

arch element has the ability to resist a large portion of the applied load [9]. So it is very important to look for the change of the area of the arch element during the different loading stages, as it will be shown in section 3.

In the Modified Lattice Model, the diagonal tension member of concrete resists the principal tensile stress resulting from shear force. The stress-strain relation of tension member of concrete has been taken as expressed in Eq. (1) and Eq. (2) [7] and as shown in Fig. 3.

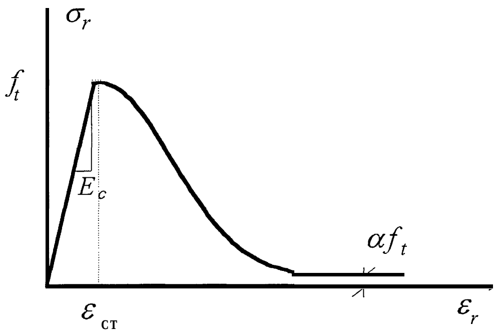

Fig. 3 Tensile Stress-Strain Curve of Concrete

For ascending branch $(\varepsilon_r < \varepsilon_{cr})$

$$\sigma_r = E_c \varepsilon_r \tag{1}$$

For descending branch $(\varepsilon_r \geq \varepsilon_{cr})$

$$\sigma_r = (1-\alpha) f_t \exp\left[-m^2\left(\frac{\varepsilon_r}{\varepsilon_{cr}} - 1\right)^2\right] + \alpha f_t \tag{2}$$

Where ε_r and σ_r are the strain and the stress of the tension element, respectively as shown in Fig. 3. Eq. (1) shows the elastic behavior before cracking. In Eq. (2), m can be varied to simulate appropriate fracture energy for plain concrete. Appropriate a value can be chosen to simulate the residual stress in the final stage of damage for simulating tension-stiffening effect in reinforced concrete [7]. In this research m=O. 5 and α=0. 0 are adopted.

The diagonal compression member of concrete and the arch member shall resist the diagonal compression caused by shear. To consider the compression-softening behavior of crushed concrete, the model proposed by Collins et al. [12] is adopted. In that model, the softening coefficient was proposed as a function of the transverse tensile strain. So, the tension and compression members are considered as a pair together as shown in Eq. (3). The stress-strain relationship for reinforcing bars is assumed to be elasto-plastic for the case of tension and compression members.

$$\sigma_c = -\eta f_c' \left(2\left(\frac{\varepsilon_c}{\varepsilon_o}\right) - \left(\frac{\varepsilon_c}{\varepsilon_o}\right)^2\right) \tag{3a}$$

Where,

$$\eta = \frac{\mathbf{10}}{\mathbf{0.8 - 0.34}\left(\frac{\varepsilon_r}{\varepsilon_o}\right)} \leq 1.0 \tag{3b}$$

And the strain at the peak stress ε_o = *-0.002.*

3. **Adoption of the minimum total potential energy**

The calculation of the total potential energy in the Modified Lattice Model has a significant effect during the calculation. It is found that there is a relation between the area of the arch element and the corresponding total potential energy of the structure. Niwa et al. [10] showed that if the ratio of the width of the arch element is assumed to be "t", the value of "t" is determined by minimizing the total potential energy for the whole structure. But in this work, it is found that this thickness is increasing gradually during the loading from the elastic stage up to the complete failure of the beam. It means that the area of the diagonal members is decreased gradually during the progress of different loading stages [5,6].

The physical explanation of the adoption of minimum total potential energy may be given using the triangular model shown in Fig. 4. The cross-section area of each of the side 1 and 2 has been divided into two different materials with two different modulus of elasticity E_1 and E_2 representing the truss element and the arch element, respectively. The ratio of the width of the arch element is assumed to be "t" from the total width of the member. The member 3 is a common material with a definite modulus of elasticity. The total potential energy of the structure is calculated from Eq. (4).

$$\pi = 1/2\int \sigma\varepsilon dv - Pu \tag{4}$$

Where u is the vertical displacement of the structure under the applied load "P". Take $\partial\pi/\partial t = 0$ to get the "t" value corresponding to the minimum total potential energy and substitute it in the energy equation. Fig. 5 shows the relation of the total potential energy and the applied load "P" for the different values of "t". From this figure we find that the point

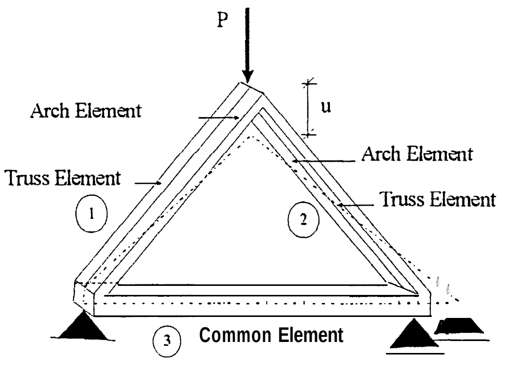

Fig .4 Triangular Model

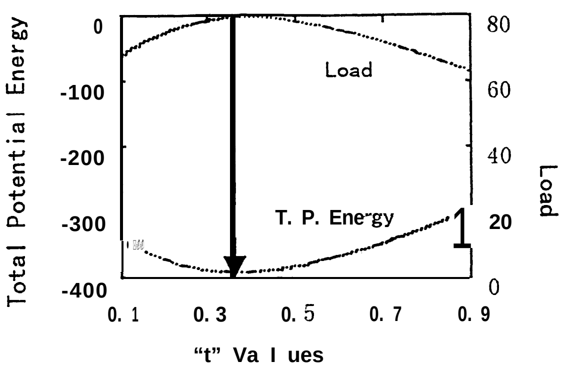

Fig. 5 Variation of T.P. Energy and Applied Load with "t" Values

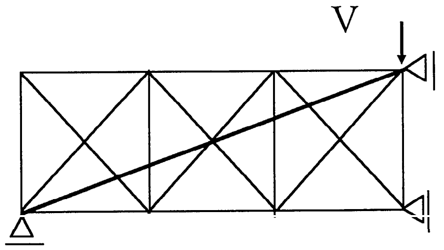
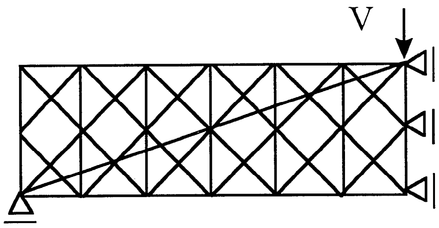
corresponding to minimum total potential energy corresponds to the maximum applied load at a definite value of "t". It means that, using this model at the minimum total potential energy we can get the stiffest beam case. Hence, in the Modified Lattice Model we calculate the total potential energy for different "t" values starting from 0.1 ~ 0.9 with a very small increment. By minimizing the total potential energy we can get the corresponding "t" value. From this "t" value we can calculate the area of the arch element and the subdiagonal elements for each step of the calculation.

4. APPROPRIATE DISCRETIZATION METHOD FOR TRUSS MEMBER

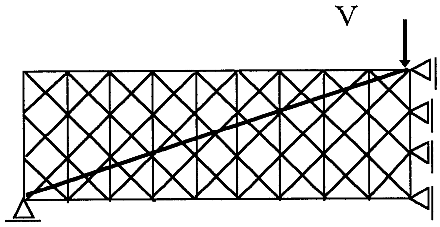
In this section a clarification of the appropriate discretization of lattice members which angle may be firstly predetermined as 45 degrees is given. To investigate the extent of the discretization, three different truss models depending on the number of diagonal pairs along the depth of the beam are investigated. The three different forms are as shown in Fig. 6. To determine the most appropriate discretization model among these three model forms, we investigated different reinforced concrete beams in order to compare the results of the Modified Lattice Model with the experimental results. The comparison of the calculated results by the Modified Lattice Model and the normal lattice model is shown in Fig. 7



(a) Model (1)



(b) Model (2)



(c) Model (3)

Fig. 6 Truss Models for Simulation (a) Model (1), (b) Model (2) And (c) Model (3)

(Ohuchi's experiment [11]). The number of subsection diagonal members is increased from model (1) to model (2) and to model (3). After cracking, the neutral axis of the beam starts to move upward during the development of the cracks. The height of the development of the cracks depends on the cross-section of the beam and the value of the steel reinforcement ratio. In case of model 2 the depth of the developed crack was similar to the experimental results during the calculation, i. e. the numerical results are close to the experimental results using this model. Therefore, it is preferable to use model (2) to implement the Modified Lattice Model. Comparing the results of the three models, we find the cracking load has been decreased starting from model (1) to model (3). In the case of model (1), the elastic energy of the failure elements is much higher than that in model (2). Also in the case of model (2) it is much higher than that in the case of model (3). The reason of that is the increasing of number of subsection diagonal members. The strain energy has been decreased with the decrease in the original length of failure elements. However, the ultimate loads using these three models are almost same because of the similarity of the fracture energy for the three different models. From these experimental data, we can say that the Modified Lattice Model can capture the displacement behavior adequately and almost reach to the same response as the original beam, especially the displacement at the peak load is similar to the experimental results. This is better than any other truss model.

The change of the thickness of the arch element is drawn in Fig. 8 (Ohuchi's experiment beam [11]). According to the Modified Lattice Model analysis, the thickness of the arch element is increasing

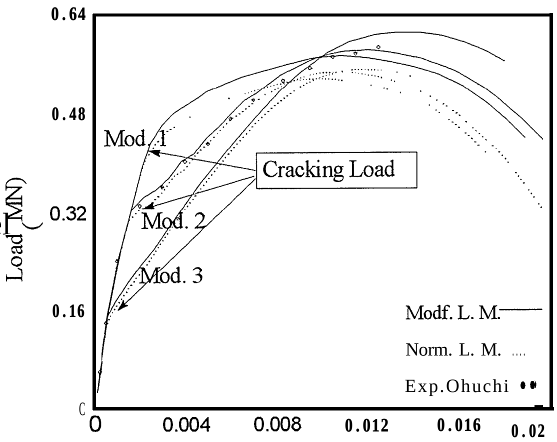


Fig. 7 Comparison of Lattice Models With Experiment data

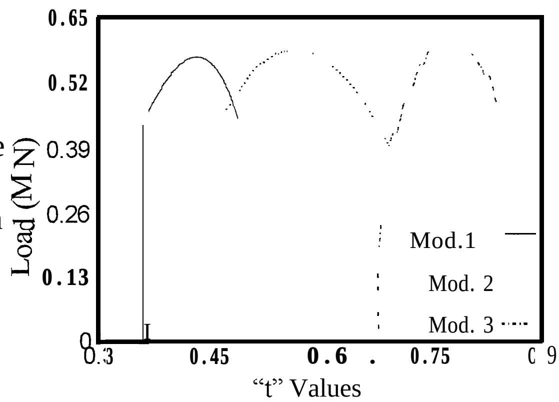

Fig. 8 Comparison of "t" Values for The Three Models

gradually from the elastic stage, in which it remains constant, up to the complete failure of the beam. After the peak point, the depth of the arch element is decreased due to the extension of the cracks. So, the thickness of the arch element has increased gradually in order to maintain the effect of the arch element up to the failure point. As have been discussed above, most appropriate truss discretization is the model (2). This suggests that the probable arch width is around 0.4b in the early loading stage which increases with the load up to 0.7b.

5. APPLICATION OF THE MODIFIED LATTICE MODEL FOR SHEAR FAILURE SIMULATION

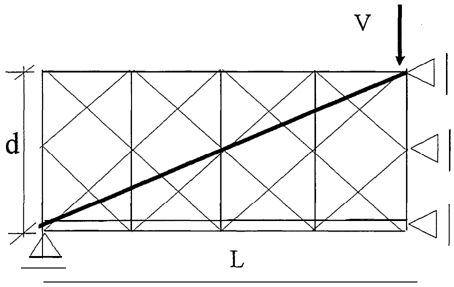

Fig. 9 Illustrative Beam Example

The Modified Lattice Model is easily applicable to simulate the shear failure mechanism for the reinforced concrete beams. Clark's experiment [2] was chosen as an example for the simulation. Fig. 9 shows the Modified Lattice Model for the reinforced concrete beam [2]. The stresses in diagonal members of concrete and stirrups and the stress of arch member are examined. From the output results of the simulation, using the Modified Lattice Model, it is found that at the primary cracking stage, the concrete elements in the bottom cord start to crack first as shown in Fig. 10 (a). Then the initiation of the diagonal cracking happens as shown in Fig. 10 (b). The initiation of the yielding of stirrups starts to take place. Although the stirrups start yielding and the diagonal tension elements have cracked, but the beam still continue to be loaded up to the complete failure. That is because of the existence of some stirrups without yielding and also the arch element, which continues up to the complete failure of the structure. At the final stage, all the stirrups yielded. At that time the arch element crushed immediately. From this simulation for the failure of that beam we can consider it as a shear failure.

6. ILLUSTRATIVE EXAMPLE

To investigate the change of the stress states in each member inside the reinforced concrete beam using the suggested Modified Lattice Model Clarck's experiment [2] in Fig. 9 is studied as an example. Studying only the average of the solid members located in the center of the shear span as in Fig. 11. The change of the average stress in diagonal members of concrete and stirrups and the stress of arch member are examined. The stresses are calculated and shown

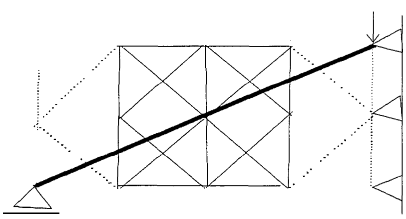

Fig. **11** Average Members in the Centre of Shear span

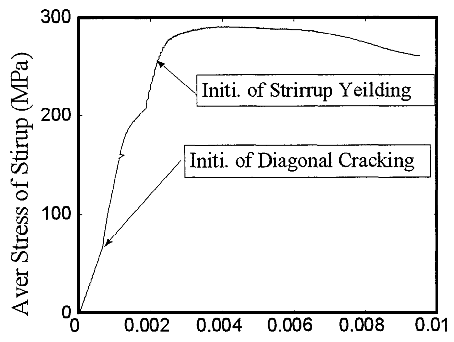
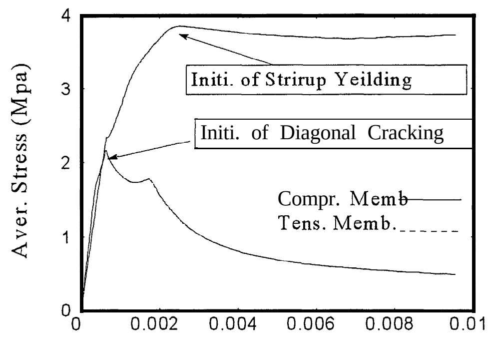
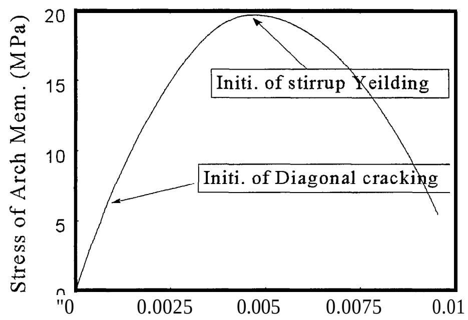


(a) Average Stress of Stirrups



(b) Average Stress of Diagonal tension and Compression Members

in Fig. 12 with the increase in the displacement of the loading point. From Fig. 12, it is clear **that the** average tensile stress of diagonal tension members of concrete is decreasing rapidly after the initiation of diagonal cracking. On the other hand, the average compressive stress of diagonal compression members of concrete and average tensile stress of stirrups are increasing significantly as shown in Fig. 12(a), and (b). The average stress of diagonal compression members has the tendency to remain almost constant after exhibiting a certain amount of increase in the average stress. The average stress in stirrups is slightly increasing with the increase in the displacement after the initiation of yielding. However, the compressive stress in arch member exhibits a significant increase after the initiation of stirrup yielding, however, due to the softening in compression, the arch member reaches to the ultimate state as in Fig. 12(c). Hence, the predicted shear failure mode for this beam is compression failure of arch member after the initiation of stirrup yielding. This is quite similar to the experimental results.



(c) Stress of Arch Member

Fig. (12) Change of Average Stress in each Member

7. CONCLUSIONS

In the proposed Modified Lattice Model, a reinforced concrete beam subjected to shear force is converted into a simple truss and arch members by the consideration of the minimum total potential energy for the structure at each step of loading. A nonlinear incremental analysis is performed. The conclusions obtained from this research are as follows:

1. By minimizing the total potential energy of the reinforced concrete beam, we get only one value for the thickness of the arch element, which corresponds to the stiffest case of the structure which is quite similar to the original response of the experimental analysis.
2. The modified Lattice Model has the tendency to estimate the stiffness of the beam closer to the experimental results. Furthermore, the predicted displacement at the peak is almost similar to the experimental results.

3. The thickness of the arch member, which plays a very important role in the Modified Lattice Model, is increasing gradually with the increase in displacement of the loading point after the initiation of diagonal cracks up to the complete failure of the beam.
4. Model (2) is the appropriate discretization to implement the Modified Lattice Model analysis.
5. Using the different forms of the Modified Lattice Model, the ultimate load is almost kept constant but the cracking load is decreasing depending on the strain energy of the cracked element.
6. Although the Modified Model is a more simplified method than the normal finite element method, it can capture the shear behavior of concrete beams throughout the change of the shear resisting mechanism.

Durability of elastomeric building sealants — results from a five year programme

Till Boettger and Hartmut Bolte
University of Leipzig, Leipzig, Germany

Abstract
An extensive and comprehensive multi-year durability study was undertaken in which a series of high-performance sealant products were artificially and naturally aged in an effort to determine test methods and test regimes most likely to simulate in-service conditions. Sixteen elastomeric products were evaluated of which fourteen were sealants based on either polysulphide, polyurethane or silicone compounds. The remaining products, an ethylene-propylene-diene-monomer and a polychloroprene, were used as a basis of comparison to the ageing effects on rubbery compounds subjected to both artificial and natural ageing. Both free-film and model joint compounds were tested. Artificial ageing was conducted using different weathering apparatus and consisted of various combinations of exposure to fluorescent or Xenon lamp Ultra violet radiation, simultaneous heat ageing at temperatures ranging from 60 to 140°C and, water condensation or spray. Natural ageing took place on a site located near the test laboratories and characterised by its temperate climate and industrial setting. The change in materials properties was characterised through mechanical tests (tensile strength and elongation at break), thermo-analytical methods and chemical spectroscopy including attenuated total reflectance and photo-acoustic Fourier transform infrared spectroscopy. Results from specimens aged artificially are compared with those aged from 5 years open air weathering in Leipzig. As well, results on model joints are compared with those obtained from testing free-films. These preliminary results strongly suggest that the research should continue such that a comprehensive assessment of different ageing regimes and their effects on various sealant products can be ascertained. This work would then provide a fundamental basis for developing useful and predictive assessment tests for sealant products currently in use.
Keywords: accelerated ageing, chemical spectroscopy, correlation, cyclic movement, elastomeric sealants, free films, joint models, natural weathering, thermo-analytical, time compression factor.

1 Introduction

There exist a number of problems associated with developing useful tests to assess the long-term performance of sealants. To adequately assess their long-term performance, a great deal of testing and time is required in relation to the actual time in-service. Typically, the long-term performance of sealant products is assessed on the basis of practical experience derived from field studies [8]. Field studies undertaken to the evaluate products tested in present study will be reported in a subsequent conference to be held in Berlin this June [2]. The present work focuses on the results of laboratory studies using artificial and natural ageing conditions as a basis for developing standard test methods. To yield useful and reproducible results, standard test methods require simplified test conditions, reduced testing periods and test conditions in which the number of factors causing ageing are minimised. An understanding of factors that influence the long-term testing of building sealants is critical to the development of suitable test methods

2 Experimental

2.1 Materials

The elastomeric sealants evaluated in this study are given in Table 1 below. The products are representative of the most widely used high-performance products, namely, silicone, polysulphide and polyurethane based sealants. In order to offer some comparison to the properties of other rubbery compounds used in building construction, the sealant products were compared to both polychloroprene an EPDM rubber compounds. The colour and curing system are provided for each of the 16 products tested. Two types of joint specimen were prepared: free-film specimens having dimensions of 900 mm x 80 mm x 2-3 mm, and model joint specimens conforming to ISO 8339 [10].

Table 1 — Material types, curing systems and colours

No.	Material type	Curing system	Colour
A5		1 part neutral cure, Oxime based	Grey
A6		1 part basic cure, Amine-Oxime based	Grey
A7		1 part neutral cure, Oxime based	White
A8	Silicone rubber	1 part neutral cure, Oxime based	White
A17		1 part neutral cure, Alkoxy-Titanium based	White
A18		1 part neutral cure, Benzamido-Titanium based	Grey
A19		1 part neutral cure, Benzamide based	White
A21		1 part acid cure, Acetate based	White
B9	Polysulphide	2-part Manganese dioxide cure	Grey
B10	rubber	2-part Manganese dioxide cure	Grey
B12		2-part Manganese dioxide cure	Black
B22		2-part Lead dioxide cure	Grey
B28		Prefabricated	Grey
C23	Polyurethane	1-part	Grey
D24	Polychloroprene	vulcanised	Black
E25	EPDM rubber	vulcanised	Black

2.2 Test series

Six different series of tests samples were prepared such that the effects of weathering using different accelerated ageing techniques could be compared to that of natural ageing (Table 2). The majority of tests were conducted on free films; however, results of tests were compared to those obtained on model joints.

Table 2 — Description of test series and related apparatus for conducting ageing studies

Test series No.	Description	Apparatus
1	Fluorescent UV radiation and heat ageing at + 50°C	UVCON (Atlas); UVA 340 lamps
2	Xenon arc UV radiation and heat ageing at + 50°C	Suntest CPS (Heraeus); NXE 1500 lamps
3	Thermal ageing at different temperatures up to + 90°C	Heat ageing ovens
4	Test Series No. 1 combined with extension and compression of model joints	UVCON (Atlas); UVA 340 lamps
5	Natural weathering at an outdoor site in Leipzig	Nil
6	Control specimens stored in laboratory conditions (DIN 53386-A [4])	Nil

Details regarding the test conditions and specimen exposure regimes are given below for each of the test series.

2.2.1 Ageing using fluorescent UV radiation and heat

Free-film specimens were evaluated for changes in mechanical properties and variations in chemical structure after every 1000 hours exposure for up to a total 6000 hours exposure in the accelerated weathering apparatus given in Table 1 above. Four different cycles were used to assess variations in the ageing regimes, including:

i.) 8hrs UV at + 60°C; 4 hrs heat ageing at + 50°C
ii.) 8hrs UV at + 70°C; 4 hrs heat ageing at + 50°C
iii.) 8hrs UV at + 80°C; 4 hrs heat ageing at + 50°C
iv.) 8hrs UV at + 90°C; 4 hrs heat ageing at + 50°C

2.2.2 Ageing using Xenon-arc radiation, heat and water spray

Specimens were likewise subjected to exposure intervals of 1000 hours for up to 6000 hours of total exposure. Mechanical properties were determined and chemical analysis was performed on free-film specimens after each ageing interval. Over a 21-day period, the ageing cycle consisted of 3 consecutive cycles of:

- 3 days at + 80°C; 1 day of H_2O; 2 days at + 80°C; 1 day of H_2O.

2.2.3 Thermal ageing
Thermal ageing was conducted on free-film specimens over a 6000-hour period with ageing intervals of 1000 hours respectively. Two sets of heat ageing tests were carried out: the first subjected specimens to temperatures ranging from + 60°C to + 90°C over extended periods of time; the second set was used to subject specimens to heat ageing at higher temperatures (i.e., + 100°C, +110°C, +120°C, +140°C) but for shorter intervals (i.e., up to 3500 hours total exposure with intervals of 500 hours)

2.2.4 Artificial ageing combined with extension and compression
Model joints prepared in accordance with ISO 8339 [10] were subjected to artificial ageing conditions for periods of up to 6000 hours. Strains were applied (± 7.5% and ± 12.5% of joint width) to these joints (ISO 9047 [11]) prior to the start of each ageing interval of 1000 hours. The ageing regime consisted of:

- 8hrs UV at + 60°C; 4 hrs heat ageing at + 50°C
- 8hrs UV at + 70°C; 4 hrs heat ageing at + 50°C
- 8hrs UV at + 80°C; 4 hrs heat ageing at + 50°C

During the ageing process, strains were altered from the extended state to the compressed state every two weeks.

2.2.5 Natural ageing
Free-film and model joint compounds (ISO 8339 [10]) were exposed to natural ageing at an outdoor test site located in Leipzig, that has a temperature climate and local conditions suggest and industrial setting. This ageing regime started in January 1993. The model joint compounds were also subjected to two strain levels: ± 7.5% and ± 12.5% of joint width. Changes in extension and compression were made at the same intervals as was previously given above in 2.2.4.

2.3 Test methods

2.3.1 Mechanical tests
Prior to testing, all samples were stored in standard conditions of 23°C and 50% RH in accordance with DIN 50014 [3]. Following this, three strips were cut from specimens of 45-mm length and tested in tension according to both DIN 53504 [5] and ISO 33 [9] respectively. Both tensile strength and elongation at break were recorded for each of the specimens. Tensile tests on thin strips potentially eliminate the effect of substrate since for the majority of sealant products this does not have a negative effect [1].

Tensile tests on model joint compounds was carried out using ISO 8339 [10] and provided information regarding the tensile strength and elongation at break and the tensile modulus.

2.3.2 Physical-chemical tests
The glass transition temperature of weathered samples was determined using a dynamic differential scanning calorimeter (DSC), model DSC 200 (Netzsch Geraeteban). Chemical changes at the surface of the weathered samples were examined using attenuated total reflectance (ATR) Fourier transform infrared (FTIR) spectroscopy (IMPACT 400, Nicolet). As well, photo acoustic (PAS) FTIR

spectroscopy was used to examine the surface of samples that had a severely degraded surface since this technique readily lends itself to chemical analysis in instances where surfaces are sufficiently deteriorated as to render the ATR method useless. For the PAS technique, a MTEC model 300 photoacoustic cell was used to collect the requisite data.

3 Results

The results from these ageing tests indicated that almost all of the materials survived artificial ageing at temperatures between + 60 and + 120°C. Specific results of tensile testing of artificially and naturally aged free-film specimens is provided in the first two parts of this section and results regarding model joints are discussed in subsequent parts. No detailed description of the results obtained from the chemical analysis is provided in this paper although a summary statement is given in the final part of this section.

3.1 Tensile tests on free-films

3.1.1 Artificial ageing
Based on the results obtained from these tests, the 16 products evaluated in this study can be classified in essentially three (3) different materials "types", corresponding to their response to artificial ageing and related physical characteristics. These are:

i.) Type 1 materials have elongation at break (ε_r) that change as a function of temperature in accordance with the Arrhenius equation whilst not having any evident nor significant effect on the strength at break. An example of a Type 1 material is provided in Figures 1-4 that depict changes in properties of product B28. Type 1 materials include products: B9, B10, B22, B28, C23, D24 and E25

ii.) Materials characteristic of Type 2 suggest that the tensile strength at break (σ_r) follow the Arrhenius relationship whereas the strain at break is not coupled to changes in temperature. An example of this relationship is given in Figures 5-8 showing changes in σ_r over different exposure times for product A17. Materials in this category include products A17 and B12.

iii.) Type 3 materials are characterised by little or no aged-induced changes in a given ageing regime. Essentially, the materials are only slightly or completely insensitive to the effects of heat, UV and water in the exposure regimes and over the time intervals over which they were tested. This is evident in instances where the ageing effects act alone or indeed where the ageing period was prolonged from 6000 hours to 12000 hours. Representative of this material type is product A19, whose results are provided in Figures 9-12 respectively. Materials of this type include products: A5, A6, A7, A8, A18, A19 and A21.

3.1.2 Comparison of artificial ageing and natural weathering
At this stage, data for specimens exposed to natural weathering over a 5 year period is available for the 16 products evaluated. An important result from these tests

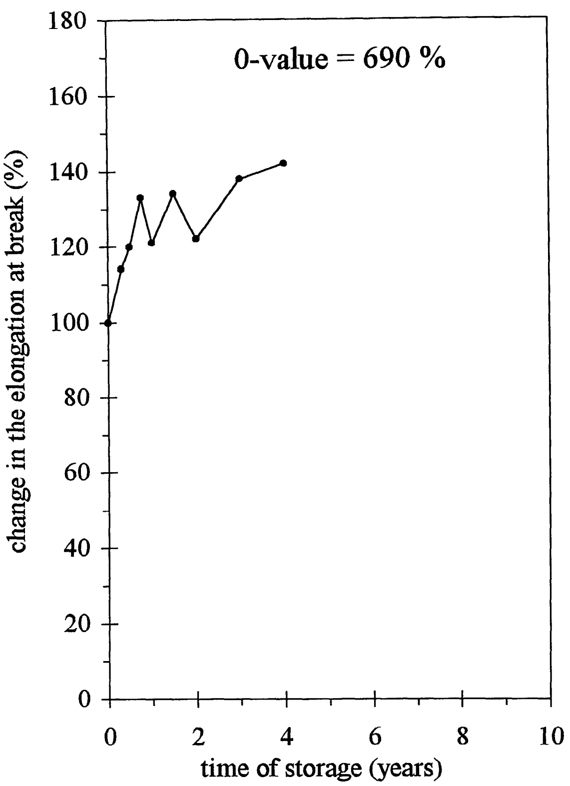

Fig. 1: Material B 28 - natural weathering

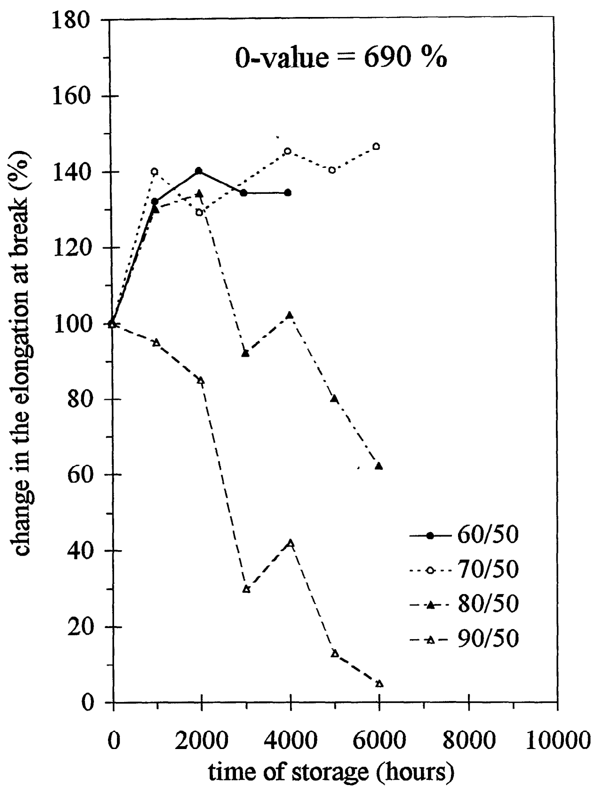

Fig. 2: Material B 28 - accelerated ageing UVCON

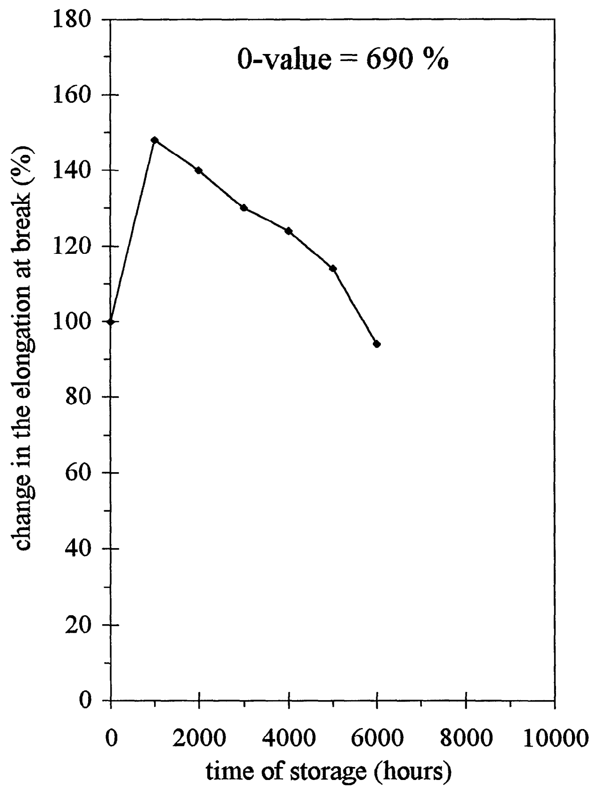

Fig. 3: Material B 28 - accelerated ageing SUNTEST

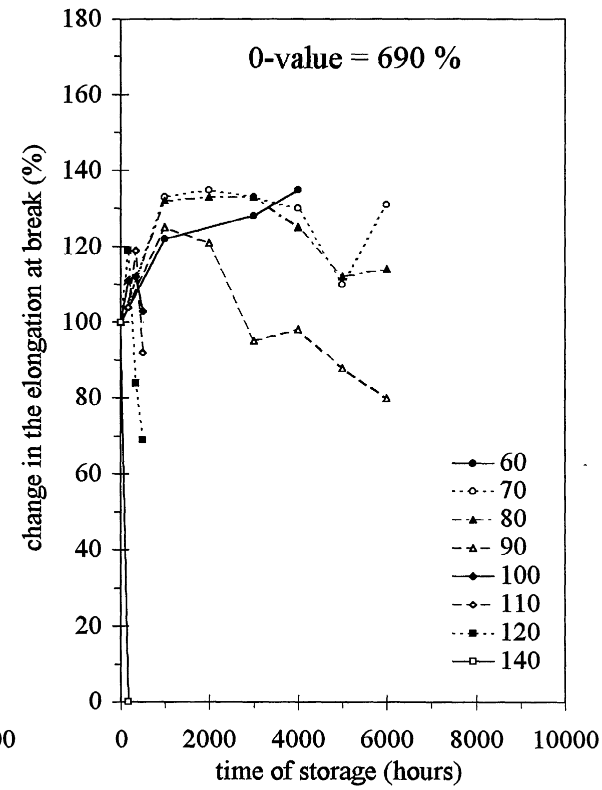

Fig. 4: Material B 28 - accelerated ageing OVEN

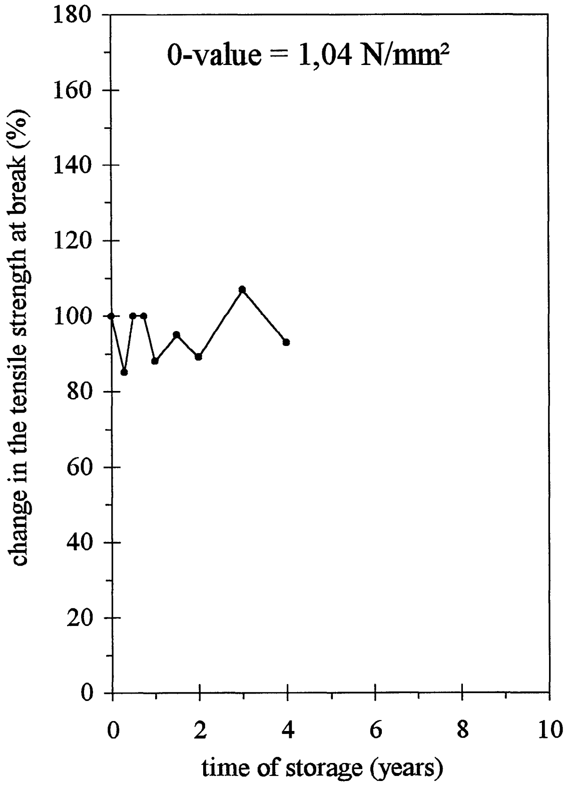

Fig. 5: Material A 17 - natural weathering

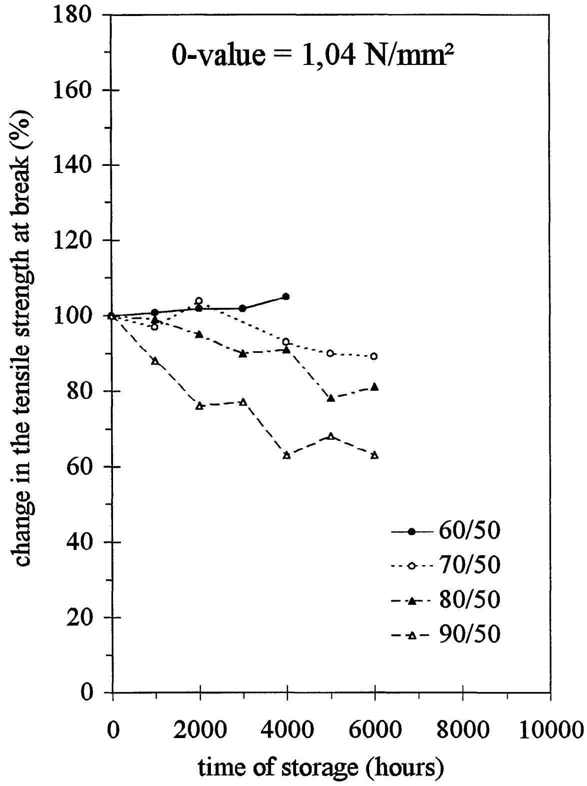

Fig. 6: Material A 17 - accelerated ageing UVCON

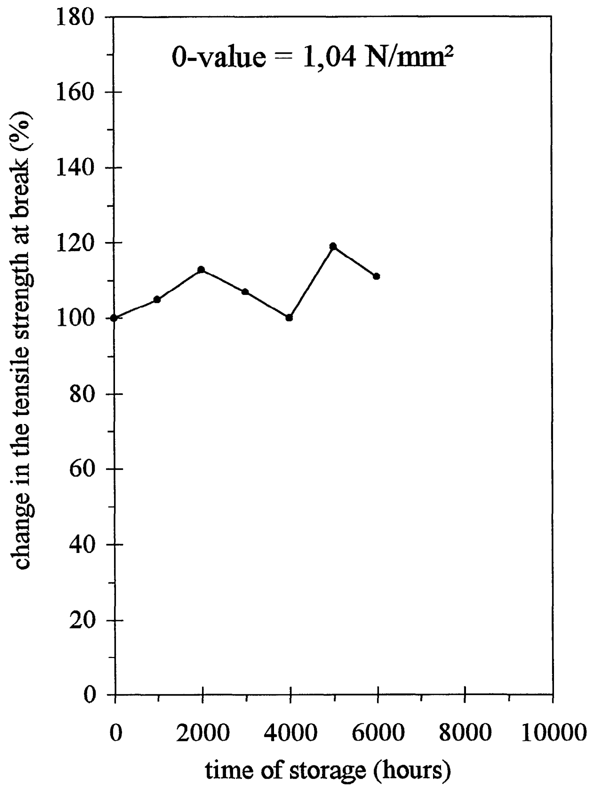

Fig. 7: Material A 17 - accelerated ageing SUNTEST

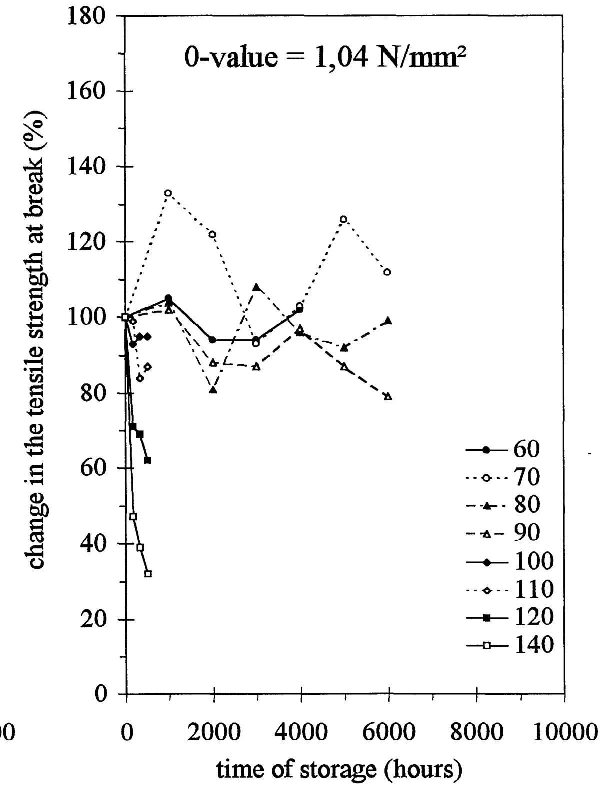

Fig. 8: Material A 17 - accelerated ageing OVEN

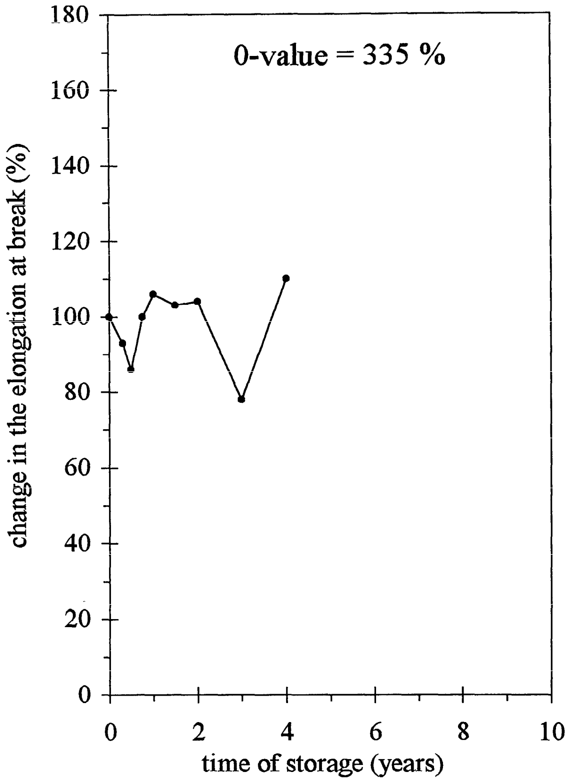

Fig. 9: Material A 19 - natural weathering

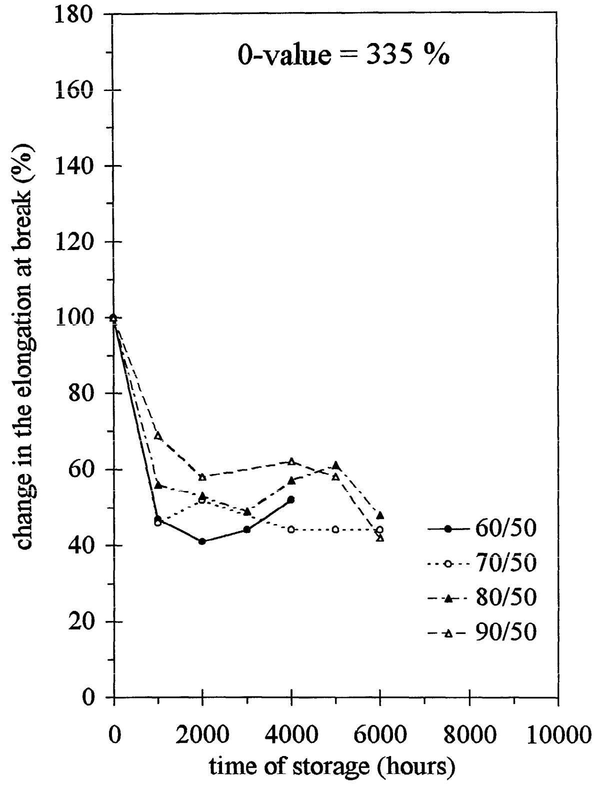

Fig. 10 Material A 19 - accelerated ageing UVCON

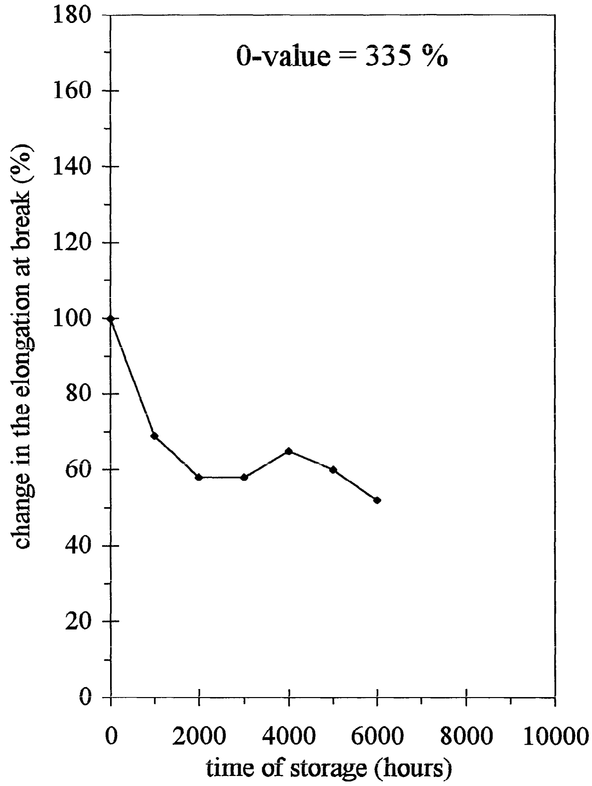

Fig. 11: Material A 19 - accelerated ageing SUNTEST

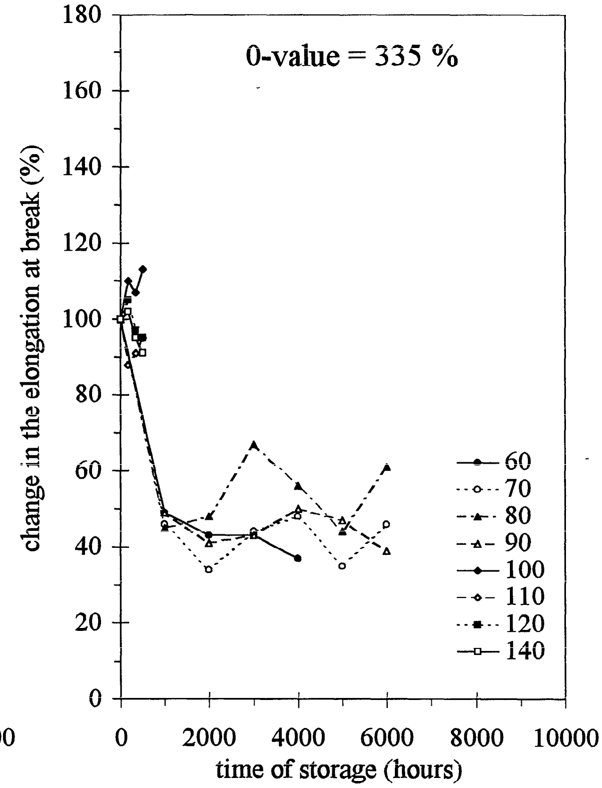

Fig. 12: Material A 19 - accelerated ageing OVEN

showed that post-curing can take place over one year in certain materials and actual ageing appears to only take place thereafter.

For civil engineering applications in-service temperature for sealants are not expected to exceed 70°C and typically, higher test temperature are likewise not used. Assuming results between natural ageing over 4 years and artificial ageing over 36 weeks (6000 hours) correlate reasonable well, one can then postulate that there exists a time-compression factor of 1:6 (32 weeks: 4 x 52 weeks). The current results indicate that virtually all sealants can be tested to temperatures of at least 90°C without adverse effects. Assuming that this can be extended to higher temperatures as wee, time-compression factors for different test temperatures can be calculated from the Arrhenius equation as provided in Table 3 below.

Table 3 — Estimated time-compression factors at given temperatures

Test temperature °C	Time-compression factor
70	1:6
80	1:12
90	1:24
100	1:48
110	1:96
120	1:192

It is to be noted that each 10°C increase in test temperature doubles the time-compression factor. The implications regarding this proposal suggest that considerable savings in time and costs can accrue provided the applicability of test temperatures in excess of 70°C can be substantiated by additional work. Based on these promising initial results, the current test series is being extended. As well, the degree of correlation declines only slightly with increases in test temperature within the range of temperatures examined in this study.

3.2 Tests on model joints in comparison to free-films

Model joints were tested on 10 of the 16 products evaluated in this study. Changes in tensile strength and elongation at break for specimens exposed to 4 years natural weathering were similar to results obtained from free-films with the exception of material A5. In this case, results obtained for the elongation at break from the free-film specimen did not correspond to that of the model joint compound; it is not possible at this time to offer an explanation for this occurrence. In the case of materials A5, A6, A7, A8 and C23, it was possible to obtain values for both the tensile strength and elongation at break whereas for the remaining materials, adhesion was lost prior to being obtaining useful results.

Model joints subjected to artificial ageing series No. 1 provided similar results to those aged in natural conditions based on results of tensile tests on products A5 and A6. It must also be noted that post-curing occurs more slowly in model joints as compared to free-films and as well, the effect of UV radiation is less pronounced in model joint specimens. Ultra violet radiation essentially produces only surface effects. Results for values of modulus at 50 and 100% extension did not provide as clear an indication of changes in performance as was evident for either the tensile strength or elongation at break and hence, these values have not been reported here.

3.3 Comparison of Ageing with movement cycles

The results of this section as based on three products namely, A5, A6 and C23. Products A5 and A6 were chosen as being representative because they were found to be particularly resistant to artificial ageing, as was seen in previous test results. As well, all these products preferentially had excellent adhesion to the concrete substrate and consequently failed in cohesion. Product C23 is the weakest material despite its' excellent adhesion to concrete.

The remaining tests have not yet been completed however the status of the various test series is provided below in Table 4.

Table 4 — Description and status of Natural and Artificial weathering test series for elastomeric sealant products

Series description	Status
NW[1] with and without extension of +25%[†]	5 years natural exposure
NW with 1 extension/compression cycle /yr.: 6 months at +12% (winter); 6 months at -12% (summer)	1 year natural exposure
NW with 6 extension/compression cycles /yr.: 1 month at +12%; 1 month at –12%	1 year natural exposure
AW[2] using UV CON at 80°C /50°C and extension/compression cycling, alternating every 1000 hrs between +12.5% (at –20 °C) and –12.5% (at 80°C)	Complete after 6000 hours exposure
AW using UV CON at 70°C /50°C with extension/compression cycling, alternating every 2 wk. between +12.5% (at –20 °C) and –12.5% (at 70°C)	Complete after 6000 hours exposure
AW using UV CON at 60°C /50°C with extension/compression cycling, alternating every 2 wk. between +12.5% (at –20 °C) and –12.5% (at 60°C)	4000 (of 6000) hours completed

1. NW – Natural weathering
2. AW – Artificial weathering

† + Indicates extension and - compression

Preliminary results from this test series suggest that continuos extension alone has only a very slight effect whilst artificial ageing with simultaneous extension-compression cycling has a significant negative effect. Work in the area of artificial ageing should continue with emphasis on separate extension-compression cycles having lesser effects than those previously undertaken. It is likely that these would more closely resemble in-service conditions.

3.4 Physical-chemical test methods

Based on results obtained to date, the use of DSC appears to be the most suitable method for investigating changes in glass transition temperature (T_g) for elastomeric sealants. In many instances, a loose correlation between mechanical properties and T_g has been observed.

With respect to the use of ATR-FTIR, it has been observed that this method does not provide useful results since it requires a near perfect contact between the ATR crystal and the surface of the sealant sample. This condition very often is not met because the surface of the degraded polymer is comparatively rough and uneven in relation to the un-degraded specimen. On the other hand, PAS is the technique of choice for sealant materials since surface roughness is not important in this technique and changes in chemical spectrum can readily be obtained using this method.

4 Proposal for standard test methods

4.1 Free-film and model joints

Free-film specimens should be used where adhesion to the substrate is not critical to evaluating the product. Specifically, this applies to those materials that are used as a jointing tape or 'Band-Aid' jointing product. Where previous trials have shown that the sealant adhesion to the substrate is likely to remain, or indeed, increase over the long-term, then the use of free-film testing is considered adequate. In all other cases, tests on model joints are preferred.

4.2 Thermal or combined ageing

Thermal ageing alone is suitable for those elastomeric sealants that have at least some sensitivity to UV radiation. Of the 16 materials evaluated in this study, the products that could be tested in this fashion include A5, A6, A7, A8, A19, A21, D24 and E25. The simplicity of thermal; ageing lends itself very well to accelerated ageing, e.g., it is possible to test these products at 120°C as opposed to the typical test temperature of 70°C. Testing at 120°C would provide a time-compression factor of 1:192 and this would permit estimating the effects of ageing over 11 years with a test conducted in 500 hours (3 weeks). The results could potentially be extrapolated to 22 years.

Combined ageing should be used for all products that have a certain higher degree of UV sensitivity. These materials include A17, A18, B9, B10, B12, B22, B28 and C23. The time-compression factor is 1:24 for tests conducted at 90°C and this implies a test time of 3000 hours (18 weeks) that would simulate ageing over about 8 years. Other possible suggestions include conducting the test over 500 hours (3 weeks) such that 2.5 years of ageing is simulated.

5 Conclusions

Considerable work has been undertaken to artificially and natural age a series of high-performance sealant products in an effort to determine test methods and test regimes most likely to simulate in-service conditions. This substantial set of result remains to be fully reviewed, however, in this report the following is apparent:

- Post-curing can take place over one year in certain materials and actual ageing appears to only take place thereafter.
- Virtually all sealants can be tested to temperatures of at least 90°C without adverse effects.

- Changes in tensile strength and elongation at break for specimens exposed to 4 years natural weathering were similar to results obtained from free-films (with the exception of 1 of 8 silicone-based materials).
- Continuous extension alone has only a very slight effect whilst artificial ageing with simultaneous extension-compression cycling has a significant and negative effect on performance indicators.
- The use of DSC appears to be the most suitable method for investigating changes in glass transition temperature (T_g) for elastomeric sealants.
- Photoacoustic FTIR spectroscopy is the technique of choice for sealant materials since surface roughness is not important in this technique and changes in chemical spectrum can readily be obtained using this method.

The research should continue such that a comprehensive assessment of different ageing regimes and their effects on various sealant products can be ascertained. This work would then provide a fundamental basis for developing useful and predictive assessment tests for sealant products currently in use.

Service life and safety prediction of concrete slabs at filling stations

S. Gunnarsson, J.-D. Wörner
Institute for Structural Analysis, Darmstadt University of Technology, Germany

Abstract
In Germany there are almost 19.000 filling stations. Water-pollution-prevention-regulations have become stricter and in order to fulfill the new demands the bulk majority of filling stations have to renew their tanking area. Modest approximations render the tanking area of a filling station has a common size of 200 m² and the renewing costs of tanking area being DM 200/m². So the total tanking area which has to fulfill the water-pollution-prevention-regulations comes to 3,8km² and the total costs comes to 760 Mio. DM. Thus the life expectancy of concrete slabs in terms of tightness is a matter of environmental and economical importance.
In-situ tests gave the mean depth of penetration at filling stations after averagely 5 years of service less than 40mm. Non of the measured penetrations was larger than 1/3 of the existing slab thickness. The penetration at concrete/joint is not larger than in an area of concrete only. Between porosity and penetration there is a clear relationship and this relationship is stronger than of tanking operations or age of lane. Based on those tests, reference tests in laboratory and calculations the life expectancy was evaluated and found to exceed 30 years.
Keywords: Life expectancy, penetration fuels in concrete, filling stations.

1. Introduction

In a cooperation between the German Society for Petroleum and Coal Science and Technology, (DGMK), and TU-Darmstadt tests and calculations were carried out [2]. The aims of this cooperation were:

- to render a state of the art regarding the penetration of fuels at filling stations
- evaluate the life expectancy of the concrete slabs in the filling area

The evaluation of the life expectancy was based on the DAfStb - Guideline [1]. In this guideline the term tightness is defined in the following way: The penetration front of the fluidal medium does not proveably reach (with a margin of safety) the action-opposite side of the concrete structure during its time of action.

Hence uncracked concrete structures can be regarded tight when the following critera is fulfilled:

$$d \geq e_{tk} \cdot \gamma_e$$

were:
- d : thickness of concrete structure
- e_{tk} : characteristisc depth of penetration ($e_{tk} = 1{,}35 \cdot e_{t,m}$)
- $e_{t,m}$: mean depth of penetration, test result
- γ_e : safety factor for penetration

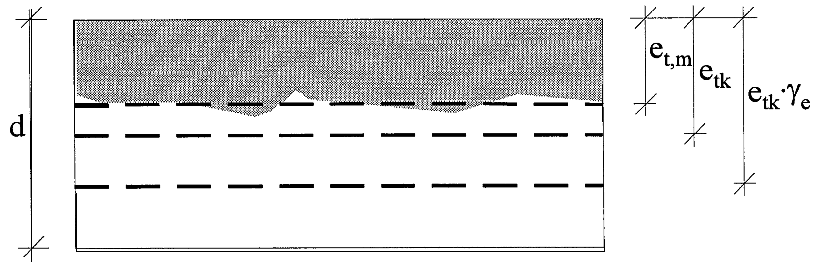

Figure 1 Defintion of tightness according to DAfStb-Guideline [1]

Knowing the penetration e_t at time t, [1] gives the following model to calculate the penetration e_{t1} at another time t_1 :

$$e_{t1m} = e_{tm} \cdot (t_1 / t)^{1/2}$$

2. Results

2.1 In-situ results

The in-situ tests were carried out at 9 filling stations numbered T1-T9. Relevant station data is shown in figure 2.

No.	location	slab size [m·m]	d slab thick. [cm]	reinforce-ment	petrol sold [l/month]	diesel sold [l/month]	date of service start	date of test	age of slab [months]
T 1	country	8,1 x 8,4	20	Q257 U	50.000	60.000	10/89	9/95	71
T 2	highway	5,9 x 3,7	20	no inform.	non	130.000	5/90	9/95	64
T 3	city	7,4 x 6,4	13-20	Q188 O+U	75.000	25 .000	10/90	2/96	64
T 4	city	4,4 x 4,5	20	Q188 o+u	97.000	15.000	11/90	2/96	63
T 5	city	4,8x5,9	18	Q188 o+u	non	30.000	6/91	2/96	56
T 6	city	5,0 x 4,2	24	2Q188 0	120.000	30.000	7/92	3/96	44
T 7	city	5,4 x 3,7	21-25	4188 o+u	non	150.000	6/92	3/96	45
T 8	city	3,5 x 3,0	21	Q188 M	non	40.000	11/91	3/96	52
T 9	city	3,2 x 3,0	18-22	non	non	70.000	8/91	4/96	56

Figure 2 Data of tested filling stations

The width of the joints was between 13 and 20 mm.The depth was between 11 and 25 mm. The mean depth of penetration was measured from bore cores taken from concrete only and the concrete at the joints of slabs. Also the porosity was measured. The results are listed for each of the filling stations in figure 3.

Filling station	Mean depth of penetration $e_{t,m}$ [mm]		Total porosity [%]
	concrete	concrete/ joint	
T 1	21	no value measured	11,3
T 2	29	no value measured	13,0
T 3	39	no value measured	11,9
T 4	15	no value measured	10,0
T 5	32	30	13,4
T 6	60	50	16,1
T 7	53	50	14.6
T 8	73	no value measured	18,0
T 9	32	32	13,6
mean $\bar{e}_t$	39	40	
Standard deviation σ_{e_t}	19	11	

Figure 3 Mean depth of penetration $e_{t,m}$ and porosity (in-situ)

The following relationships to penetration were investigated:

- porosity
- number of tanking operations
- age of lane

The penetration as a function of tanking porosity is shown in figure 4.

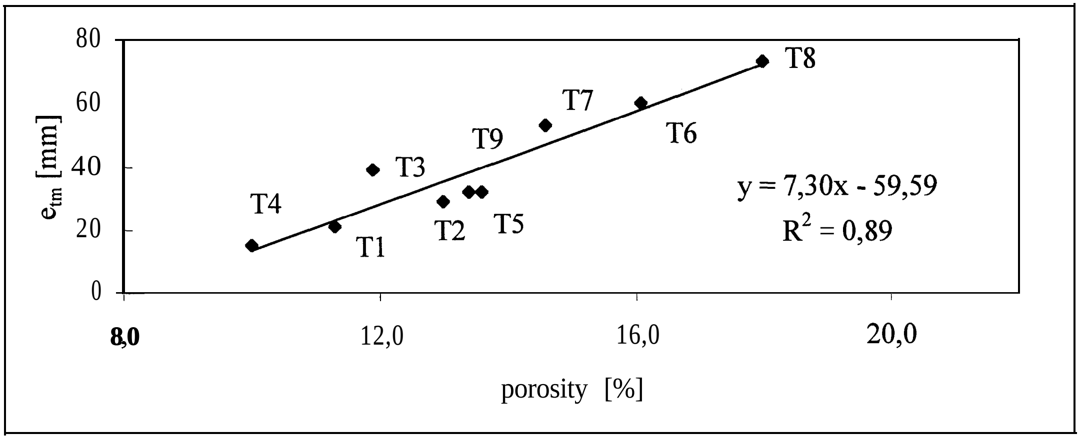

Figure 4 Penetration as a function of tanking operations

From figure 4 a clear correlation between penetration and number of tanking operations can be seen.

To evalute the effective number of tanking operations the following assumptions were made:

- the average tanking amount per tanking operation equals 40 liters [2]
- by each tanking operation the spilled amount equals 4 ml [3]

Addtionally tests made in Darmstadt have shown that the penetration of petroleum being about 0,16 times the penetration due to diesel oil. This can be explained trough the higher evaporation rate of petroleum.

Based on those assumptions and the consumption data in figure 2 the effective number of tanking operation from the date of service start till the date of testing was estimated, see figure 5.

Filling station	Tanking operations [10^3]
T 1	121
T 2	208
T 3	59
T 4	48
T 5	42
T 6	54
T 7	169
T 8	52
T 9	98

Figure 5 Number of tanking operations

The penetration as a function of tanking operations is shown in figure 6.

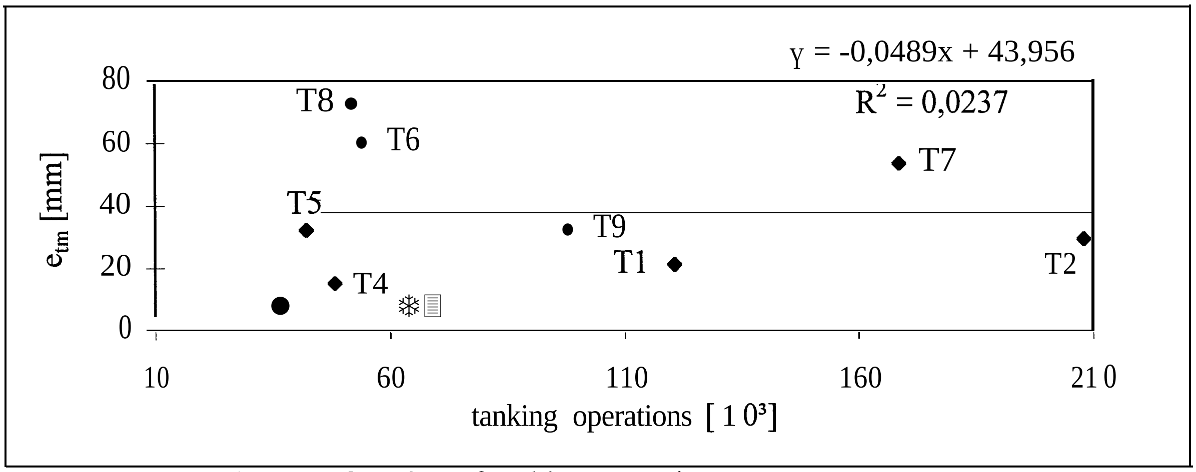

Figure 6 Penetration as a function of tanking operations

From figure 6 no correlation between penetration and number of tanking operations can be seen.

The penetration as a function of tanking operations is shown in figure 7.

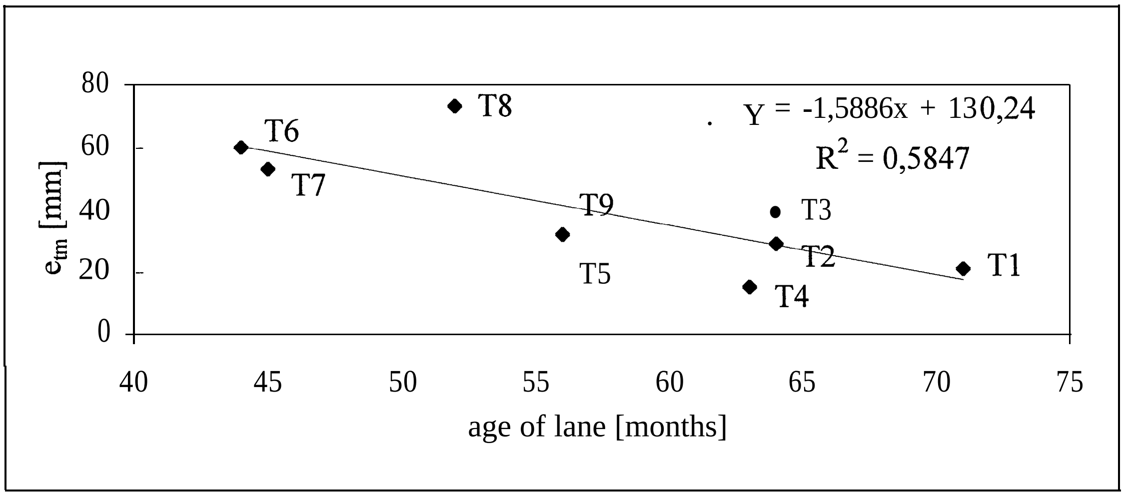

Figure 7 Penetration as a function of age of lane

From figure 7 a weak negative correlation between penetration and number of tanking operations can be seen.

Based on the results in figure 3 - figure 7 the following can be said:

- The mean depth of penetration at filling stations after averagely 5 years of service is less than 40mm.
- Non of the measured penetrations was larger than 1/3 of the existing slab thickness.
- The penetration at concrete/joint is not larger than in an area of concrete only.
- Between porosity and penetration there is a clear relationship and this relationship is stronger than of tanking operations or age of lane.

2.2 Laboratory results

A concrete was mixed, cured and acted upon intermittently according to[1]. Also an uncontamined piece of concrete was taken from filling station Tl and loaded identically. Thus a comparison between the in-situ tests and laboratory action was possible. The results are shown in figure 8.

	Depth of penetration $e_{t,m}$ [mm]					
Duration and type of fluid action	28 days each 5 hours (∑ 140 hours)		144 hours continuous		6 years tanking spillage	
Test- Medium	diesel oil		diesel oil		diesel oil/ petroleum	
Test area	concrete	concrete/ joint	concrete	concrete/ joint	concrete	concrete/ joint
Laboratory concrete	12	15	14	13	-	-
In-situ concrete T1 (no pre spillage)	20	13	15	13	-	
In-situ concrete T1 (max. spillage)	-	-	-	-	21	-

Figure 8 Mean depth of penetration $e_{t,m}$ (laboratory)

Based on the results in Figure 8 the following can be said:

- The mean penetration resulting from the laboratory action according to [1] is comparable to the penetration resulting from 6 years at filling station T1 .
- The penetration values at concrete joints are not exceeding those for continuous concrete area.

3. Life expectancy

Using the data achieved in the in-situ and labor tests and the penetration model in [1] the life expectancy was evaluated in two ways:

a) using the 5th percentiles of the penetration and the penetration model from [1]
b) using the penetration with a safety value of γ_e = 1,5 and the penetration model from [1]

The evaluation and comparison of those two different approaches is shown in the following:

a) 5th percentiles of the penetration and the penetration model from[1]

Meanvalue $\bar{e}_{t\,m}$ = 39 mm, standard deviation σ = 19 mm, number of stations n= 9

5th percentiles: $e_k^{5\%} = \bar{e}_k + k \cdot \sigma$ = 39 mm + 2,193·19 mm
= 80 mm < 200 mm (thickness of the slab)

Using the model from [1] gives:

$e_{t,m} = e_{t1,m} \cdot (t/t_1)^{1/2}$ with: $e_{t1,m}$ = 39 mm and t_1 = a

So the life expectancy, time = t, for a slab thickness e_{tm} = d = 20 cm:
$t = (d / e_{t1}^{5\%})^2 \cdot t_1 = (20\ cm / 8{,}0\ cm)^2 \cdot 5\ a = 6{,}3 \cdot 5\ a = 32\ a$

b) penetration with a safety value of γ_e = 1,5 and the penetration model from[1]

using the penetration model and the permitted value of penetration from [1] then the life expectancy, time = t, for a concrete slab of = 20 cm:

$t = (d / \gamma_e \bullet 1{,}35 \cdot e_{t.m})^2 \cdot t_1 = (20\ cm/1{,}5 \cdot 1{,}35 \cdot 3{,}9\ cm)^2 \cdot 5\ a = 32\ a$

Both approaches render the same life expectancy of 32 years.

Recycling of concrete in Sweden

Some case studies and experimental casting

C. Molin
BARAB AB, Stockholm, Sweden

Abstract

Until quite recently, there was no recycling of reinforced concrete in Sweden. However, interest in its potential has increased significantly during the 1990s. A not insignificant number of residential buildings from 1960-75 have recently been demolished, usually in areas where there is little work. Other demolition projects have included older factories, bridges, hospitals and so on. From some of them, almost all the concrete has been completely recycled.

Most of these investigations have been financed by The Development Fund of the Swedish Construction Industry (SBUF). Development work deals with aspects such as selective demolition, transport, various applications for crushed concrete and test procedures. Optimum recycling flow rate and practical considerations are described.

A particularly interesting result is the fact that even the fine fraction of the crushed concrete can be reused for the manufacture of normal concrete grades: for example, K25 concrete was produced using 250 kg cement/m^3 with a normal dosing of plasticizer. Such concrete can suitably be made at the demolition site if new construction work is also being carried out.
Key words: Concrete recycling, demolition

1 Introduction

There is a general trend today to attempt to conserve natural resources, reduce the quantity of waste produced by society and protect the environment.

Much building waste is still disposed of unsorted in various types of landfill. Increasingly, they are being filled with large quantities of unsorted and uncrushed concrete, from which reinforcement bars are projecting. There is an increased need of sorting for reuse and reduction of gross volumes.

Environmental and natural resource considerations will make it increasingly difficult to obtain permission to open new gravel pits. The limited number of pits that do manage to obtain permission will be sited at greater distances from concrete batching plants or other points of use, resulting in higher transport costs.

In recent years, the costs of landfill disposal have risen significantly: in some local authority areas, this cost may even exceed the actual cost of demolition and transport.

It should be possible to make much greater use of crushed concrete, bricks etc. as filling material and sub-base for minor roads, factory yards, local authority facilities etc. In addition, experience from other countries indicates that the use of crushed concrete as aggregate for new concrete in building construction is very successful. In this context, this refers to the use of the coarse fraction [1].

In a number of places in Sweden there are apartment buildings, mainly from the 1960s and 1970s, which are virtually empty, leading to the creation of slums and rising maintenance costs. There are also commercial buildings, such as factories, which are not used. A common feature of them all is that they consist largely of concrete: in residential buildings, for example, concrete accounts for over 80 % of the weight.

In general, the case studies and experimental casting that have been performed have had the objective of increasing recycling and the degree of reuse of crushed demolition concrete.

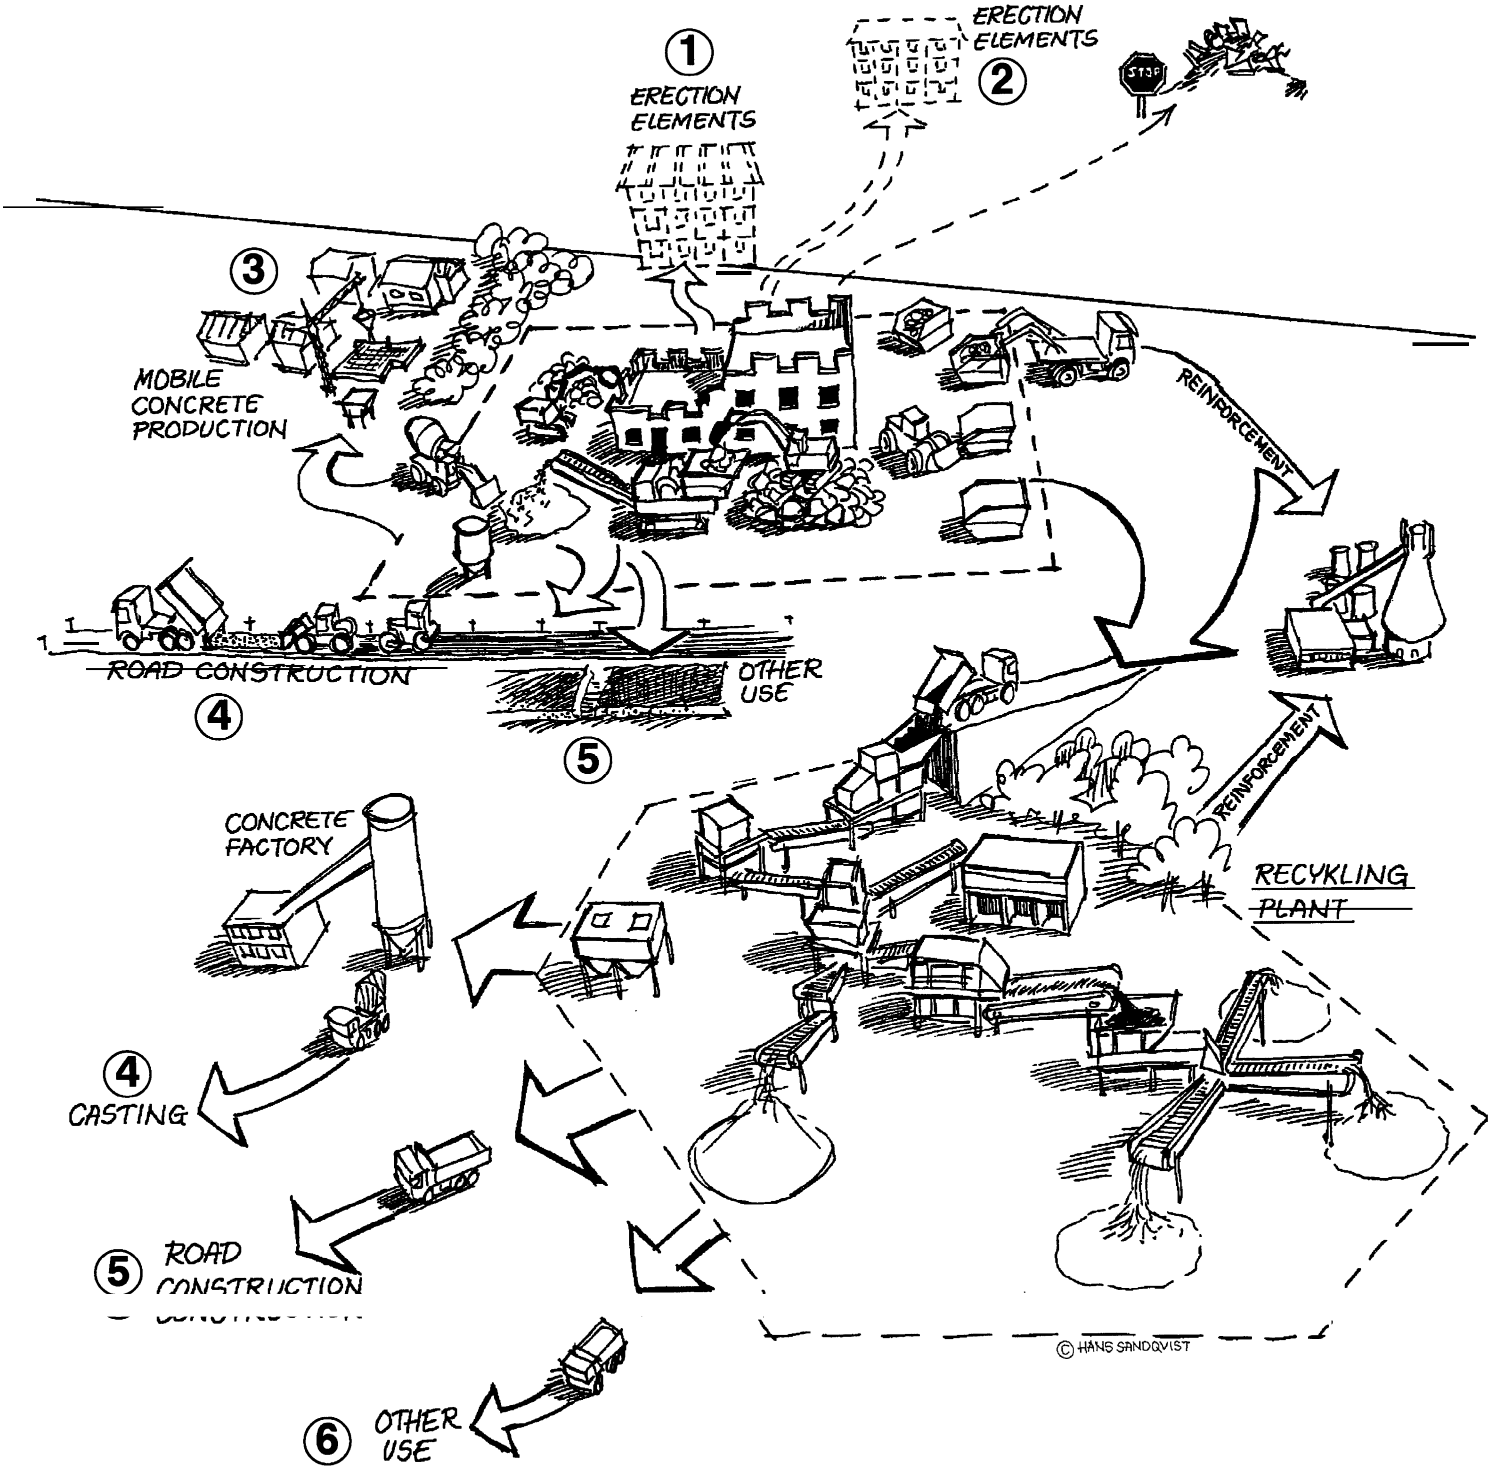
2 Case studies of demolition and reuse

2.1 A general study of a number of demolition objects

Studies of a larger number of demolition projects indicate an optimum recycling flow as follows, [2],[3]. They indicate that recycling at site or in the vicinity is preferable. In addition, efforts should be made to achieve as great a conversion of the crushed concrete as possible, i.e. preferably to produce new concrete at the site, using the crushed concrete as aggregate. This will mean that only cement will need to be transported to the site.

Crushed concrete is highly suitable for hardcore layers and sub-bases in roads, yards etc. The lowest form of recycling involves using the material as fill. If reuse at site is not possible, the crushed concrete (or larger pieces of a manageable size) and the cut reinforcing bars can be transported to a recycling plant. This will provide better opportunities for conversion, e.g. through the production of prefabricated concrete items using the recycled concrete.

RILEM's recommendations, based on experience from continental applications and a few Swedish cases, indicate that aggregate larger than 4 mm can be replaced by crushed concrete. In certain cases this will produce, for the same workability, a concrete of marginally poorer quality. It is also possible to produce new concrete in



Black arrows = Short transport
Light arrows = Distant transport

① to ⑥ = Grade of priority; ① = Higest priority which all the aggregate has been replaced by crushed concrete. However, this increases the need of water for mixing, resulting in a higher water/cement ratio and poorer quality. Such concrete can be used only for simpler purposes.

Crushed concrete is an excellent material for substrate and sub-bases in roads etc. Field and laboratory trials show that the load-carrying capacity and stability are at least as good or better than the corresponding characteristics of gravel produced from crushed rock or uncrushed natural gravel, as commonly used. However, in many cases, the grind test value specified in VÄG 94 is not achieved by crushed concrete. However, this test value is normally irrelevant for load-carrying and reinforcement layers.

Summarising, experience from a number of different types of larger demolition projects and available plant leads to the following recommendations:

1. A demolition plan should be drawn up. It should include a brief description of the project, with a clear presentation of any hazardous materials, demolition methods to be employed and the disposal of waste products.
2. The quality of the concrete must be determined in order to facilitate the maximum possible degree of reuse and processing. Characteristics such as compressive , strength, carbonation, chlorides, heavy metals and environmentally hazardous organic substances should be considered.
3. The structure of the building needs to be freed of cladding materials, roofs, windows, internal structures and building services systems. Contaminated concrete needs to be demolished separately.
4. For normal concrete buildings, having wall thicknesses less than 500 mm, demolition should be carried out primarily by cutting and/or nibbling equipment.
5. The sizes of the pieces should suit the jaw size and capacity of the crusher to be used, as well as its ability to cope with reinforcement, the thickness of the demolished material and amount of reinforcement in it.
6. Crusher size and capacity should be capable of dealing with the total quantity of demolition material to be produced. Appropriate rule of thumb guides are as follows:

- Up to about 1000 tonnes:
  Crusher weight: 15-25 tonnes
  Capacity: 50- 100 tonnes/h
- Up to about 3000 tonnes:
  Crusher weight: 25-50 tonnes
  Capacity: 100-l 50 tonnes/h
- Up to about 10 000 tonnes:
  Crusher weight: 50-80 tonnes
  Capacity: 5 1 O-300 tonnes/h

2.2 A study of a larger hospital

The demolition of a larger building on the old Långbro hospital site was selected for study for a number of reasons: partly because the purchaser, the contractor and the demolition contractor wanted to demolish the building with as little environmental impact as possible, and partly because the structure of the building was representative of a large number of concrete buildings in Sweden [4].

The building consisted of site-cast concrete with lightweight concrete insulation. The maximum height was ten floors, and the total quantity of concrete amounted to **6800** tonnes.

Under the circumstances, demolition was carried out effectively, despite the need for step-by-step selective demolition and the high proportion of asbestos and blue radon-emitting lightweight concrete. Both these materials were disposed of in landfill, despite the fact that the lightweight concrete could have been used as a filling material in groundworks.

All the crushed concrete was recycled. A smaller amount was used as aggregate in fresh concrete mixed at site in a mobile automatic concrete-mixer. Most of the crushed concrete was used for various types of ground improvement at the site and for hardcore material beneath apartment buildings. The reinforcing bars were separated as part of the crushing process and were recycled through a steel mill.

It should be clear that the greatest obstacle in the way of complete and proper recycling of concrete is the fact that it is not generally known that, in most applications, crushed concrete can replace the use of sand, gravel and macadam. There is a need for information and the drawing up of relevant performance specifications attuned to the recycling approach.

Demolition plans are needed. They should be made more detailed, so that practical problems can be foreseen before the demolition work starts. During the planning stage, it is also appropriate carefully and in detail to plan the recycling potential, preferably in the immediate area.

There is good potential for improving the efficiency of environmentally responsible demolition through the use of concrete shears. There is a need for technical development of the shears themselves, as well as for appropriate selection of the correct type of shears to suit the building being demolished.

Demolition produces considerable quantities of dust and noise, as does crushing. Resolute steps need to be taken to protect personnel and third parties from unnecessary disturbance. This means that impact-type demolition equipment should be used only where unavoidable, e.g. where it is not possible to use concrete pulverizers.

2.3 Full-scale casting with aggregate consisting only of crushed concrete

Test pieces 3 x 3 x 0.1 m were cast, producing the following quality characteristics which were dependent primarily on the methods used for reducing the water content of the fresh concrete [5].

2.3.1 Test results

Quality / method	Without vacuum or plasticizer	Without vacuum, with plasticizer	With vacuum, without plasticizer	With vacuum and plasticizer
Cylinder strength, compressive, MPa	20.8	30.3	22.3	32.7
Surface hardness, MPa	15.5	25.6	29.5	34.3
Porosity, %	33.4	28.4	26.8	25.9
Workability	2.8	4.7	2.8	4.7

1 = good workability
6 = unsatisfactory workability

2.3.2 Discussion

RILEM/1993/ gives a reason for why fine fractions in the crushed concrete are regarded as unsuitable: they often contain contaminants. This is not a problem in those cases where the original concrete is known and has been evaluated from a contamination point of view, as is the case in this particular study. RILEM also refers to inadequate documentation concerning the effect of the fine fraction on strength and durability.
Intensive work to rectify this shortcoming has started.

There is a clear benefit if the entire fine fraction can be recycled for concrete manufacture. This fraction should not cause any problem for ground reuse: if anything, the contrary applies.

The O-8 mm gravel that was investigated was very coarse, lying immediately below Curve B in the grading diagram. Here and there, the 8-30 mm stone fraction was found to contain a quantity of fines less than 1 mm, which may provide an explanation for the wide spread of the results.

There was some difference in temperature between the two pouring days, which may also explain why it was difficult to control the consistency with progressive increase in the quantity of water in order to produce the required consistency and workability. This behaviour was even more apparent with high proportions of plasticizer.

Some strength values for cube samples showed too low a strength in comparison with the cylinder compressive strength. The lowest proportion was about 60 %: 80 % would be more normal. One explanation for this could be that the very uppermost layer of concrete in the batch can easily be of somewhat poorer quality. Samples for cubes and consistency testing were always taken prior to casting the blocks. The cube value related only to one sample cube, while the cylinder value related to two samples.

The quantity of cement used was 250 kg/m^3. This particularly low cement admixture ratio was deliberately chosen in order to ensure that the investigation would produce quality results that were on the safe side, and because any minimisation of the cement content is always desirable due to the considerable contribution of carbon dioxide to the atmosphere resulting from the manufacture of cement.

High proportions of plasticizer produced surprisingly high concrete strength, and this applied particularly when a stabilising dose of glycerine was added.

2.3.3 Conclusions

- Normal concrete for use in the construction of buildings can advantageously be produced using aggregate consisting solely of crushed recycled concrete.
- Suitable applications can be simple slab on ground foundations, soleplates, walls and ceiling/floor structures.
- Transport of heavy aggregate can be avoided if the new concrete is produced in the vicinity of the crushing plant (mobile).
- Transport requirements can be greatly reduced if the recycled concrete is produced at the demolition site and if it is also used in the vicinity for the production of fresh concrete.
- Using a cement proportion of at least 250 kg/m^3 and a normal quantity of plasticizer, concrete with a strength of about 25 MPa can be produced.
- The use of plasticizer results in a significant improvement in the compressive strength.
- Vacuum application produces a significant increase in the surface hardness.
- Vacuum application significantly reduces porosity.
- Porosity is considerably higher than for concrete made with normal aggregate.

Ecological Building Design

T. Häkkinen and M. Saari
VTT Building Technology, Espoo, Finland

Abstract

In an ecological building design process, the design solutions do not only depend on the economical and functional factors but also on the environmental impact of these solutions. However, in building processes the lack of resources means that unambiguous and simplified data concerning the environmental impacts of alternative solutions should be available. In addition, design process starts from prliminary guidelines and only finally results in detailed solutions and selection of materials and products. Tools concerning the environmental meaning of different kinds of preliminary choices would be needed.

The environmental quality of a building depends on the material and energy flows during its entire lifetime. Thus the environmental requirements presented by the client should deal with the quantity and quality of energy used for heating, the service life and flexibility of the building and the envirnmental quality of building products.

In order to present environmental requirements for buildings we need to be able to focus the requirements. In addition, target values, typical values or the range of typical values concerning the energy and material flows of buildings are needed. The environmental superiority can only be assessed compared to reference values. In connection with energy saving building research, target values have been developed with regard to the use of energy, electricity and water durng the service life of buildings. However, these values should be accompanied with the knowledge concerning the environmental burdens of different kinds of energy sources.

An environmental building design process can only be successful, if it is provided with adequate design methods and tools. The most important design methods for ecological building design are energy saving design, service life design and design of flexibility and eco-based selection of building products.

Keyword: Ecological building design, environmental building

1 Introduction

In an ecological building design process, the design solutions do not only depend on the economical and functional factors but also on the environmental impact of these solutions. However, in building processes, the lack of resources means that unambiguous and simplified data concerning the environmental impacts of different solutions should be available. In addition, the design process starts from preliminary guidelines and only finally results in detailed soltions and selection of materials and products. This is why it is difficult to account for environmental data of building products and building solutions in the beginning of a design process. Tools concerning the environmental meaning of different kinds o preliminary choices would be needed.

The basic ecological criteria for buildings and building products should be the same as generally understood. This means that the basic environmental criteria for the environmental quality of the building products are the effect on the preservation of bidiversity and the adaption of activities on the natural resources and tolerance of nature.

The environmental impact of building products comes from the use of resources and the induced harmful emissions during the entire life cycle of the building products. This includes the:

- extraction of raw materials and production of products,
- procurement of energy,
- transportation, assembling and building,
- use and maintenance and
- demolition and final disposal or recycling.

However, the environmental assessment of building products is not limited to the application of LCA tools. It also requires the development of these methodologies especially with regard to the emphasised importance of service period of building products.

The environmental quality of building products does not only depend on the material and energy flows connected to the production and use of the product. It is also a function of the service life length and in some cases also of the effect of the product o the environmental burdens of the house, for example through the thermal properties of the product.

2 Environmental requirements stated by the client

The basic requirements for sustainable construction include:

- the ability of the client to present environmental requirements
- the readiness of the designer to produce a solution corresponding to the environmental requirements and
- the willingness and the ability of the producer to declare the environmental properties of products.

The environmental quality of a building depends on the material and energy flows during its entire lifetime. Thus the environmental requirements presented by the client should deal with:

- the quantity and quality of energy used for heating,
- the service life and flexibility of the building and
- the environmental quality of building products.

The majority of environmental burdens come from the energy use for heating of building spaces and water during the service life of the building. Based on this, the most important environmental property of a house is the U-value of the building envelope ad the other properties that affect the energy consumption during service life. However, if we look at the matter not only from the product-life-cycle point of view but also consider the significance of the requirements with regard to the producers of buildings and building products, it is also the environmental quality of the products that is of concerns. It is the requirements concerning the more environmental technical installation roducts and the environmental quality of other building products that sends a message to the building industry that environmental issues should be taken into account.

In order to present environmental requirements for buildings we need environmental analyses of buildings in order to focus the requirements. These analyses have been performed in several research projects. At this moment the target values, typical values or the range of typical values concerning the energy and material flows of buildings are eeded. The environmental superiority can only be assessed compared to reference values. In connection with the energy saving building research target, values have been developed with regard to the use of energy, electricity and water during the service lfe of buildings. However, these values should be accompanied with the knowledge concerning the environmental burdens of different kinds of energy sources. On the other hand, we do not have such environmental target values for building elements. In order toproduce' these, we should agree upon the basic principles of Life Cycle Inventories (LCIs) for building products, publish these LCIs and calculate typical environmental values for different kinds of building elements.

3 Building headings, indexing and LCA information

In the building sector, lists of headings for the arrangement and presentation of information used in design, construction, maintenance and repair of buildings, are agreed upon internationally. The first of such lists is the CIB Master /1/. The master lit order can be used in the preparation of many types of documents. It enables technical documents to be arranged in a consistent form. What headings are used, how much information is placed under a heading, and how far explanatory subheadings are inserted, are matters for authors, taking into account the subject, users'needs, and the purpose of the document. The CIB list (1993) includes 12 master headings, among of which are REQUIREMENTS and PERFORMANCE (behaviour of product or service in use).

Under the heading REQUIREMENTS one can refer to a regulation or other requirement, e.g. technical specification of a public authority, which the product or service is intended to satisfy. In addition, the six essential requirements listed in the Construcion Products Directive (89/106/EEC and 93/68/EEC) are:

1. mechanical resistance and stability,
2. safety in case of fire,
3. hygiene, health and the environment,
4. safety in use,
5. protection against noise and
6. energy economy and heat retention.

The Construction Products Directive states the environmental effects as an essential requirement and it also mentions the life cycle methodology as an assessment method for the environmental effects. Because of its scope it does not deal with the whole ife cycle of construction products, but only products in use.

Under the heading PERFORMANCE, the properties or behaviour in use are listed, such as structural, thermal, acoustic, service life and durability, etc.. In the Finnish version /2/ “environmental” quality is also included. A corresponding definition would also be important in the international Master List. The following addition is suggested /3/:

Environmental Quality:

Information under this heading is relevant to essential requirement 3: Hygiene, health and the environment. Attributes to be considered include: the consumption of energy and raw materials and inducing of harmful emissions during the entire life cycle, potential reuse or recycling, service life and its preconditions, and final disposal.

The building sector makes use of indexing systems of building products as product data is transmitted from producers to designers. With regard to delivery of environmental information of building products to building designers, consistent descriptions fo the products or functional units should be applied or worked out. In the European countries different kinds of indexing systems with regard to building products are used. For example in Finland “CONSTRUCTION 90” indexing is used. This indexing is composed of 10 main classes (such as surface and complementing products, electrical equipment, HVAC equipment, etc.). The main classes are divided into subclasses of three extra levels. The same kinds of systems but not identical systems are also used in other European countries. Many of those, like indexing applied in the Nordic countries and in the UK (Construction Indexing/SFB), are originally based on the SFB (Samarbetskommitte’ för byggfragor) indexing. As environmental information with regard to building products is delivered or as environmental databases of building products are planned, the indexing of the products should ideally be based on the applied systems. This is no problem within one country, but with regard to data transmission in European scale, haronised indexing is required.

4 Ecological design

4.1 Introduction

In the design process the decisive solutions with regard to materials and energy flows during the building lifetime and thus with regard to the environmental quality are /3/

the dimensioning of spaces, the design of flexibility and service life and the dsign of mechanical engineering (HVAC).

An environmental building design process can only be successful if it is provided with adequate design methods and tools. The most important design methods for ecological building design can stated as follows:

- energy saving design,
- service life design and design of flexibility and
- eco-based selection of building products.

In building process all the decisions that deal with the use of land, materials and energy affect the environmental impacts of the designed building. The required tools and systematics for environmental assessment of a building solution can thus be liste as follows:

- assessment of energy consumption (programme)
- the estimation of the energy consumption of building (assessment programme)
- the determination of quantities (calculation programme)
- the environmental profiles of fuels and electricity (data bases)
- the environmental profiles of building products (data bases) and
- a computation programme in order to calculate the environmental burdens of the whole building and its use, based on knowledge concerning the material and energy flows and their environmental profiles.

However, these tools, programmes and databases are not design tools but tools for the assessment and characterisation of the design solution.

4.2 Energy saving design

In order to formulate the requirements concerning the energy consumption and corresponding emissions, the client needs reference or target values on energy consumption of various building types.

A minimum level for energy saving building design is normally regulated by building authorities. However, energy saving design has been an object of very thorough research during the last years and design process should be provided with corresponding design methods and guidelines. Guidelines on energy saving design should be formulated so that one could consider both the energy effects and the corresponding effects on emissions already in preliminay decision making within building planning:

1 Design of building lot
- building location
- type of the building

2 Preliminary design
- architectural design
- preliminary HVAC design

3 Selection of constructions
- walls
- end walls
- party walls
- base floor
- roof constructions

- windows
- doors
- sunshades

4 Selection of HVAC systems

- heating systems
- heat recovery
- heat delivery
- ventilation systems
- water supply and sewage
- electric system
- control systems.

4.3 Connection of service life design to ecological design

Service life design methods have bee studied within RILEM, CIB and IS0 and process descriptions have been published. However, the critical issue today in service life design is the lack of information concerning the service life behaviour of building products.

The principle of service life design is to ensure that the predicted service is longer than the design life. If service life design is understood as a target aiming at the assurance of potential service life and minimising waste of materials, it can be sen as an important tool for ecological building design.

Service life is the period of time after installation during which all essential properties meet or exceed minimum acceptable values, when routinely maintained /4/. The decline in the performance of products with time may originate from physical degradation or obsolescence.

The designer should obtain the service life information from the manufacturer. From the point of view of ecological building design, the service life in years actually is less important than the adequate information concerning the conditions and limitatons for fulfilling of the potential service life (for example, service conditions and maintenance), and also the adequate information concerning recycling (possibilities to recycle and reuse, use as energy source, burning in households, etc.) or final disposal (possible obstacles for disposal on dumping sites, etc.). This information should be delivered from manufactures to designers and further from designrs to the users of buildings. Also the corresponding documents for the information transmissions should be designed and agreed upon.

4.4 Environmental selection of building products

Environmental selection of building products requires instruction files for designers dealing with building products and building elements including ecological parameters. Life Cycle Inventory (LCI) data is especially suitable for product design. However, if it is used for the selection of building products, high quality datais required. In order to use environmental information in a design process, the environmental data of building products must be simplified and unambiguous data. In order to use unambiguous environmental data of building products in design process and whe selecting building products, we should agree upon the declaration formats, the basic assessment methods and rules and the specifying of the data quality. In order to have comparable results we should agree upon the basic assessment principles concerning

- system boundaries,
- allocation rules,
- environmental parameters,
- prediction of service life,
- dealing with energy,
- consideration of effects on the energy saving of buildings,
- data coverage,
- description of data quality and
- impact assessment and weighting of results.

We should also agree upon the environmental parameters to be taken into account, such as:

- energy content,
- raw materials,
- emissions and
- other properties, such as durability and recycling.

Also the delivery and updating of data should be organised. The problems concerning this become considerably more important when building products are exported and imported.

By the initiation of the Finnish Building Industry Association (RTT) , a research project was carried out that aimed at the formulation of environmental declaration of building products /5/. Attention was paid to the “life cycle responsibility” of the producers with respect to the products. That means that the environmental declaration of building products should not only include the ecological parameters concerning the production stage, but also guidance given by the producer concerning the environmentally harmless use, demolishing, recycling and final disposal of the products. The project report includes the environmenal profiles of basic building materials produced in Finland /5/. The assessment is based on the material and energy flows reported by the producers.

The development of the environmental declarations for building materials is going on at the Building Information Institute together with VTT. The aim is to establish and publish the environmental declarations for 50 building products in Finland durig the next year. Nordic cooperation with regard to the environmental declaration of building products has started.

Another research project has also- started in Finland studying the environmental quality of technical installations and systems in buildings. The project aims at the development of the environmental declarations of building products so that the propeties of the technical installations and systems and their effect on the energy saving during the building life time can be taken into account.

Summary

The environmental quality of buildings depends in essence on the material and energy flows during its life time. This means that the environmental requirements stated by the client should concern the quantity and quality of energy used for heating and ventilation, the service life and flexibility of the building and the environmental quality of building proucts.

An environmental building design process can only be successful, if it is provided with adequate design methods and tools. The most important design methods for ecological building design are energy saving design, service life design and design of fexibility and eco-based selection of building products.

In addition, if the compliance of the building solution with the stated environmental requirements could be verified, it would help marketing new environmental and technical solutions - not as solutions as such, but as solutions enabling certain environmental properties of buildings.

Abstract
This paper presents further steps in the development of reliability-based approaches for the durability design and service life prediction of building components which integrate the requirements of safety, serviceability and durability. In general, the load and resistance should be modelled as stochastic processes and the resulting durability problem is formulated in a time-dependent probabilistic format. Using the classical reliability approach, the resulting time-dependent reliability problem is transformed into a time-independent reliability problem through the adoption of an extreme-value probability distribution for the maximum lifetime load. The resistance degradation and its variability are included in the model, and the probabilistic design problem is transformed into a deterministic (or semi-probabilistic) problem using the first-order second moment theory. This semi-probabilistic integrated approach to durability design and prediction overcomes the shortcomings of the empirical factorial approach and the complexities of a fully time-dependent probabilistic method. An alternative approach using stochastic process theory is proposed to formulate the durability design problem as a crossing problem for which the probability of failure within the component lifetime is obtained from the first-passage probability for the stochastic process. In addition, a service life-based formulation of the durability design and prediction problems is presented in order to illustrate its equivalence with the performance-based formulation.
It is shown that in principle the same probabilistic approaches used for the development of structural design approaches for safety and serviceability are also applicable for durability design. The durability design objective is to keep the probability of failure within a specified time interval (or service life) below a certain threshold value that depends on the consequences of failure of the component or system. It is expected that in the near future, further simplifications of the proposed approaches will be made leading to practical and reliability-based methods to durability design or service life prediction. These simplified methods will be implemented in the design of durable new structures and optimal life-cycle maintenance management of existing structures.
Keywords: Crossing problem, deterioration, durability, performance, random variable, semi-probabilistic, service life, stochastic process, time-dependent reliability.

1. Introduction

The existing construction practice based on minimum initial cost and the lack of practical and reliable methods for service life prediction and life-cycle maintenance management have contributed to the significant backlog of deficient infrastructures and have inhibited any competition based on life-cycle cost optimization. This situation is worsened by the limited funds allocated for the maintenance and rehabilitation of the various infrastructure systems. Furthermore, the current design philosophy for safety and serviceability adopted by major design codes may be inadequate in certain conditions (e.g. aggressive environments) because of the assumption of the time-invariance of the resistance. Moreover, the existing qualitative ("deemed-to-satisfy") code requirements for durability are empirical with no explicit formulation in terms of performance or intended service life.

In general, the resistance of a building component is a random variable that decreases over time, which in turn, reduces the reliability and may accelerate the risk of failure and shortens its service life. In addition, the load (or action) is also a time-dependent quantity that is also random in both magnitude and time of occurrence. Therefore, a realistic modelling of both the resistance and load, and a solution to the corresponding time-dependent reliability problem require the use of stochastic processes theory. In a second stage, this time-dependent reliability problem should be simplified into a time-independent probabilistic problem. It should be emphasized that a probabilistic modelling of the durability problem will enable a rational determination of the service life or "end of life" of a component by considering both the service and economic life through life-cycle cost optimization including the costs of inspection, maintenance, repair, failure and replacement. In the last stage of the development, the approach for durability design and prediction should be time-independent and deterministic (or semi-probabilistic), in which the randomness and time-dependence of the load and resistance have been considered through appropriate probability distributions and partial safety factors (Fig. 1).

The development and implementation of such a practical approach to durability design and prediction will require calibration through extensive performance and service life data in various environments for different building components. For design and maintenance purposes, the objective is to keep the probability of failure within a given time interval (e.g. service life) to an acceptable level that depends on the consequences of failure of the building component or system. The durability design and prediction problems can be solved using either the component performance or component service life formats.

2. Existing approaches to service life prediction and durability design,

Despite the fact that thousands of papers related to material and component durability have been published over the past two decades, they had a negligible impact on the development of an effective approach for durability design [1]. Three guides for the durability of buildings have been proposed in Britain [2], Japan [3] and Canada [4]. The British and Canadian guides address qualitatively the issues of durability of structural and building envelope elements throughout the building life-cycle, while the Japanese guide (AIJ) proposes a factor-based or *"factorial"* approach for the prediction of the service life of building components. However, the use of these guides is very limited given the lack of reliable quantitative durability design and prediction procedures, in addition, no proof of the correctness of these guides has been given yet. Further, it can be added that these methods are not fully developed at a practical level. The designer/engineer using these methods may be liable for the damage due to the durability design made on the basis of these guides. For this reason, the BS 7543 is hardly used in Britain, however, the attempt of producing a durability guide is a positive development. The feasibility of the Japanese "AIJ" factorial approach for the prediction of the durability of building components has been examined [5]. The factorial approach is a simplified methodology for service life prediction in which an assumed "standard life" of a building component is adjusted by different factors that take into account the quality of the component and its incorporation within the building [3,5]. An international standard on the "*Design Life of Buildings*" is being developed by ISO/TC59/SC3/WG9, which is intended to provide a methodology for the prediction of the durability of building components based on the factorial approach [5]. In the literature, there is a limited body of work related to the formulation and solution of the time-dependent reliability design problem [8-18].

The prediction of the performance or service life of a building system and its components is a very complex problem as it depends on several factors including the loading, aggressivity of the environment, quality and frequency of maintenance, quality of materials and workmanship. Given the time-dependence and large uncertainties of the performance of building components and the associated risks of failure, it is necessary to adopt a stochastic model and use the stochastic process theory [6] for the prediction of the performance or service life at the first stage (Fig.l). At a later stage, it will be necessary to simplify this time-dependent probabilistic model into a time-independent deterministic model that has been calibrated through extensive performance and service life data (Fig.l). A practical and reliable durability design approach should overcome the shortcomings of the "AIJ" empirical factorial approach and the complexities of a full time-dependent probabilistic approach. It should be similar in format to the existing semi-probabilistic structural design approach adopted by various standards [7], i.e. the basis is probabilistic but the design approach is deterministic.

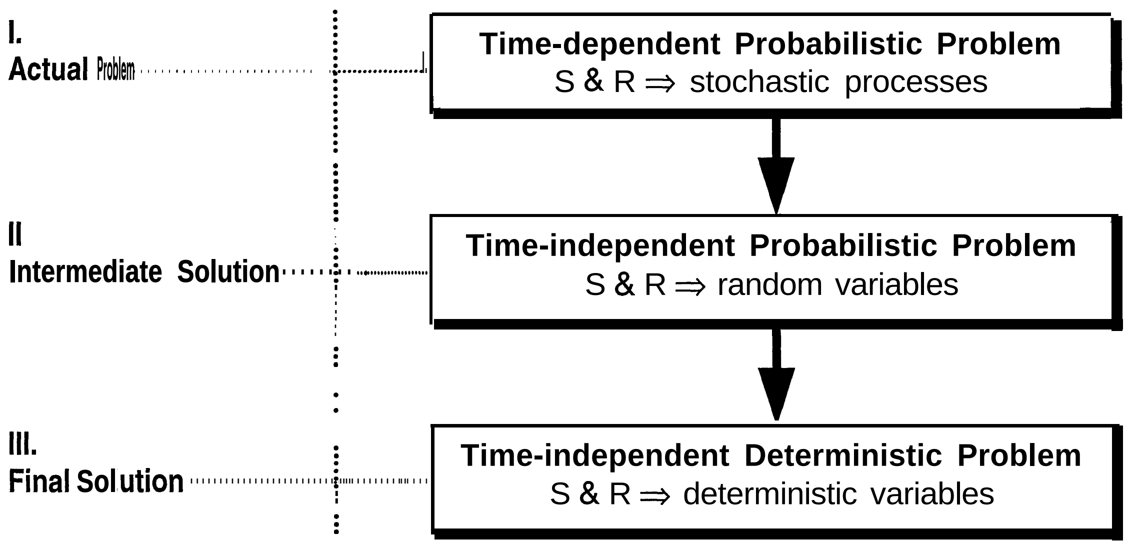

Figure 1. Development process for service-life design and prediction methodology

Such a probabilistic format will enable a rational determination of the "end of *life*" for a system or its components by evaluating both the service life (minimum performance) and economic life through life-cycle cost optimization including the costs of inspection, maintenance and failure. In addition to life cycle costing, building regulations should define the minimum reliability level for durability design based on economic and./ or legal obligations.

3. Time-dependent reliability analysis

Generally, the load (action) S and resistance R (capacity) are time-dependent random variables. Very often the load tends to increase, while the resistance tends to decrease due to deterioration induced by aggressive environmental factors, higher than expected loads or fatigue damage as shown in Fig.2. For the case of reinforced concrete structures, the most damaging environmental factors for concrete are freeze-thaw cycling, sulfate attack, alkali-silicate reactions and temperature, while corrosion due to chloride attack or carbonation is the most damaging factor for steel reinforcement. Therefore, a realistic modelling of the load and resistance requires the use of stochastic processes (Fig.2). The solution of the corresponding time-dependent reliability problem can be derived using stochastic process theory. Models for such processes may include discrete Poisson or Markov processes or continuous Gaussian processes.

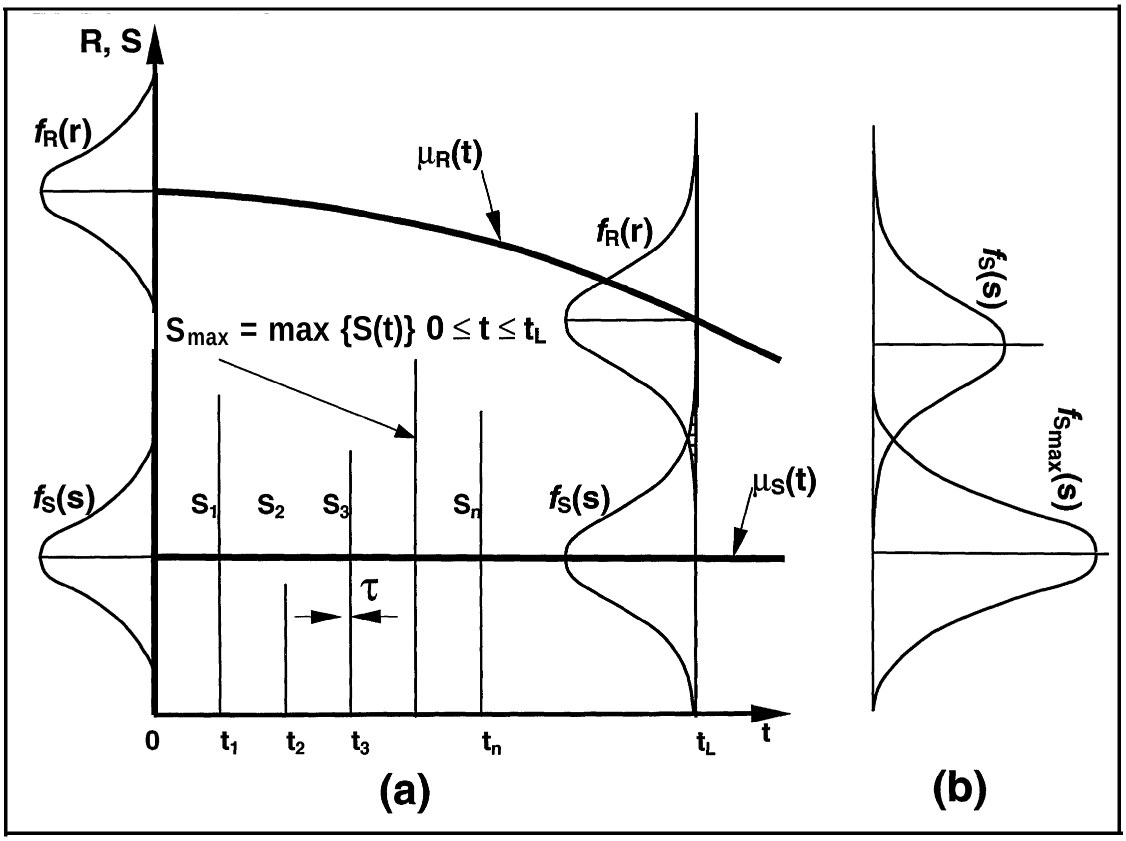

Figure 2: (a) Representation of load and resistance as stochastic processes; (b) Probability density functions of point-in-time and lifetime maximum loads

The *instantaneous probability of failure* $P_f(t)$ is defined as:

$$P_f(t) = P[R(t) \leq S(t)] \quad (1)$$

in which $P_f(t)$, R(t), and S(t) are the instantaneous probability of failure, resistance and load effect at time t, respectively. If the instantaneous probability density functions (pdf) $f_R(r,t)$ and fs(s,t) of the point-in-time resistance R(t) and load S(t), respectively are known, and if R(t) and S(t) are independent, (1) can be calculated from the following convolution integral:

$$P_f(t) = \int_0^\infty F_R(s,t)\, f_S(s,t) ds \quad (2)$$

in which $F_R(s,t)$ is the cumulative distribution function (cdf) of R(t). However, in time-dependent reliability analysis, the quantity of interest is not the above instantaneous probability of failure, but rather the probability of failure over an interval of time [O-t] or $[0\text{-}t_L]$, where t_L may represent the lifetime or service life of the structure. The determination of this probability of failure is not a straightforward task. This probability of failure can be obtained by integrating the above instantaneous probability of failure over the interval $[0\text{-}t_L]$. However, this is not possible owing to the correlation between the instantaneous probability of failure values at times t and $(t+\delta t)$ as $\delta t \rightarrow 0$, which is due to the correlation of the stochastic processes themselves [9].

3.1 Time-dependent reliability analysis using classical reliability approach

The classical reliability approach to this stochastic problem is based on the lifetime maximum load concept. It was adopted in the derivation of the probability based limit states design codes [7]. In this approach, the resistance is assumed time invariant, while the load is considered as a stochastic process. The approach is based on the fact that the structure will not fail, if it survives the maximum load S_{max}, that will occur during the time interval [O-t], which is represented by an extreme-value distribution. If the load history is modelled as a sequence of n identically distributed and statistically independent random variables (Fig.2) with cdf $F_S(s)$, and pdf fs(s), then the cdf and pdf (shown in Fig.2) of the maximum load S_{max} in the interval $[0\text{-}t_L]$ are given by [11]:

$$F_{Smax}(s) = [F_S(s)]^n \quad (3a)$$

$$f_{Smax}(s) = n[F_S(s)]^{n-1} f_S(s) \quad (3b)$$

If the number of loads n is very large, F_{Smax} asymptotically approaches an extreme-value distribution (e.g. Type I or II asymptotic forms). Therefore, the probability of failure within the interval $[0\text{-}t_L]$ denoted $P_f[0\text{-}t_L]$ is given by [11]:

$$P_f[0\text{-}t_L] = \int_0^\infty [1 - F_{Smax}(r)]\, f_R(r) dr = \int_0^\infty F_R(s) f_{Smax}(s) ds \quad (4)$$

The above integral does not contain the factor time or the number of loads n which have been included in the derivation of the distribution of the lifetime maximum load S_{max}. Hence, the original time-dependent reliability problem has been transformed into a much simpler time-independent reliability problem through the use of an extreme-value representation of the probability distribution of the maximum load that will occur during the structure lifetime. The objective in design is to keep the above probability of failure during the service life below some maximum acceptable threshold value (P_{fmax}). The value of P_{fmax} depends on several factors related to the consequences of failure such as cost of repair or replacement, risk of loss of life, importance of the component in the system, and type of failure. To simplify the computation of the above limit states probabilities in Eq. (4), first-order, second moment reliability analysis methods referred to as FOSM or FORM have been developed since the late 1960's [7,8,9,10]. The FOSM methods were used to derive the load and resistance safety factors for limit-states design of major structural design codes in North America and Western Europe. Generally, in structural design, the pdf of resistance is often considered as lognormal, while that of the load is taken as an extreme-value Type I. However, to illustrate the practicality of the FOSM approach, both R and S_{max} are assumed as having lognormal distributions. Therefore, the overall safety factor R/S_{max} has also a lognormal distribution and the limit state probability can be expressed as:

$$P_f[0\text{-}\ t_L] = P\ [R/\ S_{max} < 1] = P\ [\ln R/\ S_{max} < 0] \tag{5a}$$

$$P_f[0\text{-}\ t_L] = \Phi\ [\ln\ (\mu_R/\mu_{Smax}) / \sqrt{(V_R{}^2 + V_{Smax}{}^2)}\ ] \leq P_{fmax} = \Phi(-\beta) \tag{5b}$$

in which μ_R, μ_{Smax} are the mean values of R and S_{max}, respectively; V_R, V_{Smax} are the coefficients of variation of R and S_{max}, respectively; Φ is the standard normal distribution function; and β is the so-called reliability index. The above approximation is valid if the coefficients of variation of R and S_{max} are less than 0.3, which is a relatively low value for most practical problems in building design. The above equation can be transformed to yield:

$$e^{-\beta\alpha V_D}\ \mu_R \geq (e^{\beta\alpha V_{Smax}})\ \mu_{Smax} \tag{6a}$$

or $$\phi\ \mu_R\ \geq \gamma\ \mu_{Smax} \tag{6b}$$

The above equation is similar to the current standard equations for limit states design, where $\phi\ (=e^{-\beta\alpha V_R} < 1)$ is the understrength safety factor and ($\gamma = e^{\beta\alpha V_{Smax}} > 1$) is the overload safety factor and a is a separation function [9]. Equation (6b) represents the current semi-probabilistic load and resistance factor design (LRFD) method adopted by the structural concrete and steel design codes. This design approach is very practical because it is totally deterministic, and reliable, since the partial safety factors have been derived probabilistically by taking into account the uncertainties in the resistance and load and the consequences of failure. For the time-dependent resistance problem, where the resistance decreases with time due to material degradation, the probability distribution of interest for the resistance should be the *lifetime minimum value.* However, it is highly unlikely that the occurrence of the lifetime maximum load will coincide with the lifetime minimum resistance [9]. Within the above framework, it may be possible to model the uncertainties related to the lifetime resistance that will account for the resistance reduction with time due to material degradation. Assume that the lifetime resistance R can be expressed as follows:

$$R = D\ R_o \tag{7}$$

in which R= lifetime resistance; D = degradation factor due to aggressive environmental factors (independent of the load history); and R_o= initial resistance of the non-deteriorated component. If we assume that both R_o and D are lognormally distributed, then, R is also lognormally distributed, with a mean value μ_R and a coefficient of variation V_R given by:

$$\mu_R = \mu_D \mu_{Ro} \quad (8a)$$

$$V_R = \sqrt{V_D^2 + V_{Ro}^2} \quad (8b)$$

in which μ_D (≤ 1) is the mean deterioration factor; μ_{Ro} is the mean initial resistance; V_D V_{Ro} are the corresponding coefficients of variation. The above equations show that the mean lifetime resistance is lower than the initial value, while the uncertainty associated with it increases due to the added variability of the deterioration factor. Using Eqs. (5) and (6), and assuming the same α factor, the following design equation can be derived:

$$(e^{-\beta\alpha^2 V_D}) \, \mu_D \times (e^{-\beta\alpha^2 V_{Ro}}) \, \mu_{Ro} \geq (e^{\beta\alpha V_{Smax}}) \, \mu_{Smax} \quad (9a)$$

or $$\psi \, \mu_D \times \phi \, \mu_{Ro} \geq \gamma \, \mu_{Smax} \quad (9b)$$

in which $\psi \, [= e^{-\beta\alpha^2 V_D} < 1]$ = partial safety factor that accounts for the uncertainties in the resistance degradation due to environmental factors; $\phi \, [= e^{-\beta\alpha^2 V_{Ro}} < 1]$ = initial resistance understrength safety factor; and $\gamma \, [= e^{\beta\alpha V_{Smax}} > 1]$ =overload safety factor. Reliable data on the degradation of the resistance and its variability in different environments are required to derive reliable values for the above safety factors. The above design equation is similar in format to the current standard design expressed in Eq. (6). This is a semi-probabilistic design approach that integrates the requirements of safety (or serviceability) and durability.

3.2 Time-dependent reliability analysis using stochastic process theory

In this section, an alternative reliability-based approach to the durability design and prediction problems is proposed using stochastic process theory. As mentioned earlier, models of stochastic processes include discrete Poisson, Markov processes and continuous Gaussian processes. A problem of great importance in time-dependent reliability analysis using stochastic process theory is that of the *first crossing* by a stochastic process of a given barrier or curve. The stochastic process may represent a load S(t), and the curve may represent a strength R(t) as in Fig.2. This constitutes a so-called *"crossing problem"* [9]. The time at which S(t) crosses the barrier R(t) for the first time is the *time to failure* and is a random variable. The probability that R(t) is less than S(t) occurs within [O-t] is called the *"first passage probability"* [8,9]. The first passage probability is equivalent to the probability of failure within [O-t] expressed by Eq. (4). As pointed out in the previous section, the solution of the crossing problem is rather difficult, because the complete history of the stochastic processes within [O-t] should be considered. If the number of loads N(t) within the interval [O-t] is a random variable described by a Poisson counting process, then:

$$P[N(t)=n] = (\nu t)^n e^{-\nu t}/n! \quad (10)$$

in which ν is the intensity of the Poisson process (or mean of occurrence of the loads). The waiting time t_k for the occurrence of the k^{th} load is a random variable and is gamma distributed [8]. Therefore, the cdf $F_{tn}(t)$ for the time t_n which must elapse before the occurrence of the nth load is obtained as follows:

$$F_{tn}(t) = P\,[t_n \leq t] = 1 - P\,[t_n > t] = 1 - P\,[N(t) < n] = 1 - \sum_{k=0}^{n-1} (\nu t)^k e^{-\nu t}/k! \quad (11)$$

Of particular interest is the waiting time t_1 before the occurrence of the first load within [O-t], which is exponentially distributed and is given by:

$$F_{t1}(t) = P\,[t_1 \le t] = 1 - e^{-\nu t} \qquad (12)$$

The above equation represents the *first passage probability* [9]. If we consider a Poisson spike process as shown in Fig.2, which is defined by its intensity v (constant) and rectangular pulses of magnitude S_k and duration τ. The load S_k is a random variable independent between pulses with a cdf $F_S(s)$. The first passage probability can be obtained for the limit case as $\tau \to 0$. The probability of an upcrossing $\nu_R^+(t)$ of level R(t) is given by [9]:

$$\nu_R^+(t) = \lim_{\Delta t \to 0} \left[P\{ [S(t) \le R(t)] \cap [S(t+At) > R(t)] \}\nu \right] / At \qquad (13a)$$

$$\nu_R^+(t) = F_S[R(t)]\{1 - F_S[R(t)]\}\,\nu \qquad (13b)$$

The above equation expresses the intensity of a Poisson process and is referred to as *"upcrossing rate"* [9]. If R(t) is large, the upcrossing rate becomes:

$$\nu_R^+(t) = \{1 - F_S[R(t)]\}\,\nu \qquad (13c)$$

Using Eq. (12), the first passage probability or the probability of failure within $[0\text{-}t_L]$ is:

$$P_f[0\text{-}t_L] = 1 - \exp\,[-\nu_R^+(t)\,t_L] = 1 - \exp\left[-\{1 - F_S[R(t)]\}\nu t_L\right] \qquad (14)$$

Thus, the probability of failure is a function of the lifetime or service life (t_L) of the structure. If v is a function of time v(t), then νt_L should be replaced in Eq. (14) by $\int \nu(\tau)d\tau$. If the resistance is assumed to deteriorate with time according to Eq. (7), and if the degradation function D=D(t) is assumed independent of the load history (which is the case of deterioration due to environmental factors), and R_o is a random variable with a pdf $f_{Ro}(r)$, then Eq. (14) becomes [11,141:

$$P_f[0\text{-}t_L] = 1 - \int_0^\infty \exp\left[-\nu\{t_L - \int_0^{t_r} F_S[D(t)R_o]dt\}\right] f_{Ro}(r)dr \qquad (15)$$

An approach for durability design and maintenance is obtained by limiting the above probability to an allowable level that depends on the consequences of failure. The implementation of the above requires further simplifications to derive a practical design and prediction procedure similar to the semi-probabilistic approach in section 3.1.

3.3 Performance- vs. service life -based durability design and prediction

The probability of failure in the time interval [O-t], $P_f[0\text{-}t]$ defined above is equivalent to the event: the service life T (or t_L) is less than t [11,12,13], i.e.:

$$P_f[0\text{-}t] = P\{ R(t) \le S(t) \text{ in } [O\text{-}t]\} = P\,(T \le t) = F_T(t) \qquad (16)$$

in which the service life T is a random variable, and F_T is the corresponding cumulative distribution function. The probability density function of T, $f_T(t)$, also called the unconditional failure rate function [8,12], is given by:

$$f_T(t) = dF_T(t)/dt \qquad (17a)$$

thus $f_T(t)dt = P\,(t < T \le t+dt) = P\{ R < S \text{ in } [t, t+dt] \text{ and } R > S \text{ in } [O\text{-}t]\}$ (17b)

The hazard or conditional failure rate function $h_T(t)$, is defined as the probability of failure per unit time conditional upon survival to time t, i.e.:

$$h_T(t)dt = P\ (\ t < T \leq t{+}dt\ \mid T > t) = P\{R < S \text{ in } [t, t{+}dt] \mid R > S \text{ in } [0\text{-}t]\} \quad (18a)$$

thus: $$h_T(t) = f_T(t)/[\,1\text{-}FT(t)] = d\{\ln[1 - FT(t)]\}/dt \quad (18b)$$

For low values of FT(t) (in the order of 10^{-4}), $f_T(t)$ and $h_T(t)$ can be made equal. Using (17a) and (Mb), the following relationships are obtained:

$$FT(t) = 1 - \exp\left[-\int_0^t h_T(\tau)\, d\tau\right] \quad (19a)$$

and $$f_T(t) = h_T(t)\ \exp\left[-\int_0^t h_T(\tau)\, d\tau\right] \quad (19b)$$

The above equations show the equivalence of the performance-based and service life-based formats for the formulation of the durability design and service life prediction problems. The application of either of the two formats will yield the same solution. If failures occur purely at random, the hazard function is constant and represents an exponential distribution. However, if the failure is due to deterioration and wearing out, the hazard function increases with time, and if $h_T(t)$ increases with time as follows:

$$h_T(t) = (\beta/\alpha)(t/\alpha)^{\beta-1} \quad (20a)$$

then $$FT(t) = P_f\,[O\text{-}t] = 1 - \exp[-(t/\alpha)^{\beta}] \quad (20b)$$

which represents a Weibull distribution, where α and β are the scale and shape parameters, respectively. As discussed earlier, the derivation of a reliable design is based on limiting the above lifetime probability of failure to some acceptable threshold value that depends on the consequences of failure.

4. Conclusions

Reliability-based approaches for durability design and prediction of building components are proposed. The durability design and prediction of service life of building components has been formulated as a time-dependent reliability problem. The time-dependent reliability problem has been simplified into a time-independent reliability problem using an extreme-value probability distribution for the maximum lifetime load. The resistance degradation and its variability are included in the model, and the probabilistic design problem is then transformed into a deterministic (or semi-probabilistic) design problem using the first-order second moment theory. This semi-probabilistic integrated approach to durability design overcomes the shortcomings of the empirical factorial approach and the complexities of a fully probabilistic design method. A second approach based on stochastic process theory is developed, in which the durability design or prediction problem is formulated as a crossing problem, for which the lifetime probability of failure is obtained from the first passage probability. Durability design and service life prediction are based on keeping the lifetime probability of failure below a certain target value that depends on the consequences of failure of the component or system. The proposed approaches constitute further steps towards reliability-based durability design and prediction.

IRIS, National Research Council of Italy, Bari, Italy

Abstract

The growing understanding regarding limitations of natural resources together with a better knowledge of relations between building, urban and environmental quality provides for new initiatives to improve the building process. In particular, these new initiatives are focusing on developing concepts and proper approaches in support of sustainable development.

To attain this goal, the roles and tasks of the various operators, i.e. designers, constructors, managers, surveyors, etc., must be revised and as well general principles must be translated into specific practical instructions.

The current research focus consists of providing guidelines, suggestions and case studies for the planning, design, construction and the selection, use and re-use of materials towards achieving sustainability in construction.

In order to single out the best design decisions to attain sustainability requirements, the creation of a database to store solutions applied in different contexts would serve many useful purposes.

In this framework the Internet plays a significant role as a "mine" of information. However, with the rapidly growing number of Web sites, it can be very difficult to locate what it is needed; on one hand time is wasted in unproductive navigation and on the other hand, a lack of transfer and communication of available data there still exists.

A productive search needs good planning and knowledge of the proper tools to use. The paper presents the first results achieved in information retrieval on the Web, using intelligent agents and specifically related' to sustainable construction. The results are available on the web site "Sustainable Building Resource" (http://area.ba.cnr.it/iris/sustain) a "clearinghouse" for information, applied research, and Internet links about basic principles of sustainable design.

Keywords: Sustainable building, Building Design, Design for Durability, Internet

1 Introduction

The growing interest in sustainability is widely highlighted by various definitions that appear in the technical literature. The understanding of what the sustainable development is and of how it can be pursued in the building design practice necessarily requires the translation of the various general principles already set in more fields (economics, energy, industry, politics, etc.) into specific goals and operative criteria with reference to the roles the different categories of operators have to carry out.

In order to single out the best design decisions towards the sustainability requirement, the creation of a database in which to store examples of solutions already applied by designers in different contexts would serve many useful purposes.

Very useful as well seems to be the systematic analysis and optimization of the whole buildings' life-cycle taking into the due consideration the materials used in the construction, the disposal of their debris, the management, maintenance and the final destination of the building at the end of its service life.

The effective management and circulation of such data demands innovative information technologies; consequently, the research here presented has been focused on the Internet both as a mine of information and as an ideal and very accessible channel for communication and information exchange.

2 The Survey on the Internet

The rapidly increasing use of the Internet is creating a more and more complex computing environment: sources of information are augmenting together with their content; very many news (study and research reports, articles, etc.) are available but the Internet users have to figure out how to find them.

Surfing the Internet is a technique equivalent to looking for information in a library without using the catalog. You can use this technique effectively only when you've found a group of pages that are related to the topic you are researching. The WWW Virtual library (http://vlib.stanford.edu/Overview.html) is a noticeable starting point. Once you have found a contents page related to your topic, you may wish to follow each of the links to each of the pages in search of valuable information.

Other sources of information are newsgroups (collections of discussions related to certain topics). To find the names of relevant newsgroups, you can visit http://www.tile.net/ or http://www.dejanews.com/home_bg.shtml.

Search Engines are usually the quickest way to locate information on the Internet. These engines are free to use, because they are supported by advertisers who post banners on the search result pages. Most of such engines use a complex algorithm or set of calculations to analyze the web pages. The results they deliver depend on what the engine "thinks" it is the most relevant. However even with a tightly focused search statement it is possible to get hundreds of documents in answer. The available search engines differ for the type of search they can perform. The consequent substantial difference in their search results marks out the need to use all the available engines.

So we are testing the use of search agents, an emerging technology that help to do things like find and filter information, customize views of information, automate the information research work. Unlike the search tools, the agents are software applications to buy, install, and run from the desktop. It is possible to enter the search query offline, and then the agent runs it through anywhere from half a dozen to 30 or more individual search engines at a time. Instead to visit each search site in turn, the agent query the resources, collect the responses and present them on a single page (Figure 1).

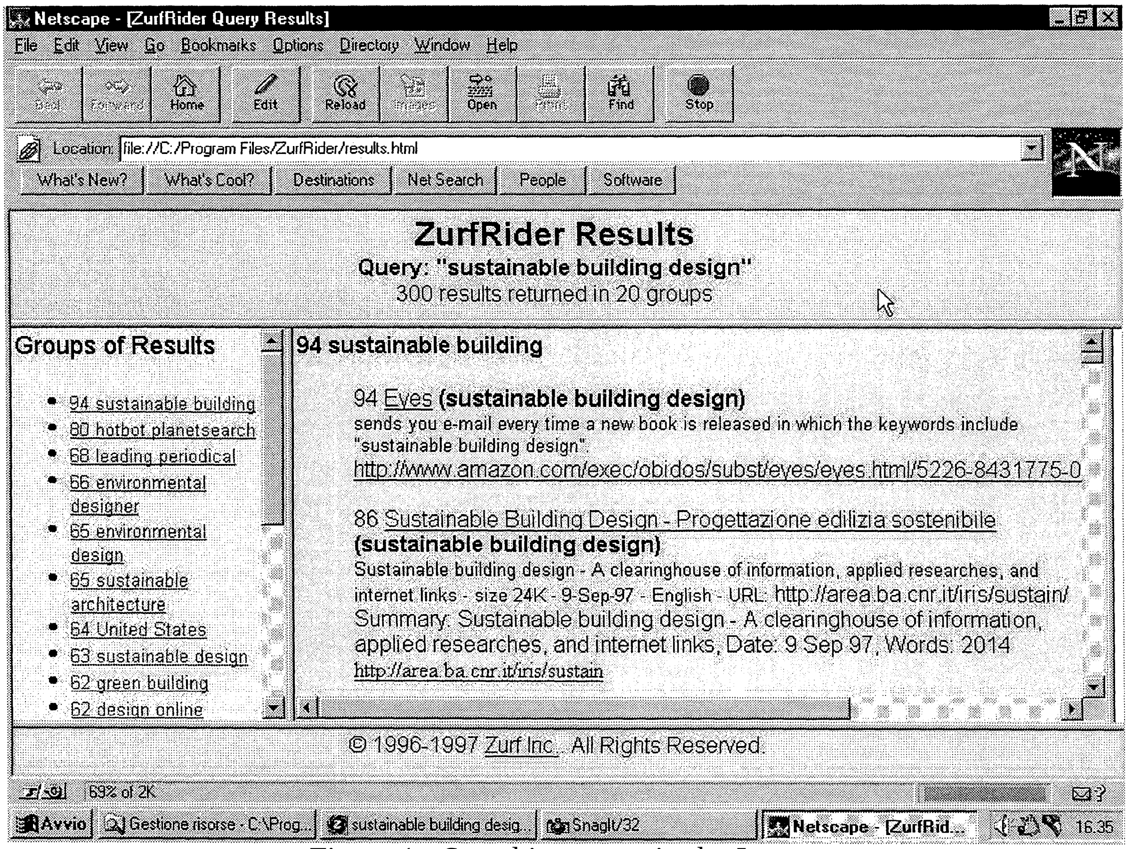

Figure 1 - Searching agent in the Internet

3 Sustainable Design and Construction

Our survey on the Internet shows that not all countries share the same views about sustainable building, and that the amount of attention to the various topics varies greatly (Table 1). For this reason the different approaches have been grouped and classified on the basis of their essential features, as a necessary first step towards the building of the database [1]. A first analysis of the search results shows that building design can provide good contributions to the sustainability in the following ways:

- meeting lower energy requirements;
- bringing down the life-cycle costs of the components to be used;
- making a wide use of renewable resources and materials;
- adopting technologies for passive energy behaviour;
- combining a wider use of renewable resources and a more efficient use of the non-renewable ones, probably the best way to pursue at the moment;
- using appropriate technologies;
- involving all the categories of building operators in the goal.

Sustainable architecture Environmental architecture	Building design strategies represent only one of the steps towards the building of a sustainable community. In the most radical approaches is exclusively allowed the use of renewable resources and passive technology (www.arch.wsu.edu/information/sustain/home.html))
Sustainable Building Sustainable Construction Environmental building	The main goal is the minimization of building environmental impact by the identification and the choice of adequate technologies. The building is analyzed during its life cycle: from the extraction of raw materials, to the phase of construction and demolition (sustbuild.chalmers.se/progplan.htm) The optimization of the building environmental performances can be gained utilizing renewable resources or utilizing efficiently the non-renewable ones. At the same time the design process requires the participation of all actors involved (www.bmg.kt.se/www/bmg/baoh/eaob/htm).
Sustainable design Sustainable building design	In this approach sustainability is considered not only as a technological problem, but also as a requirement of classical design principles and concepts such as standard and final users. Refusing conceptual generalization the context becomes the real base for defining design criteria (greenbuilding.ca/setpoint.html).
Green design Green building	The reference point is the minimization of the environmental impact linked to building construction and rehabilitation. Particular attention is paid to the use of natural resources. Green can mean both utilizing recycled materials or efficient energy use or efficient use of resources and as a process. In this case, it starts with the risk detection linked to the design and the selection of those that must be minimized. Then the proposed design alternatives are selected considering, among evaluation criteria, the client economic requirements (greenbuilding.ca/abn12epg.html)
Built environment Environnement construit	Buildings are studied from a multidisciplinary perspective referring to the building technologies or to the relationships between building and environmental components such as the social and the economical ones: -performance systems which meet the environmental or users requirements (envist .cmu.edu/research/built.html); -housing typological transformations in a specific social context (dawww.epfl.ch/info/recherche/irec/textel.html)
Architettura bioecologica Bioarchitettura	The bioarchitecture can be seen as the cultural root of the ecological study of building and environment relations the objectives is to plan in order not to alter the ecological equilibrium of the place that is taken as an essential reference in the design (www.vol.it/ABRUZZO/BIOARCHITETTURA/leggi.html)
Appropriate Technologies	Here the principal commitment consists in promoting the use of appropriate technologies, above all in developing countries where the main characteristics are in the course of being identified (obelix.polito.it/forum)
Earth architecture Bioconstruction	Building system utilizing earth and renewable materials (www.ran.org/ran/ran _campaigns/rain _wood/wood con/earth_arc.html)

Table 1 - Searching in the Internet by keywords

Although a considerable amount of energy can be saved by resorting to innovative solutions (e.g. bioclimatic architecture, advanced building materials) at present it appears to be more appropriate to focus on strategies not interfering with traditional building methods [2].

In this Design for Durability, the new discipline that deals with the optimization and innovation of the design choices to meet service life requirements can provide great contribution to sustainability by a more efficient use of the traditional building materials and a proper use of innovative, renewable materials.

The building design can in fact incorporate sustainability principles effectively and economically by adopting solutions suitable to reasonably produce appreciable benefits. In table 2 a list of sustainability goals associated to lists of relevant solutions already tested in building works carried out in different countries is presented [3]. This table highlights a significant part of the concrete and simple possibilities to reduce nowadays the impact of buildings still to be designed. It can also stimulate further research of new solutions with higher sustainability by designers.

	GOALS	POSSIBLE SOLUTIONS
DESIGN	reduction of non-renewable materials consumption	reduction of «virgin» wood consumption (reuse of wood and lumber) materials life-cycle analysis[a]
	reduction of non-renewable energy consumption	use of materials with low embodied energy use of simple assemblage systems use of «passive» solar design technologies [b] collection and filtering of rainwater for domestic use [c] collection and reuse of gray water for irrigation’“’ collection and treatment of sanitary wastes for the production of methane gas and fertilizers [c]
	reduction of construction costs	use of locally available materials (reduction of transportation costs) use of «humble» building techniques (reduction of costs)
	minimization of impacts on air	use of non-polluting materials
	improvement of the human well-being in building	use of low voltage current generation systems (photovoltaic cells) «active» use of vegetation [d]
CONSTRUCTION	reduction of construction waste production	ordering of products with minimal packaging selling back of exceeding materials to producers ordering of products in fixed dimensions reuse of moulds (and reselling of scrap wood) reuse of excavated soil
	reduction of demolition waste production	pre-selection and registration of waste materials (previous evaluation of quality and quantity of materials) «in-situ» separation of waste materials
	minimization of impacts on soil	previous specification of areas for the storage of materials minimization of deforestation minimization of soil disturbance caused by excavation minimization of access roads construction
	protection of aquifer system	prohibition of the collection of rainwater
	minimization of impacts on watercourses	deviation of waste water and collection into absorption trenches use of rainwater
	minimization of impacts on air	use of non-polluting materials

(a) the development of models for life-cycle evaluation is one of the objectives of the ((Waste and Recycling - Cleaner Technology 1993-97» Plan (Danish Minister of Environment)
(b) solar panels, photovoltaic cells, natural ventilation, materials with great thermic inertia
(c) goals accomplished by a foundation system consisting of separate interlocking lightweight concrete containing the processing and storage equipment necessary to supply the utility necessities
(d) employment of the electrochemical properties of plants to improve air quality.

Table 2 - Possible solutions to incorporate sustainability in building

The economic limits are typically one of the main concerns in the design stage together with the reduction of the consumption of nonrenewable materials and energy. The latter is also the ultimate goal of several national laws and of the E.U. directives as well. In the construction stage, sustainability can be pursued securing appropriate maintenance and protection from the deterioration agents of the exposure environment.

Also the re-use and the recycle of building materials allows the cut down of the consumption of non-renewable materials and energy and the consequent reductions of the materials' disposal and of the relevant costs.

Information, applied research, and Internet links on the basic principles of sustainable design are available on the web site "Sustainable Building Resource" (figure 2). The site aims also to promote an Internet ring to share knowledge and information about sustainable building. People interested in this campaign are invited to insert a special banner in their web page (figure 3), in order to put a link with the web pages that have been marked in "Sustainable Building Resource" (the banner can be copied directly at http://area.ba.cnr.it/iris/sustain/ring.htm). Site to site links, in fact, increases the probability that a web site can be found; it may bring in much more meaningful traffic than indexing the site by search engines.

4 Sustainability and Design for Durability

Sustainability has to be intended as the final goal of the work in the field of durability and therefore a key issue of Design for Durability, the new discipline that deals with the optimization and innovation of the design choices to meet service life requirements.

A good practice of the planning, design and management of buildings' service life can in fact guarantee - and has to - a significant saving of natural and not renewable resources.

Design for Durability can effectively incorporate sustainability in very many ways. Looking for instance at the selection and use of materials:

- improvement, where this is globally advantageous (coherence with architecture, design service life, transportation distance, etc.) of the use of renewable materials;
- improvement of the engineering of the building design e.g. increase of the dismountability and recyclability of building elements; reduction (i.e. optimization) of the quantities of the not renewable materials (nowadays with a better design: shapes, thickness, mix-design, reinforcements, etc. and execution it is possible to realize concrete structures 20 - 30 % lighter but with the same structural performances of the more traditional and heavy; obviously it requires to invest much more on the detailed design, on the quality of materials and on the practice accuracy);
- organization of stocks and databanks for dismantled materials;
- rationalization of the transportation of building materials;
- characterization of the functional characteristics of building materials (for service life design) together with information on the impact of their production (quantity of energy, recycled parts, recyclability, etc.).

As to the improvement of the building performances which can contribute to a better environment:

- less heating and especially less air conditioning to get the same comfort conditions;
- better natural lighting;
- more vegetation;
- less defects;
- more protection and better conservation of the parts which are more stressed: roofs, claddings, etc.

Looking at the building operators:

- better education of all the practitioners and building operators with regard to the planning, design and management of buildings' service life and to the building's environmental impact.

Many other items can be added and developed in the next future still remaining in the field of building service life planning, design and management.

5 Conclusions

Building design can provide good contributions to the sustainability of the whole building process. Building design can incorporate sustainability principles effectively and economically by adopting solutions suitable to reasonably produce appreciable benefits.

The Internet plays a significant role, as a mine of information and as a great platform for electronic publishing useful to building designers as well.

By the use of search agents to find and filter the technical information available on the Internet it is easier and takes less time. This has been tested in a research sponsored by the Italian National Research Council as illustrated in the paper.

Also Design for Durability, the new discipline that deals with the optimization and innovation of the design choices to meet service life requirements, can provide great contribution to sustainability by helping the designers to make a more efficient use of the traditional building materials and a proper use of the innovative, renewable materials.

Degradation of Portland cement and Portland ash cement concrete

S. Miletić and M. Ilić
IMS Institute for Materials Testing, Beograd, Yugoslavia
M. Djurić, J. Ranogajec and R. Marinković-Nedučin
Faculty of Technology, Novi Sad, Yugoslavia

Abstract
Degradation of concrete, as well as the related protection and ensuring of concrete structures against aggressive impacts by chemical agents, regardless whether this concerns liquid, gas or even solid phase under certain conditions, represents a complex problem of utmost importance for the economy in general, and especially for building construction and the construction industry.

Japanese researchers Matsufuji, Koyama and Harada proposed an estimation equation which can be used to predict the progress of deterioration for various building materials, and an attempt is made to summarize and classify the deterioration phenomena of each material used in a building. This equation give the degree of degradation in the function of the environment where materials are exposed, properties of deteriorating parts and degradation process time.

This paper shows the utilization of proposed equation with the influence by the composition of Portland cement clinker and of cement, on the degradation of cement stone by the impact of the aggressive environment. Solution of ammonium sulphate was selected as the representative of the aggressive environment, bearing in mind that in nature these ions are frequently encountered in underground waters which come into contact with concrete.

The results showed that there is a considerable compliance of the got results with the proposed model for the prediction of degradation process.
Keywords: Degradation, concrete, Portland cement, fly ash

1 Introduction

Chemical degradation of concrete is the consequence of reactions between the constituents of cement stone, i.e. calcium silicates, calcium aluminates and above all calcium hydroxide, as well as other constituents, with certain substances from water, solutions of soil, gases, vapours, etc. The most important aggressive agents are: SO_4^{2-}, Mg^{2+}, NH_4^+, Cl-, H+, HCO_3^-[1-3].

When we speak about sulphate degradation, we primarily think of the impact by sulphate ions on cement stone. The sulphate ion is the cause of one of the most dangerous corrosions - the corrosion of expansion and swelling - because it causes the occurrence of expansive compounds, first of all ettringite- $C_3A{\cdot}3CaSO_4{\cdot}32H_2O$, in the shape of prismatic crystals.

For the process of concrete degradation under the impact of sulphates, it is essential which cation is linked with the sulphate ion. Namely, cations linked with sulphate ions can be divided into three characteristic groups. The third group of sulphates, that is $(NH_4)_2SO_4$ and H_2SO_4, covers the most aggressive compounds. In case of impact by these compounds on concrete, neither balancing nor creation of protective gel takes place. The destruction of concrete, in this case, occurs not only due to expansion, but also because of intensive dissolution of cement stone.

1.1 Proposed degradation model

Japanese researchers Matsufuji, Koyama and Harada [4] proposed an estimation equation which can be used to predict the progress of deterioration for various building materials, and an attempt is made to summarize and classify the deterioration phenomena of each material used in a building.

Environmental forces have a direct effect on deterioration together with gases and liquids, which also have an indirect effect. Those deterioration factors are defined as environmental factors contributing to deterioration.

Generally, the deterioration of building materials progresses as the environmental factors permeated and otherwise affect the materials. An estimation of deterioration is shown in Figure 1 with the assumption that the environmental factors, which act on defect-free internal parts, are influenced by the property of the parts that have already deteriorated.

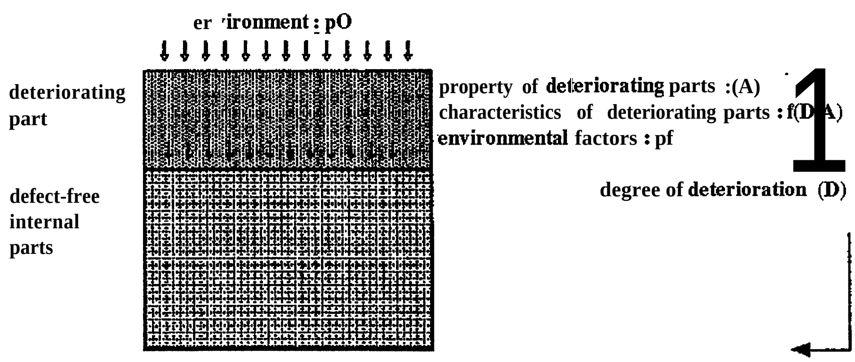

Fig. 1 An estimation of deterioration

The affect of the environmental factors (*pf*) depend on the environment where materials are exposed (*pO*) and the characteristics of the deteriorating parts between *pO* and *pf*. Also, the characteristics of the deteriorating parts can basically be presented by the function (*f(D,A)*). D is the degree of deterioration of the material itself and *A* is the property of the deteriorating part. As the result, pf can be represented as shown:

$$pf = pO + f(D,A) \qquad /1/$$

If we assume that the deterioration speed is proportional to pf, the diferential equation representing the deterioration speed (*dD/dt*) will be as shown in Equation /2/

$$dD/dt = k\ pf \qquad /2/$$

k is the constant for proportion.

Further, if we assume that the characteristic values of deteriorating parts, *f(D,A) can* be represented as the product of the degree of deterioration and the deteriorating material, Equation /3/ can be obtained from Equation /2/.

$$dD/dt = b + aD \qquad /3/$$

dD/dt is the deterioration speed.
b is a constant related to *pO*.
a is a constant related to the properties of deteriorating parts.

From Equation /3/, considering that *D-O* at time *t=O*, the degree of deterioration (*D*) can be represented as shown in Equation /4/ and Equation /5/.

at time $a=O$, $D = b\ t$ /4/

at time $a \neq 0$, $D = bla\ (exp(at)-1)$ /5/

where *D* is a degree of degradation,

a is a constant depend on the environment where materials are exposed,

b is a constant related to the properties of deteriorating parts,

t is degradation process time.

The above results can be represented as shown in Figure 2 and the deterioration of building materials can be classified into the three patterns shown below according to the value of *a*.

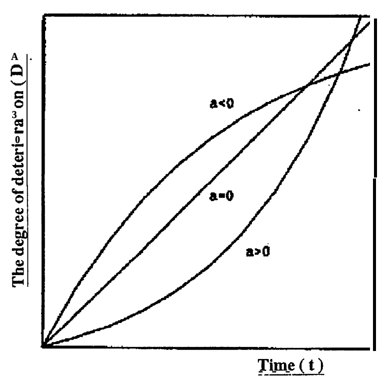

Fig. 2 The deterioration patterns of building materials

a) Alignment type: when $a=0$

In Equation /3/, when $a=0$, the deteriorating parts do not affect pf even if deterioration has progressed. Accordingly, the deterioration effects on building materials can usually be considered to equal pO. In this case, deterioration speed does not depend on the current status of deterioration, so it is the simplest model for the estimation.

b) Convergence type: when $a<0$

When $a<0$, the speed of deterioration depends on the current degree of deterioration, but the speed is falling gradually. That is, the deteriorating parts reduce external force causing deterioration. In this type of deterioration pattern the speed of deterioration increases at the beginning and is zero at the end.

c) Multiplication type: when $a>0$

When $a>0$, the speed of deterioration depends on the current degree of deterioration. In this type of deterioration pattern, the more the degree of deterioration progresses, the higher the speed becomes.

Bearing in mind all the above-mentioned, the basic idea and motivation for the work on this paper is to wide the knowledge so important for the prediction of the construction life-time and sustainable construction [6-10].

2 Experimental

The programme for researching degradation of cement by the impact of sulphate corrosion envisaged characterization of Portland cement and Portland fly ash cement manufactured in our country:

- Portland cement 1 (PC1)
- Portland cement 1 with the addition (replacement of clinker) of 30% of fly ash (PAC 1)
- Portland cement 2 (PC2)
- Portland cement 2 with the addition (replacement of clinker) of 30% of fly ash (PAC2)

Complete testings of the chemical composition of all materials were carried out, same as the testings of physico-chemical and mechanical properties of cements, and the potential phase analysis of clinkers was given. In the second part, the testings of the influence by the selected aggressive solution on concrete were carried out.

2.1 Method for testing the influence of aggressive environment

The 10% solution of ammonium-sulphate was used as the aggressive environment according to the Koch-Steinegger's method [5], to the influence of which cements were exposed. This method was selected as the basic procedure in determining corrosion degradation of cements. Exceptions of the method were made by testing after 7, 14, 28, 56, 90, 180 and 270 days instead of usual testing terms.

Results were presented by the mass change of the testing samples through time, by bonded SO_4^{2-} content calculated from the SO_4^{2-} content in solution, and by the degradation coefficients which were calculated as supplement of the corrosion coefficients of the testing samples.

2.2 Other testing methods used in this work

1. Determining the strength (EN 196-1)
2. Chemical analysis (EN 196-2)
3. Determining the setting time (EN 196-3)
4. Determining the sieve residue (EN 196-6)
5. Determining the specific surface (EN 196-6)
6. Calculating the potential mineralogical analysis (ASTM C 150)

3 Results and discussion

The selected aggressive environment represented very strong aggressiveness to ensure fast results for the real conditions which can be present in underground waters in the territory of our country.

The potential phase analysis, for the Portland cement clinkers is given in Table 1. It can be seen that used kinds of cement differ on the percentage content of C_3A in clinkers 6.60% to 13.3 1%, which has its impact regarding sulphate resistance. The difference in the C_3S content was significant regarding sulphate resistance also.

Potential phase composition, % mass	Portland cement clinker 1	Portland cement clinker 2
C_3S	57.54	66.98
C_2S	13.50	12.72
C_3A	13.31	6.60
C_4AF	8.67	9.10

Table 1 Potential phase composition of portland cement clinker

Chemical composition,% mass	Fly ash
LO1	5.68
SiO_2 + Al_2O_3 + Fe_2O_3	84.06
CaO	6.52
MgO	2.65
SO_3	0.05
S	0.02
Na_2O	0.30
K_2O	0.70
Insoluble residue	76.61

Table 2 Fly ash chemical composition

Table 2 presented the chemical composition of mineral admixture - fly ash. Fly ash, by its chemical composition, shows traditional ash, which makes it relatively suitable for application in concrete (suitable content of the sum of oxides SiO_2, Al_2O_3 and Fe_2O_3, and the low content of CaO also). MgO, sulphate and alkalies content were low also.

As regards the chemical composition, physico-chemical characteristics, flexural and compressive strengths all the cements satisfy the conditions for quality of the Yugoslav standard JUS B.C1.011.[7-9].

In this way, complete characterization was implemented regarding all the cements used in this work. The results of testings of the impacts by aggressive solution, that is, the degradation by sulphate corrosion of cements, carried out in line with mentioned method, are presented, by mass change, bonded SO_4^{2-} content and degradation coefficients, in Figs 3 to 8.

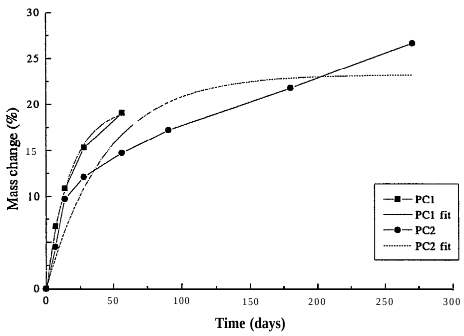

Fig. 3 Experimental and estimated curves for mass change for Portland cements

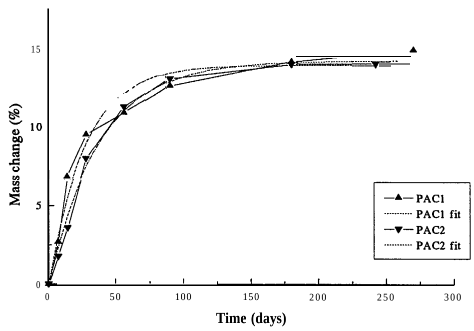

Fig. 4 Experimental and estimated curves for mass change for Portland ash cements

Figs 3 and 4 presented mass change of concrete testing samples exposed to the aggressive ammonium-sulphate solution. Curves PC1 fit, PC2 fit, PAC1 fit and PAC2 fit presented estimated curves from Equation /5/ for the mass change.

Due to fast mass change and ettringite formation PC1 testing samples lasted for 56 days only, but PC2 testing samples lasted for whole 270 days. It is obvious that C_3A clinker content played important role. Cements with the ash addition lasted for 270 days also, confirming that ash played protective role against ammonium-sulphate solution aggressive impact.

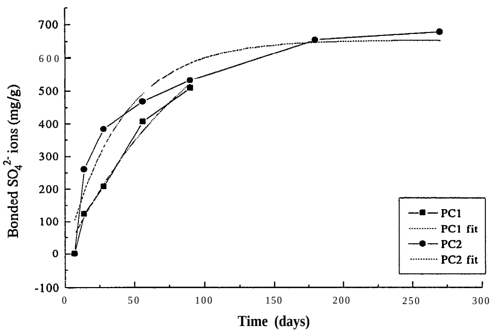

Fig. 5 Experimental and estimated curves for the bonded SO_4^{2-} ions for Portland cements

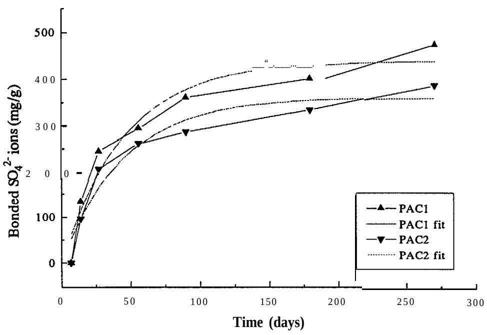

Fig. 6 Experimental and estimated curves for the bonded SO_4^{2-} ions for Portland ash cements

Figs 5 and 6 presented bonded SO_4^{2-} content. to concrete testing samples from the aggressive ammonium-sulphate solution. Curves PC1 fit, PC2 fit, PAC1 fit and PAC2 fit presented estimated curves from Equation /5/ for the bonded SO_4^{2-} content.

Incorporation of sulphates from solution was rather faster to Portland cement PC2 till 90 days. After that time, testing samples from Portland cement PC1 cracked down due to ettringite formation, but the testing samples from Portland cement PC2 lasted for 270 days of examination. Incorporation of sulphates to Portland ash cements were much slower due to protective layer from hydration products formed in such kind of cements.

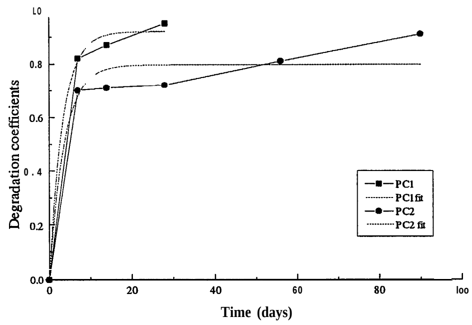

Fig. 7 Experimental and estimated curves for degradation coefficients for Portland cements

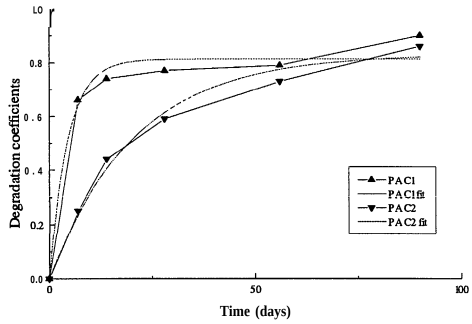

Fig. 8 Experimental and estimated curves for degradation coefficients for Portland ash cements

Figs 7 and 8 presented degradation coefficients of concrete testing samples exposed to the aggressive ammonium-sulphate solution. Curves PC1 fit, PC2 fit, PAC1 fit and PAC2 fit presented estimated curves from Equation /5/ for the degradation coefficients.

From the diagrams, it can be clearly seen that cements with the addition of 30% of ash, show convincingly best characteristics in the used aggressive solution. The increase of corrosion degradation in the very begining for all the cements is a normal phenomenon, because the creation of expansive compounds closes the pores and makes cement paste impervious to aggressive ions. However, further increase in the volume within the paste very quickly results in cracking.

As it could be seen from the Figs 3 to 8, sequence of the got results with the Matsufuji-Koyama model for the cements with the ash addition is much better than for the Portland cements. This means that, in the essence, ash in cements was forming protective layer thus slowering corrosion process and increasing durability. Portland cements, but, showed, depending on the C_3A content, either alignment type or multiplication type of degradation after initial period of forming the protective corrosion process products layer. This layer obviously became negligible due to the NH,‘” ions action thus opening new pores and accelerating corrosion process again.

4 Conclusions

The results of testing the impact by aggressive sulphate environment, that is, the degradation of the selected cements to these impacts, allow for the formulating of certain conclusions:

1. Regarding the resistance of cements to the impact by the environment with sulphate composition, it can be concluded that the lower degradation was shown by cement with a lower content of tricalciumaluminate in clinker PC2 and especially by cements with the addition of ash.

2. Sequence with the Matsufuji-Koyama model for the convergence type of degradation was very good for the cements with the ash addition, but, for the Portland cements, depending on the C_3A content, it was rather alignment or multiplication type.

Quantitative Measurement and Estimation of Driving Rain on a Building Facade

A. Högberg
Department of Building Physics, Chalmers University of Technology, Göteborg, Sweden

Abstract

One of the most serious threats to the envelope of a building is represented by driving rain; when the wall surface is made of porous material part of the rain may be absorbed and part may penetrate into cracks and joints and even cause dampness indoors. Absorption of water ruins roofs and damages walls at the onset of frosts; the moisture inside the building freezes, causing wall deterioration. Moisture in a construction or on the surface may also cause deterioration by salt decomposition, corrosion of concrete reinforcement, mould and rot, chemical conversion, biological attack and corrosion of panel walls. A sustainable construction, therefore, often requires knowledge about the moisture level and moisture variation in the structure. The project described in the paper focuses on predicting, as accurately as possible, the micro climate of outdoor building surfaces, i.e. the temperatures and moisture conditions to be used in determination of durability. The micro climate depends on both the parameters of the structure such as size, shape, type of material etc., and the meteorological loads. This paper describes a set-up for measuring the micro climate primarily focused on wind-driven rain onto a vertical building surface. The *in-situ* measurements were taken at the Fisebäck field station in Sweden. The position of the driving rain collectors were estimated using a CFD-modelling of wind induced surface pressure. Future work within the project will develop a simulation model for quantitative estimation of driving rain onto a building facade. The model is to be used to predict the surface moisture deterioration of the building envelope. The model uses meteorological data, and takes into account the location and the geometry of the construction. The amount of wind-driven rain onto the building surfaces will be described by considering the construction design, variations of wind direction, wind speed and precipitation, seasonal and daily changes.

Keywords: climatological measurement, driving rain, micro climate, simulation of wind, wind around a building

1 Introduction to micro climate - durability

The study presented here is a part of a project called *Description of the micro climate for estimating durability and lifetime: Building components exposed to natural outdoor climate.* The aim of this project is to predict, as accurately as possible, the micro climate of outer surfaces, i.e. the temperatures and moisture conditions to be used in determination of durability.

Variation in the ambient air temperatures cause the properties of the building materials and building construction to vary. The surface temperature depends on ambient temperatures, radiation exchange with the surrounding surfaces and material properties. Variation of the air temperature can give, freezing/thawing of the material (especially dangerous for porous material and surface finish), movements and cracks, and changes in material properties.

Many severe durability problems in buildings are related to moisture. A sustainable construction, therefore, often requires knowledge about the moisture level and moisture variation in the structure. This demands knowledge of material properties, regard to critical moisture levels and to moisture transport properties, and the ambient climate. Moisture reaches the building surface as precipitation, driving rain, air humidity and condensation. One of the most serious threats to the building envelope is represented by driving rain; when the building facade is made of porous material, part of the rain may be absorbed and part may penetrate into cracks and joints and even cause dampness indoors. Absorption of water ruins roofs and damages walls at the onset of frosts; the moisture inside the building components freeze, causing wall deterioration. Moisture in a construction or on the surface may also cause deterioration by salt decomposition, corrosion of concrete reinforcement, mould and rot, chemical conversion, biological attack and corrosion of panel walls.

An estimate of the micro climate at the facade surface must be based on a transformation of meteorological data obtained from a nearby weather station. However, in the present paper, a number of restrictions are made because of the fact that only natural outdoor climate is to be considered. These are: no construction in contact with soil or off-shore is dealt with; no salts or other airborne particles and pollutants are to be taken into account. This paper thus proposes a set-up for measuring the micro climate, primarily focused on wind-driven rain onto a vertical building surface. The *in-situ* measurements are taken at the Fisebäcks field station, Sweden. The position of the driving rain collectors are estimated by the help of a CFD-modelling of wind induced surface pressure.

2 The serious threat of driving rain

Driving rain, or wind-driven rain, is the horizontal component of precipitation reaching a fictitious (free driving rain) or a real vertical surface. The wetting pattern of the wall surface due to wind-driven rain depends amongst other factors on wind velocity, wind direction and type of rain (e.g. size and shape of droplets). The interaction between climatic parameters such as wind, rain and temperature, are of importance for determining the micro climate in proximity to the wall. When obtaining climatic information for building sites it is important to note the distance from the coast, the influence of adjacent urban buildings and specific structures, as well as of the landscape in the immediate vicinity of building site. As well, the geometry and orientation of the building surface affect the amount of wind-driven rain deposited on it. An example from the British Standard Code of Practice [1] showing the wetting pattern on a two-storey gable due to driving rain is provided in Figure 1.

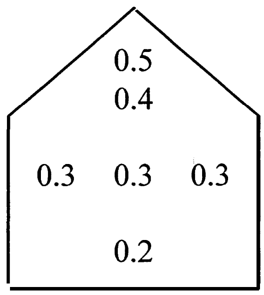

Figure 1 Wall factor for correlation of the driving rain wall indices on a two storey gable due to free driving rain [1]. The greater the wall factor, the more wind-driven rain reach the facade.

3 Review of driving rain on building facade

Driving rain is not systematically measured at meteorological stations. Since only a few locations in some countries conduct experimental measurements, the precipitated amount of driving rain is typically determined by calculation. A review of the physics and properties of driving rain and the means to measure it is offered by Lyberg [2] and van Mook [3]. In reference [2] it is mentioned that Holmgren was the first one to design a driving rain gauge to be installed on the wall in 1937 and that Hoppestad (1955) was the first person for initiate the idea of driving rain index, that in part depended on the relationship between rate of rainfall, drop size and terminal velocity. The rate of water deposition on vertical walls can be calculated according to a method provided by Lacy in [4]. Lacy developed (1965) the basic criteria for using empirical relationships between rainfall rate and drop size distribution according to work by Laws and Paterson [5]. Thereafter, Best found the relationship between the rain dropsize and terminal velocity [6], which when combined with pevious work gives:

$$r_v = \frac{2}{9} \cdot V \cdot r_h^{8/9} \tag{1}$$

where, r_v (l/m^{2}h) is the rate of driving rain on a vertical surface, r_h (mm/h) is the rainfall rate on a horizontal surface and V (m/s) is the wind speed against the wall. Several modifications of driving rain index have been suggested. Prior [7] proposed the sum of driving rain over an azimuth sector of 180°:

$$r_v = \sum r_h \cdot v \cdot \cos\theta \qquad (2)$$

where r_h is the hourly amount of precipitation on a horizontal surface and v (m/s) is mean hourly wind speed for the same hour and θ is the angle between the mean hourly wind direction and the normal with respect to the wall under consideration. Maps provided in references [1] and [8] are based on those expressions, i.e. the annual index and the spell index. The amounts of rain that would impact on a real wall must be multiplied by factors for topography, terrain roughness, obstruction and sometimes the wind. In [1] and [8] the driving rain intensity on an unobstructed fictitious vertical surface is given by the annual index and the spell index above, no wind factor is used.

Investigations of wetting patterns for various wind speeds around building, raindrop trajectory and rain drop size distribution employing CFD-models (Computional Fluid Dynamics) have been performed by Choi [9]. Choi developed a local effect factor LEF(r) and a overall local effect (LIF) for each zone of the facade according to different wind speed conditions and rain drop size distributions based on the following relationships:

$$\mathrm{LER}(r) = \frac{\text{wind driven rain intensity of radius } r \text{ raindrop}}{\text{unobstructed rainfall intensity of radius } r \text{ raindrop}} \qquad (3)$$

$$\mathrm{LIF} = \frac{\text{wind driven rain intensity on building face}}{\text{unobstructed rainfall intensity}} = \int \mathrm{LEF}(r) f(r) dr \qquad (4)$$

where *f(r)* is the probability distribution of water in the air with drops of radius r to $r+\delta r$. The CFD model is still under development and needs further evaluation against measured data; at present time it is limited to simple buildings located in simple landscapes; as which it is only practical as a research tool. It will be some time before it can be used by designers to carry out practical evaluations of the driving rain impact on buildings.

4 Planned measurement of driving rain

The *in-situ* measurements were undertaken at Chalmers field station situated at Fiskeback, Göteborg , on the west coast of Sweden. Macro climate is obtained from three different weather stations of Swedish Meteorological and Hydrological Institute (SMHI) near the field station namely, in; Save, Göteborg and Trubaduren. A reference station for measuring the meso climate near the field station is an important part of the analysis required for transforming the macro climate to micro climate. The instruments measuring the wind speed and wind direction are placed in a 10 metres high meteorological tower. The meteorological tower itself is placed on top of the field station roof.

The micro climate at the facade is recorded with instruments directly applied to the surface being considered.

4.1 Desired climatological parameters

The air pressure is obtained only as a macro climatic value at a nearby meteorological station. The most interesting climatological parameters for describing the micro climate are: air temperature, total net radiation (between the wall being investigated and its surroundings), and wind-driven rain onto a vertical building surface. At the reference station the following meteorological loads are to be measured as meso climate; wind speed and wind direction, air temperature, air humidity, global radiation, total net radiation (between the sky and the ground) for estimating the stability class of the atmospheric boundary layer, and horizontal precipitation.

4.2 Measurement equipment

Meso climate at the field station are registered by a Young model 05103 wind monitor for measuring wind speed and wind direction, a Campbell Scientific 107 thermistor probe in a radiation and precipitation shield, a Young model 41002 for measuring the air temperature, a Rotronic MP 101 for measuring the air humidity in the same shield as mentioned above, Campbell Scientific model SP1 110 a pyranometer sensor for measuring the global radiation, a REBS model Q-7 net radiometer for measuring the total net radiation for horizontal surfaces, and, a ARG1 00 rain gauge for measuring the horizontal precipitation.

Driving rain onto the wall is measured with three different gauges constructed at the Department of Building Physics, Chalmers:

- a collection plate with a tipping bucket for registration of the amount of driving rain.
- a collection "hole" in the wall with a balance as measuring unit.
- a portable collection plate with a balance as a measuring unit.

The wall being studied is also equipped with a REBS model Q-7 net radiometer for measuring the total net radiation and two Campbell Scientific 107 thermistor probes for control of the air temperature measurements. A Campbell Scientific CR10 was used for measurement and control, and was linked by a fax-modem to Chalmers.

Measurements and calculations included:

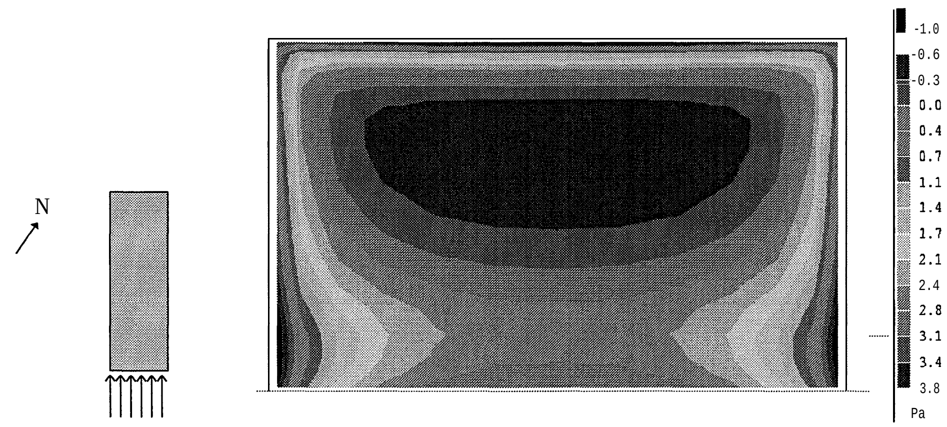
- Ambient temperatures and air humidity; frequency 5 s^{-1}, lo-minutes and 24 hours mean value, calculation of dew point based on 10 minutes average temperature value.
- Wind direction and wind speed: frequency 1 s^{-1}, 1 and 10-minutes and 24 hours mean value, maximal wind gust per hour, standard deviation for 1 and IO-minutes mean value per hour.
- Precipitation and driving rain: 1 and 1 O-minutes mean value , 1, 6, 12 and 24 hours mean value, accumulated volume of precipitation.
- Global radiation and net radiation: frequency 5 s^{-1}, 1 O-minutes mean value, 1, 6, 12 and 24 hours mean value.

5 Wind climate at the test house

Wind flow around the building at the field station was modelled in co-operation with SMHI. A steady-state simulation of the k-ε turbulence model was performed in Phoenics, a CFD-program. The following assumptions were used due to homogeneous horizontal surroundings and stratification of the atmosphere:

- the atmospheric boundary layer has neutral thermal stratification;
- the up stream wind has a power law wind velocity profile with a terrain roughness exponent of 0.14;
- friction against the building surfaces is taken into account;
- the air temperature is about 20 °C.

The building has the form of a rectangular box 22.1 meters long, 7.2 meters wide, and 4.3 meters high and has a flat roof. The orientation of the south-east gable is 150°. Distance from the house to the sea is about 50 metres. One output of the CFD-simulations gives the wind induced surface pressure for the four walls and the roof. The calculated distribution of the wind pressure (Pa) onto the south-east gable is shown in Figure 2. This illustrates the effects of the wind (3 m/s) blowing straight at the gable. This wind direction is one of the most frequent ones according to [10]. The south-east wall surface has one of the orientations with largest amounts of collected driving rain for the location Göteborg, see [11].



a) b)

Figure 2 a) The wind direction due to orientation and geometry of the building. b) The distribution of the wind pressure (Pa) at the south-east wall surface, which illustrates the effects of the wind with the speed 3 m/s.

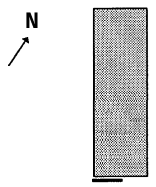
6 Position of the driving rain gauges

From field measurements it is known that the intensity of driving rain is highest close to the edges, i.e. corners and regions close to the roof. The air flow approaching the building is forced to change direction in order to flow around it. The wind velocity and direction will increase around the considered edges. The drag force representing the interaction between the air and the raindrops are not sufficiently strong to carry the rain drop around the building. At the edges, where the acceleration of the air flow field is highest, a great number of rain drops are falling out of the air stream, and will hit the wall surface. Changes in the air velocity field at the facing wall will result in steep air pressure gradients. High pressure gradients can therefore be used as an indicator for areas of the wall that are likely to represent high driving rain intensities. In Figure 2 the area with a higher pressure gradient than 0.6 Pa/m becomes the target region for driving rain collectors. The number and types of driving rain gauges on the building surfaces is presented in Table 1.

Types of driving rain gauges	south-east wall	south-west wall
a tipping bucket	6	2
a hole in the wall	**1**	**1**
a plate and balance	**6**	**2**

Table 1 The number and types of driving rain gauges on the building surfaces.

The position of the collectors on the south-east wall are shown in Figure 3. To obtain reference levels the collectors on the south-west wall are placed in an area where the estimated pressure gradients are small, i.e. at the centre and upper part of the wall.



a)

b)

Figure 3 a) The position of the collectors due to orientation of the building.
b) The position of the collectors on the south-east gable, Fiskeback.

7 Discussion and conclusions

Result from calculation performed by Choi [9] of raindrop trajectory from the equation of motion of the fluid particles moving in the wind field shows a similarity with field experiments. In order to simplify the calculation of the wind field, potential flow theory can give reasonable approximation of the air flow field at the windward face, which is the part of interest in these studies. Further simplification can be made by considering a 2-dimensional flow field along the roof and along the corners of the building. Valuable and useful approximate expressions can be developed and used in the determination of the driving rain intensity.

In this project the development of simplified simulation models will use these types of approximations. The future model is to be used to predict the deterioration of the building envelope due to surface moisture. An important part of the model is the transformation of climatological parameters, single or combinations thereof, for building purposes. The model is to take into account meteorological data as well as the location and the geometry of the construction. The amount of wind-driven rain onto the building surfaces are to be described by considering the construction design, variations of wind direction, wind speed and precipitation, on the basis of both seasonal and daily changes. The *in-situ* measurements at the Fiskeback field station will be used to validate this simulation model.

8 Acknowledgements

I would like to express my gratitude to Carl-Eric Hagentoft Prof, Chalmers, and Roger Taesler Dr, SMHI, for their supervision; and to Bengt-Åke Peterson Assoc Prof, Chalmers, Antonio Morais Eng, Chalmers, and Erik Johansson, SMHI, for their support. The project is financial supported by the Swedish Council for Building Research and by stipends from Åke och Greta Lissheds stiftelse and Adlerbertska forskningsfonden, whom also are acknowledged.

From theory into practice. Subarctic ecological building in Östersund.

K. Hagberg, H. Hällstrand, Å. Ulfsdotter Kjellman
Students at Mid Sweden University, Östersund, Sweden

The ecological planning and building engineering program at the Mid Sweden University in Östersund is based on a traditional construction engineering program but is permeated with ecological reasonings. Besides the traditional courses the students take courses in ecology, ecological town and country planning, the technology of installations, ecological planning and building, environmental management systems, indoor environment, shape and artistic work which all are courses where the ecological reasoning is the main part. The ecological planning and building engineering program is the only of its kind with a pronounced ecological profile in Sweden.

The ecological building centre in Ås is a practical project work in full scale which is mostly planned, designed and built by the students at the ecological building and planning program and building engineers in co-operation with local enterprises in the branch of building trade. When the project is finished, there will be five different houses and one small village composed of five cottages.

The first house, which will be finished during the spring of 1998 is a two storey apartment and office building. The house is built with ecological and locally produced materials. The ventilation system is based on a principle where the air goes through a small greenroom where it will be preheated and then flows in the rest of the house. The heating system is based on a wood-pellet boiler and solar collectors.

The second house is made of earth and straw clay. The earth walls are stamped in a wooden mould and become almost as hard and durable as concrete. The straw clay wall is also stamped in a wooden mould but not as compact as the earth walls.

Next stage of the development is to build an environmental laboratory, a storage and a recycling workshop, there will also be a permaculture garden in the area.

Keywords: Earth walls, ecological building centre, ecological planning and building engineering, green room, sedum plants, straw clay walls,

Introduction

At the Mid Sweden University in Östersund, which is a town in the middle of Sweden, there is a programme that educates Ecological planning and building engineers. The programme was founded in 1994 and it is the only one of its kind in Sweden, since it started two classes has graduated. The Ecological planning and building programme has a close co-operation with the Ecological building centre in Ås. Ås is located about 10 km from Östersund. This paper will give you a short introduction about the Ecological planning and building programme and the Ecological building centre in Ås.

1 The Ecological planning and building engineering programme

The ecological planning and building engineering programme at the Mid Sweden University in Östersund is based on a traditional construction engineering programme but is permeated with ecological reasoning. Besides the traditional courses such as construction, building physic, mathematics, building production and Computer Aided Design, the student also take courses which are concentrated on ecology. Those courses are:

- Ecology which is the first course in the programme, there the students learn how the ecological balance in the nature works and how to follow the law of nature.
- Ecological town and country planning. The students learn how the sustainable community of the future will be reached and developed.
- The technology of installation is a course where the students learn about the interplay between installation systems of the house and to economize the use of energy. They also learn how to take care of and use the renewable energy sources like solar energy, wind power, heat exchanger and so on.
- Ecological building and planning is a course based on real projects where the students use knowledge acquired in previous courses. The project can for example be composed of planning the living space in a house, the calculation of the framework, heating and ventilation system and find system that are suitable for the project. All through the project the students maintain contact with the customers who express their wishes and demands.
- Shape and artistic work is a course where the students are given an opportunity to develop their creative and artistic skills in modeling, painting and construction of models.
- Environmental management systems is a course where the students deepen their knowledge about environmental management systems like EMAS and IS0 14 000.
- Indoor environment. The students learn how people are affected healthwise by the indoor environment. They read about allergies and other diseases caused by a unhealthy indoor environment.
- Ecological building technique is a course that takes place each summer at the ecological building centre in Ås. The students will there have the possibility to get the six weeks long practice that is required. This is a course that gives the students a good opportunity to transform theoretical ideas into practically useful solutions.

The ecological thread permeates also the traditional courses. The students learn about environmental management systems IS0 14 000 and EMAS (Eco Management and Audit Scheme) and also about quality management systems like IS0 9 000.
By working in groups with real projects the students learn how to solve problems, find solutions and work together with other people.

This is the only construction engineering programme where the ecological approach follows the student throughout the whole education programme, from the start to the exam.

2 The ecological building centre in Ås

The building centre is an ecological and practical project work in full scale. It is mostly planned, designed and built by the students at the programme of ecological planning and building engineering in co-operation with local enterprises in the branch of building trade.

Plan of development 1995 - 2010.

Building

1. Apartment and offices
   1995-97 96,5 sq. m.
2. Experimental earthhouse
   1995-97 26,2 sq. m.
3. Environmental laboratory and experimental workshop
   1998-00 380 sq. m.
4. Storage, woodshed and underground storehouse
   1999-2001 total 80 sq. m.
5. Recycling workshop
   2001-03 120 sq. m.
6. Researchers cottage with five small houses
   2003-10, 5x30 150 sq. m.
7. Permaculture garden
   2000-2010 3000 sq. m.

All the buildings will be formed as independent research objects, since they will be constructed from different materials, built with different methods and techniques and the buildings will be heated, ventilated, etc. with different systems. Carefully measured and analysed in comparison to each other.

The exploitation of the ecological building centre depends on the sponsorship that the foundation of the ecological building centre receives from enterprises in the branch of building trade and private donators.

In the choice of construction-methods there has been a strong desire to make it possible to dismount the construction without destroying individual parts or materials.

The choice of materials for the houses in the ecological building centre are based on following criteria:

- Local presence = minimized transportation
- Locally produced = minimized transportation

- Low energy-demanding manufacturing processes
- Non pollution - non toxic materials
- No vapour barriers
- Recyclable materials

The choice of systems for the houses in the ecological building centre are based on following criteria:
- Lowest possible technical level
- High efficiency
- Easy operated
- Visible processes
- Understandable to non-technicians
- Recycling flows

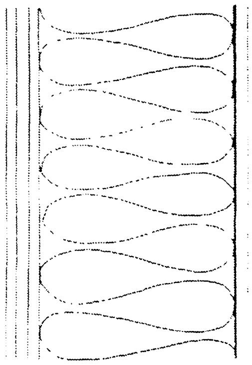
2.1 Building no 1. The two storey apartment- and office building.

Foundation-walls: The foundation-walls are bricked with LECA-blocks (cement and expanded clay-pellets), lime-mortar and reinforced concrete-footings.

The porches on both ends (east and west) of the building are constructed with post foundation down below frost line.

Bottom system of joists: On site prefabricated modules of reinforced concrete slab floor sheets, 120 mm in thickness. Top surface is covered with slate from local quarries and set in lime-mortar. There is no insulation between the groundfloor and the foundation space.

Outer walls: A double wooden framework, where the outer is carrying the load from the trusses and the truss-joist. The inner is carrying the load from the middle system of wooden joists. (Fig. 1)



23 mm wooden panels
23 mm ventilated space
12 mm wood-fibre sheet
360 mm cellulose insulation (EKOFIBER)
wood-fibre textile
16 mm wooden panels / 12 mm gypsom wallboard

Fig. 1

Boiler-room 1st floor and bathroom 2nd floor: The surrounding walls are built as a bricktower, divided in to floors by a reinforced concrete slab floor in order to lead the warmth from the boiler-room up into the bathroom without installing heat piping into the floor but still functioning as a radiant heat floor system. The bricks in the wall are known to absorb and transport damp from the moist bathroom into the surrounding areas, increasing the humidity of the indoor air, which during the winter is too dry to be pleasant for the inhabitants.

Gable outer-roof and hip-roofs over porches: Waterproof, asphalt saturated roofing felt covered with lightweight carpets of living sedum plants. During the spring, summer and autumn it's blooming in white, yellow, pink and red colours against a green bottom.

Solar-collectors: They are a part of the heating system and produce domestic hot water during late spring, summer and autumn. A circulation pump is operated by electricity from solar-voltaic cells integrated on the roof.

Heating system: The base is a wood-pellet fired boiler, with a hot water storage tank also coupled up to the solar collectors. The warmth is distributed by a system of hot water-radiators. There are secondary fireplaces in both kitchen and living room.

Ventilation system: Natural ventilation by taking advantage of the strong negative air pressure inside the house during winter conditions. Fresh-air-inlet through the permeable insulation of the greenhouse-ceiling The incoming air will hereby be both filtrated and prewarmed by absorbing the warmth which is constantly leaking out through roof-construction when colder outside.

During the summer, ventilation air is lead into the house from the shaded and more chilly northside of the building through wide, underground concrete pipes to inlets in the south facing greenhouse where the need of cooling is the biggest. By letting the air flow through underground pipes, the temperature of the air will be considerable lowered. Required airflow is created either by opening windows or by use of a chimney top-mounted fan.(fig 2)

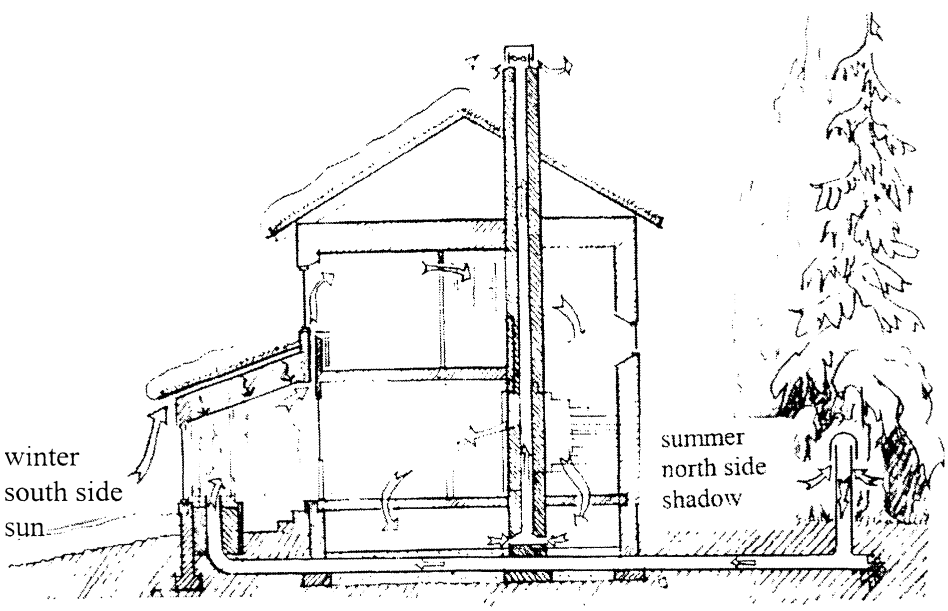


Fig. 2 Ventilation system for house no. 1

Glass partition: A glass partition is arranged between green room and living room to steer the prewarmed air entering the green room through channels and inlets further on to the upper floor bedrooms. By the strong negative air pressure the flow of air is then drawn down stairs and through air slots in the bottom system of joists further down into the ground space, where it warms the concrete slab floor before entering the exit openings of the chimney pot. Again a heat exchanger without moveable parts.

Windows: Nicely profiled wooden framed doubleglass windows with an metallic coated inside to prevent leakage of longwaved heat radiation from in to outside.

Toilet system: Low flushing urine-separating toilet. Quickly drying for later composting together with changed out greywater peat-filters and used as soil improvement in the garden.

Grey water system: Water from shower, doing the dishes and washing is collected and lead to a simple, on site manufactured peat-filter in the same cabinet as above, where also the urine UV-filter is placed. After filter treatment the greywater is mixed with the treated urine. The nutrient solution flows through pipes under the bottom system of joists into the cultivation beds of the green room. The loop of waste becoming valuable nutrients and irrigation water for growing vegetables to put on the table is closed within the outerwalls of the house.

Electrical system: Enclosed wire in conduit system are installed in order to minimize discomforts from electromagnetical fields.

Surface materials: There are used slate and limestone, solid wood from pine and spruce, gypsom wallboard and woodfibre wallboard. When available they are bought from local enterprises.

Indoor: Depending on function, linseed oil, a mix of linseed oil, turpentine and wooden-tar, slime paint, honey beeswax transparent paint, egg-linseed-oil tempera and limewash colours.

2.2 Building no 2. Experimental earhthouse

The area of the earthhouse is 26,2 sq. meters.

The foundation walls are bricked with LECA-blocks (cement and expanded claypellets). The floor is made of LECA pellets and a claymixture of clay, sand, chopped straw and water. There are two layers of this clay mixture and in the last one it is possible to add linseedoil and colourpigment to make the floor more resistant to wear, and to give it a nice shade.

The earthwalls, Piséwalls, are built directly on the foundation walls with a asphalt saturated roofing felt between. To the walls are used a wooden mould which you fill with earth and stamp compact with different tools. (Fig 3)

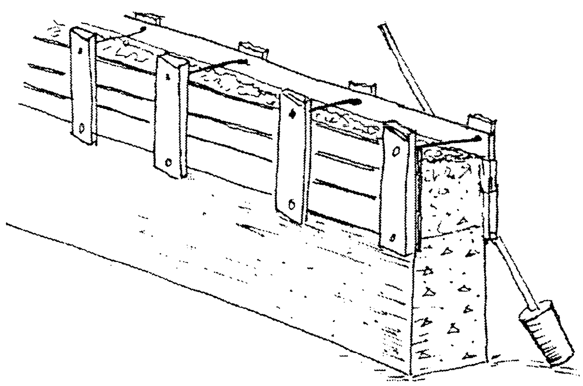

Fig.3 The construction of the mould where you stamp the pisé wall.

One of the walls are made of straw clay. A wooden framework are the base and a wooden mould (like the one used to the pisé wails) are nailed to the framework. (Fig 4)

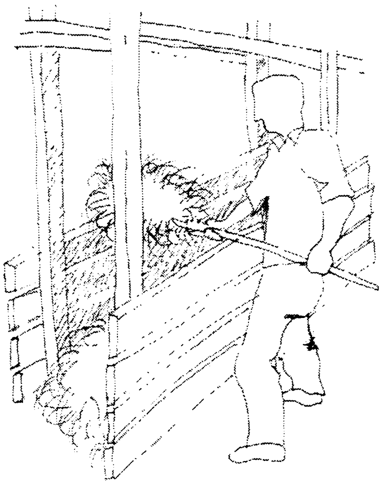

Fig. 4 The straw clay is filled in the mould.

The mould is filled with straw mixed with clay soaked in water. The straw clay is stamped compact but in the middle it is left unstamped to increase the insulation property. (Fig 5)

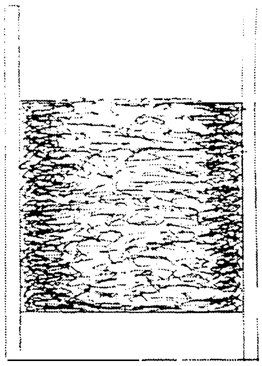

Fig.5 The straw clay stamped in its mould.

There are a clay plaster on the walls. The first plaster mixture for the straw clay wall is a mixture of clay, sand, sawdust, chopped straw, manure and water. In the second layer the manure is excluded and the part of sawdust and chopped straw is increased.

The plaster mixture for the pisé walls is a mixture of clay, sand, sawdust, fur or chopped straw and water. In the second layer the sawdust is excluded, the part of sand is increased, EKOFIBER and manure are added.

All these plaster-mixtures are easy to do and easy to work with, the plaster is spread onto the straw clay wall by the hands and onto the pisé wall with a trowel.

The windows and the door are reused from houses nearby.

The ceiling is made of “vicklingar”. It is straw clay rolled around a woodenstick. A layer of a plaster mixture made of clay, sand, chopped straw and water are spread on the “vicklingar” to give them a nice surface. These “vicklingar” give the ceiling a billowing and beautiful character. (Fig 6)

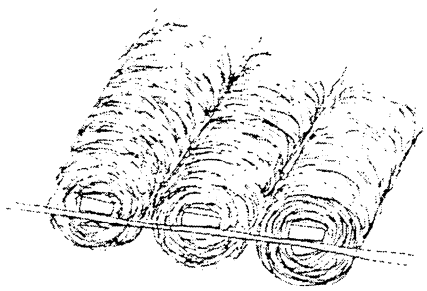

Fig. 6 “Vicklingar”

On the roof there is a waterproof asphalt saturated roofing felt covered with light weight carpets of living sedum plants. The plants are blooming in white, yellow, pink and red colours against a green bottom and give the house a very special character.

Climatic variability and climate change - implications for design and construction

T. J.S. Yates
Construction Division, Building Research Establishment, Watford, UK

This paper outlines the current state of research on the consequences for buildings of climatic variability and climate change. It has been prepared based on information provided by members of CIB Task Group 13 and it is hoped that it will provide a discussion document for future research in this increasingly important area.

It is accepted that both local and global climates have varied throughout history. Long-term variations have resulted in the Ice-ages that have so shaped the present landscape whilst shorter term variations lead to the settlement of new areas - for example the occupation of Greenland by Norse settlers at the end of the last millennium. At the end of this millennium there is a substantial body of scientific evidence that the climate is changing again as a result of the emission of 'greenhouse' gases which are leading to 'global warming'. There are potentially many serious consequences of changes in the global climate, for example the flooding of low lying areas as the sea-levels rise and the loss of ecological habitats.

The aim of CIB Task Group 13 is to begin to evaluate the sensitivity and vulnerability of the built environment to these climatic changes. The paper includes a brief introduction to climate change and then highlights some current areas that international research is highlighting as important. The paper then considers some the potential effects of climate change on the durability of building components (and prediction of service) and so complements the work of CIB W80/RILEM 140-PSL.

The final part of the paper looks towards the future potential and possible directions of long term research that will help to clarify the potential impacts and to identify where changes are required in the codes and standards that underpin the design of buildings.

1 Introduction

From the earliest times until the 20th century the design and construction of buildings has largely been controlled by three inter-related factors - the availability of materials, the ability to extract and work these materials, and the climate.

Any examination of the traditional architecture of a region or city will illustrate this idea - whether it's the use of extensive use of timber in Scandinavia, the brick buildings of the Netherlands or the marble of northern Italy. The architecture also varies with time in response to the changes in technology that allowed stone to be cut or larger timbers to be sawn. Technological developments also lead to the ability to transport materials over greater distances either because of their desirable qualities but more often because of the prestige associated with their ownership.

It was also the development of technology that seemed to signal a reduced importance for the final factor - climate - as people began to control of the environment within their buildings. Man is now able to go far beyond the simple idea of providing heat in the cold and fresh air in the summer and is able to produce 'day light' when and where it is required and to control temperature and humidity at will or in response to short-term external climatic changes. It is this area that the newly formed CIB Task Group 21(Climatic Data for Building Services) is concerned with. However, the effect of climate goes far beyond heat and light and it is necessary to relearn old skills and adapt them for new constructions so that they are able to withstand high winds, floods and droughts. Increasing importance is also being given to the need to design for durability and to predict the service life of materials, components, units and structures which is the research area of CIB Working Commission W80 (Prediction of Service Life of Building Materials and Components).

In recent years it has become clear that there may be one more climatic parameter that must be considered and that is the longer term fluctuations in climate included the long-term trends which are generally grouped together as the "greenhouse effect" and it is this area that this contribution deals with.

2 Background

The accumulation of "heat trapping" gases was first suggested by the British scientist John Tyndall in 1863, he was also the first to use the term 'greenhouse effect'. In the late 19th century Svante Arrhenius and P.C. Chamberlain considered the possibility of global warming occurring as a result of the emission of carbon dioxide from fossil fuels. In the 1940s research showed that the mean global temperature had increased by 0.25°C between 1870 and 1940 and it was suggested that the United States 'dust bowls' of the preceding decade were a result of the anthropogenic 'greenhouse effect'. Measurements made in the following 30 years (1940 -70) [1] showed the world to be cooling and by 1970 it was back to a level similar to that recorded in 1880. However, in the 1970s studies of concentrations of CO_2 and observed rises in global temperature renewed interest in the 'greenhouse effect'. By the late 1980s there were indications that the effect was real - global temperatures had risen between 0.5°C and 0.7°C since 1880 [1] with the six warmest years on record all occurring in the 1980s. The Intergovernmental Panel on

Climate Change (IPCC) provided 'official' confirmation of this by stating that the global warming of the last 100 years is unlikely to be due entirely to natural causes and that the balance of evidence suggests there is a discernible human influence on the global climate [2].

The spate of record breaking global temperatures in the last two decades has resulted in research into both past climates and potential future ones. These studies have included studies of potential impacts on most aspects of the natural environment and on many aspects of social and financial aspects - population pressures, insurance claims and the buildings. Details of the predicted changes in climate have been reported in many articles and reports and here it will suffice to say that global temperatures are predicted to rise but with regional climates of the world responding differently [2].

Studies of past climates have shown that there have been many fluctuations. Some last only a short time, for example the long dry spell in Iberia between 1993 and 1995, and design and construction cannot respond to these. If a response is made then it may take the form of the provision of additional building services. Other fluctuations have lasted hundreds of years, for example the 'Little Ice Ages' of the medieval period in northern and western Europe and on this sort of time scale the construction of buildings were able, and hopefully would still be able, to adapt to the changing environment.

In the present world it is possible to look for responses to different climates by observing building with similar functions in different climates, for example how do high-rise office blocks vary between cold and hot climates or between wet and arid climates? The adaptations can be wide ranging and include both changes in design and in the selection of materials. However, in some buildings we see designs and materials take unchanged from one region to another with consequent failures of fabric or structure.

In looking to the future there is a need to examine the possible climatic changes being predicted by the Global Circulation Models (GCMs) [2] and their potential for effecting buildings and building materials both by increasing the failure of existing structures or by a requirement for changes in building design, standards or regulations.

3 International research

Research on climate change and variability is long term - both in the sense that we are looking several decades into the future and because the range of information required cannot be gathered quickly. However, because the changes in climate are on a similar timescale researchers are in a position to carry the research and implement the results to the mutual benefit of the population.

In order to address the impact of climate change national and international research is beginning to address a range of questions including:

- the potential environmental and economic impacts of climate change on building performance, particularly the existing stock of buildings;

- the need to alter and adapt the design of future buildings in response to temporary and permanent changes in climate;

- possible changes needed to climatic design values and to design methods involving climatic actions.

One starting point has been to examine traditional responses to climates - taking the past and the present as a basis for predicting the future. This has included studies on the potential effects of climate change on the durability of building components and prediction of service life. In the long term, this work needs to be fed to international standards (CEN or ISO) so that the performance requirements can be realistic for different climates and for the whole life of the building.

One way of examining responses of building and materials to future climates is to review information on the sensitivity of materials to the present climate. However, this shows that there is a substantial lack of understanding and information. Some of the problems stem from the ever present problem of linking accelerated laboratory testing to performance under atmospheric conditions. Consequently, it is impossible to quantify the impact of a temperature rise of a few degrees, a 10% increase in UV-dose, a 10% change in driving rain, etc. It is said that the climate of a city such as Amsterdam will change into the present climate of Paris but at present it would be difficult to indicate differences in the durability of materials on these two cities or to demonstrate that the architect is responding to the slightly different climates rather than to national tastes or the available material.

Evidence suggests that the main impact may be seen in the energy demand of buildings as it is well established that the thermal performance of a building is sensitive to even a 2°C change in climate. Research in the UK [3] has estimated that the impact of climate change on ventilation and air-conditioning systems could be:

- an increase in peak electricity cooling load of 8% for 2°C
- a reduced efficiency of air-conditioning systems of 5% for 2°C
- a need to alter the design of passively cooled buildings

It is important to remember that all of these potential increases in energy consumption must be seen again a background where the requirements are to reduce CO_2 emissions in the next decade. Research in Russia [4,5] has demonstrated that a drop in temperature - as is predicted for some regions - can also be very demanding in terms of the extra energy required. For examples data [6] shows that a although a 2°C rise in temperature can reduce heat loss from a domestic building by 10-12%, a 2°C fall in temperature can increase heat loss by 20-22%.

The need for increased cooling may seem a low priority in the temperate climates of northern Europe but in areas where the temperature is more extreme the need can become a matter of life and death. Research in the United States showed that a short but intense heat wave in July 1995 caused 525 deaths in Chicago [7]. An assessment of causes for the heat-wave related deaths attributed some of the fatalities to the inability of many people to properly ventilate their residences due to fear of crime and to lack of resources for fans or air conditioning.

The other area where there has been widespread research is the effect of increases in extreme wind events. There has been extensive research on this subject in the Netherlands [8, 9] which covered both the direct effect of increased wind speeds and the incidence of tropical storms but also the indirect effects such as the impact on insurance for buildings which also effects the availability of funding for new developments.

In the UK there was considerable interest in extreme wind events after the 1987 ‘hurricane’. Review produced at the time showed that this event was unusually but not outside the range of the previous 200 years [10]. However, reviews [1 1] have shown that much of the damage occurs when the wind speed is well below the design wind speed and much of the damage is the result of poor workmanship and insufficient maintenance. Research in the UK has also show that buildings can be very susceptible to changes in wind mean wind speed and that a 15% increase would reduce the current return period for normal building design from 1 in 50 years to about 1 in 3 years. This could result in a need a start designing buildings for a return period of 1 in 1000 years to account for a future 15% increase in wind speed [12].

4 Climate change and durability of materials and components

This is an interesting area in relation to long term climate change as the whole research area relies on predicting trends and using these to provide a future perspective on possible design responses. On one hand there are the predicted trends in climate - increase in warm summers or increased rainfall - which is clearly the area in which atmospheric scientists work and which is made available through the Inter-Governmental Panel on Climate Change [2].

On the other hand there are the trends in research that are needed to relate climatic change and variability to construction needs. The effect of climate on construction can be tackled from two directions and both seem to have roles in future research. The first is usually termed ‘top down’ and concentrates on making inventories of failures that occur (or have occurred) in the building stock. Analysis of this type of data can identify the parameters that seem to be associated with failure - for example rain penetration of building fabric - and also indicate how design guidance can be amended to overcome potential problems. Naturally, this type of approach is often closely linked to other research topics, in particular those associated with designing for durability and predicted service life.

The second approach is termed ‘bottom up’ and concentrates on the analysis of mechanisms by which agents (wind, rain, etc.) give rise to failure. At first this approach can seem likely to give more generally applicable results as it is more theoretically based and may well involve modelling of some form. However, experience in other fields, including the climate change modelling, have show that the width and complexity of the models, combined with many parameter uncertainties, can lead to substantial error bars on the final results. The ‘top down’ approach tends to be more empirical and although less widely applicable, may give more meaningful and useful results.

However, it is clear that the eventual goal must be to develop predictive equations or methodologies that allow assessment of the impact of changes in climate on a whole building, for example the wind load on a whole structure, the transport of rain onto the shell of a buildings or the thermal performance of a whole building.

5 Towards the future

The driving force behind much of the future research may well be economic pressure rather than a desire for knowledge. The investment needed to construct new buildings is substantial but the amount needed for repair or remedial works in response to extreme events can be many times greater and the insurance industry is taking a considerable interest in the prediction of climate change. There are also substantial costs associated with inappropriate designs for buildings, ones that do not perform satisfactorily in their present climate. Estimates of repair costs combined with lost productivity from the occupants have shown that during the lifetime of the building these costs can exceed the original construction cost.

It seems clear that we need to be able to optimise our building designs and choice of materials to both the requirements of the occupants and the present and future environment around the building. It is also clear that the optimisation must be an iterative process that includes both the use of the building, the occupants and increasingly the need for sustainable development.

For many hundreds of years mankind has striven to control his environment and to alter the climate of his immediate surrounding. We now believe ourselves in a position to do this but this is no time for complacency and we must continue to study and adapt our buildings to meet the demands of society and the ever changing world around us.

More sustainable construction using building systems based on pre-stressed concrete elements

F. De Troyer
Department of Architecture, Urban and Regional Planning, University Leuven, Belgium
Joint co-ordinator of CIB W24 “Open Industrialisation in Building”

Abstract
Sustainability should not be analysed only on the level of building products, like for instance floor elements. The whole structure should be considered, including beams, columns, foundations and other elements. Also the layout of the building may be influenced by the set of components available within a system. The layout has an effect upon the use of resources per metre square of floor area. The element method for cost control provides a well established tool for monitoring and controlling the quantity of elements per square metre of floor area. The density per floor area will not only affect the use of resources for the construction of the building, but also for maintenance and renewal. The density of external walls, roofs and floors will have consequences upon the use of energy per square metre floor. The layout of the building can also affect the required land and thus indirectly the use of energy for transport. The most challenging problems in Life Cycle Analysis are, besides the problem of definition of a “functional unit” as discussed above, : the selection of a manageable set of indicators, the definition of system boundaries and the determination of ponderation factors for the different aspects. The text proposes to solve those difficulties by replacing Life Cycle Analysis by Life Cycle Costing. Of course the remaining problem is to determine a socially acceptable price for scarce materials, for energy and land. The main advantage is that via a system of eco-taxes costs can clearly be allocated. A long term scenario for real price evolution creates a transparent situation. This requires however a certain political courage since it will become clear that the preservation of rights of future generations will reduce the real incomes. The eco-tax offers the possibility of income corrections. An other aspect is the functional lifetime of structures. Larger spans will increase the use of materials and energy, but will also facilitate adaptations of a structure in case of changing functional requirements. A longer lifetime involves a reduction of waste and consumption of energy for demolition and recycling.
Keywords : pre-stressed concrete elements, sustainability, system building.

1 Introduction

In Belgium, as in many other countries, several suppliers offer “open building systems” mainly based on pre-stressed floor-, roof- and beam elements for industrial halls, for office buildings, for commercial buildings, etc. Since “building systems” are developed to be produced during several years it becomes worthwhile to analyse their characteristics. In recent years there has been a significant emphasis placed on evaluating the sustainability aspects of these systems.

2 Life Cycle Analysis

In order to make a relevant comparison of the environmental effects between different solutions, a basis for comparison has to be established, called the “functional unit”. One square metre of storey floor can be considered as such a functional unit.

In a recent study [1] three types of floors were compared (see Fig. 1):

1. a pre-fabricated and pre-stressed hollow-core floor;
2. a “shuttering slab floor” composed of a pre-fabricated concrete permanent shuttering on top of which an in-situ concrete layer is applied;
3. a floor completely cast in-situ on a reusable mould.

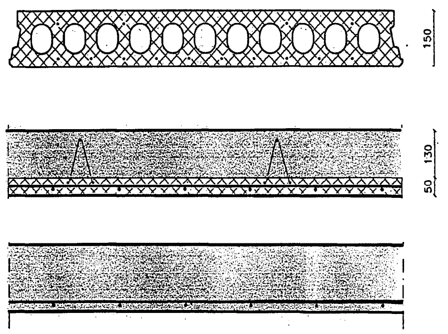

Figure 1 Three floor types

The most striking differences between the three alternatives is (Table 1) the fact that the mass of concrete and steel used per square metre of floor for the “hollow-core floor” is much less than for the other types of floors: only 62% for the concrete and ± 50% for the steel. The values are obtained for a span of 5.4 m and an overload specific for single family housing.

Table 1 : Mass in kg/m² floor

		shuttering slab floor	cast in-situ floor
concrete	263.7	423.0	423 .O
steel	3.2	6.4.	6.1

The second important difference is that for the “cast in-situ floor” propane heating is used to speed up the hardening in order to reuse the shuttering system. Each m² requires 3 litres of propane which should be converted into total energy content (including production and transport of propane).By analysing all the steps in the production cycle one obtains absolute values for the environmental effects; they can be grouped under the following headings (Table 2):

- Eutrophication: the accumulation of phosphorus and nitrogen in water, soil and air;
- Exhaustion of abiotic raw materials, mainly fossil fuel since marlstone or limestone are not scarce materials on a world-wide scale;
- Ecotoxicity: fluoranthene emission and propane production;
- Greenhouse effect: CO_2 and CH_4 emission
  Important here is that the contribution by Portland cement per kilo is three times greater than by blast-furnace cement. For the "hollow-core floor" 37.7 kg Portland cement is used per m² of floor and for the "shuttering slab floor" 16.0 kg Portland cement plus 43.8 blast-furnace cement per m² and for the "cast in-situ floor" 60.6 kg blast-furnace cement per m².
- Acidification: the deposit of acidification substances (NO,, SO_x, NH&
- Smog formed by the emission of hydrocarbons;
- Human toxicity by emission of NO_x, SO_x, CO and heavy metals.

Table 2 : Absolute values of environmental effects

	units	**hollow-core floor**	**shuttering slab floor**	**cast in situ floor**
Eutrophication	kg PO_4 10^{-3} eq.	0.0356	0.0448	0.0410
Exhaustion	10^{-12}	0.0468	0.062 1	0.0707
Ecotoxicitv	10^3m^3	2.78	5.52	5.81
Greenhouse effect	kg CO_2 eq.	55.2	58.6	53.4
Acidification	kg SO_2 eq.	0.252	0.321	0.306
ISmog	kg C_2H_4 eq.	0.0297	0.0453	0.0460
Human toxicity	kg	0.318	0.429	0.411

3 Basic problems for life cycle analysis

The most important problems related to Life Cycle Analysis (LCA)are:

- The selection of aspects considered in the analysis and their grouping in a manageable set of indicators.
- Definition of system boundaries: which steps of the production process are included and which are not, for example including production of energy carriers and all transport operations, but excluding production of capital goods.
- The gathering of reliable data for the different steps in the production. Improvements, as far as environmental aspects are concerned, require a regular updating of those parameters.
- If in one production step different (by-) products are obtained, an allocation of inputs and outputs over all the products has to be made.
- An integrated comparison: since in general some products will score better on some items and worse on others, the main problem is to develop objective criteria for the determination of ponderation factors for the different aspects.
- Waste and recycling: in this study 80% of the steel is (at the end of the 50 years) reused and 20% is unusable scrap; 70% of the concrete is reused for road construction, 20% is reused in new concrete and 10% is "lost" in the demolition process.

Each of the “problems” mentioned above requires a detailed technical discussion. In most cases pragmatic decisions have to be made since the elaboration of a “perfect” analysis will require an effort such that no results will be available in the near future. However, the danger arises that as a result, a single-value-indicator may be derived which will live its own life without all the critical considerations which should be added to this single value.

4. Pragmatic incorporation of key parameters

In view of all the methodological problems, one may suggest the formulation of the following policy:

- For dangerous emissions or for emissions which can easily be avoided, an interdiction should be imposed by the government (e.g. asbestos fibres for air ducts).
- Since many environmental effects (emission of NO_x, SOx,CH_4, CO, CO_2) are linked, directly or indirectly, to the use of fossil fuels, imposing an eco-tax on fossil fuels may be a pragmatic solution. Since the tax has to be paid for all the steps in the production process, the detailed reconstruction of the production chain is not necessary. In each step one will try to avoid as much as possible a high energy content. There is no “system demarcation problem” any more, even the energy for the production of capital goods is included. A socially acceptable transition period, where the cost of fuel increases from the present level to a socially acceptable level, has to be determined. Fundamental parameters are (Fig. 2): the final cost level (in real prices) (A and B), when the average between the current and the final level should be reached (A and C), how steep the slope will be (C, D and E).

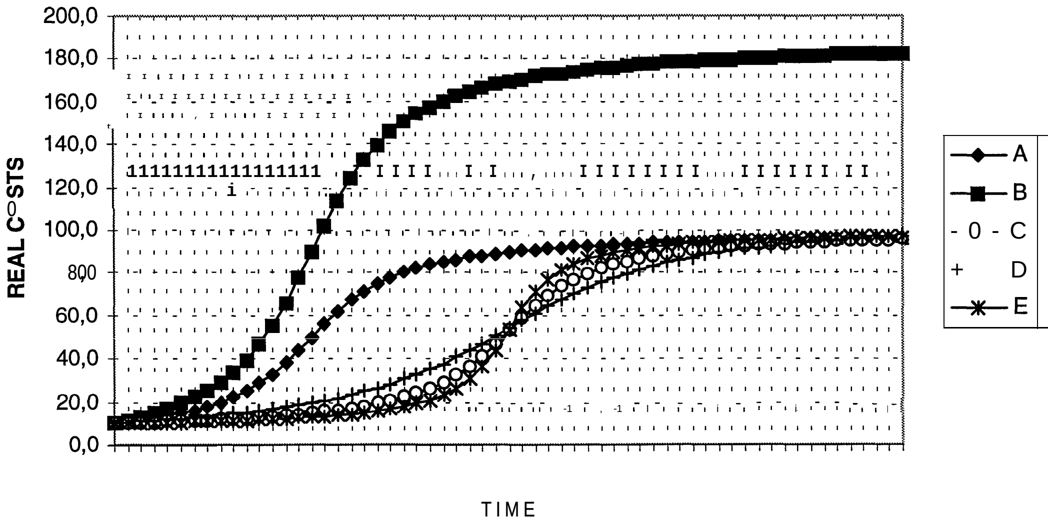

Figure 2 : Scenarios for the evolution of energy costs

5 Fundamental advantages of hollow-core floor system

What is the origin of the better score for the “hollow-core floor” in this analysis?

- First, the specific form of the floor section (I-shaped): the concrete is used in a more efficient way; there is less concrete in the middle of the floor element where the concrete contributes less to the resistance to bending forces.
- Second, the high quality concrete: since the concrete is processed in factory conditions, a closer monitoring of the process is possible, leading to a better quality and to less variation of the quality. This will lead to reduced safety factors without reduction of safety margins.
- Third, compared to the two other solutions, pre-stressed reinforcement of high quality steel ($Fe_{0.2}$ 1770/1860 instead of Fe 500) is used and so a reduction of the consumption of steel per metre square of floor is obtained.

6 Span as an important parameter

In the analysis presented above, the reference situation was a span of 5.4 m and a functional load for single family housing. Most pre-fabrication plants offer a range of floor elements with different thickness. In function of the superimposed load, when the span increases, one needs to use a thicker element. How the mass of concrete changes in function of the span for a given overload is represented in Fig. 3.

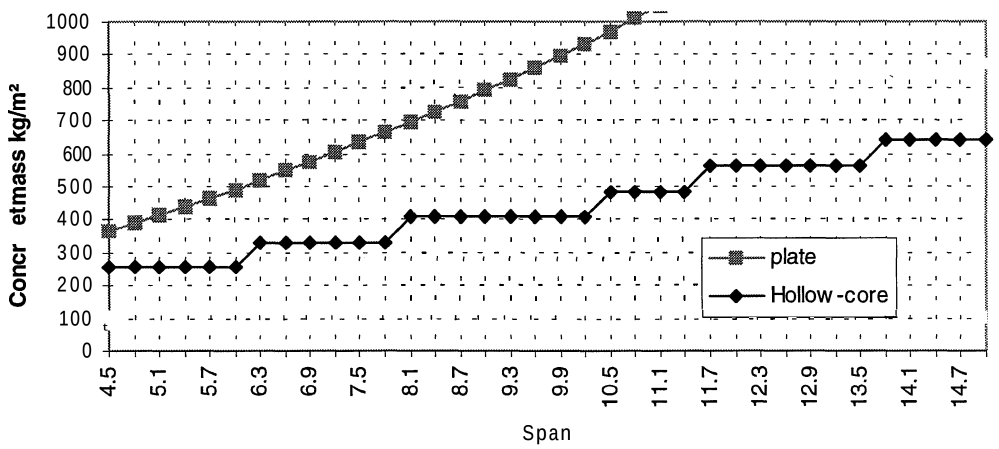

Figure 3 : Concrete mass /m² in function of span

The relation between the mass of concrete per square metre floor and the span (for the two types of floor) is also represented in Figure 3. The hypothesis here is that concrete and steel are used up to their limits. The longer the span the more significant the advantage of the hollow-core floor is in comparison to plate floor system. The inefficient use of concrete will, in the case of massive floors, lead to extra loads. From a certain span on pre-stressed elements are the only realistic solution.

7 Functional life time

By using longer spans, however, one also creates possibilities for changing the layout of the rooms without conflicting with the structure. This is extremely important for office buildings, hospitals, commercial buildings and industrial buildings. One should include in the environmental analysis the fact that, if one builds a structure with small spans, it may be unavoidable to demolish the whole structure after 10, 15 or 20 years. However, if a concrete structure fulfils the basic requirements of structural stability, fire resistance, acoustical insulation and other performance requirements, the structure may be in good technical condition for 60, 90 or even 120 years. If one considers the fact that with each demolition a fraction of the concrete (10% or more) and of the steel (20% or more) is "lost" and as well a significant amount of energy is required to demolish the structure and to transport and reuse the materials, the additional spending in larger spans may prove to be very efficient in terms of sustainability. Exact calculations require a number of hypotheses: e.g., end of functional life time, energy input for demolition and transport of recyclable fraction, type of new structure,. . .

8 Layout and sustainability

Linked to the question of selecting an appropriate span for the floor elements of a building is the problem of selecting the span of the beams [2]. For example, in the case of office buildings, the question is: is there (and will there be) a need for small cellular work spaces? (new needs due to expected speech-interactions with computers?); for landscape-offices?; or for a combination of working cells and open spaces? In function of the required flexibility, beams may be shorter or longer and may be provided in different positions (Fig. 4). One should not only look at the floor elements but at the structure as a whole including beams, columns, foundations and other elements of the

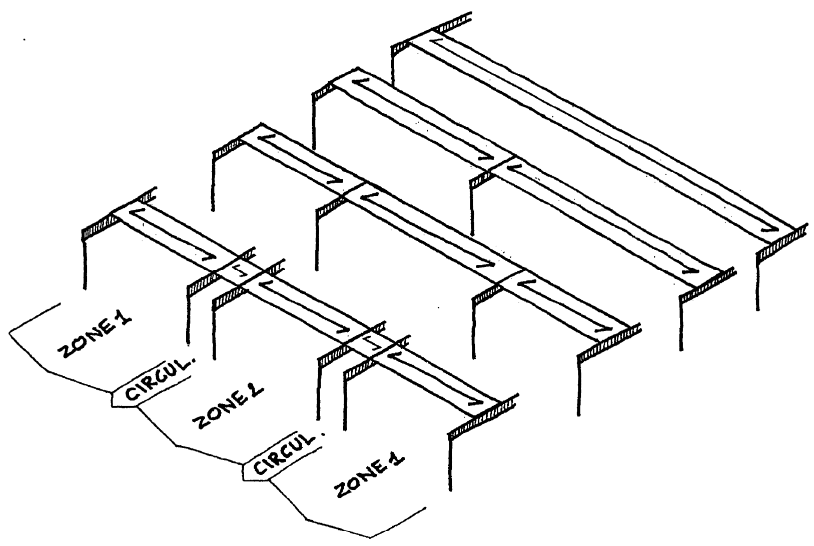

Figure 4 : Position of beams and span of floorelements

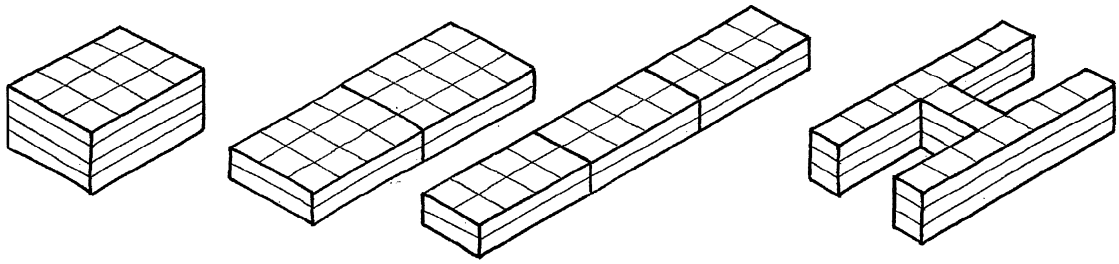
building.

In essence the decision is linked to the total depth of the building. Figure 5 shows four master plans for an office building. All of them have the same size. If we consider the quantity of roof, of external wall, of internal floor and of “floor on the ground” per square metre of usable floor, important differences are evident. These effects are controlled by the well established “element method for cost control”[3]. Following this method the cost per m^2 usable floor is obtained by the product of the unit rate of an element and the ratio of that element. The ratio is the “quantity of element/m^2 floor area”. For example in the case of a building with a ground floor and a first floor, the ratio for the first floor is 0.5 m^2 first floor/m^2 total floor. Ratios of some of the elements are mentioned in Table 3.



Plan 1 Plan 2 Plan 3 Plan 4

Figure 5 : Four different masterplans

Table 3 : Ratios for different elements (m^2 element/ m^2 usable floor)

	Plan 1	Plan 2	Plan 3	Plan 4
Roof	0.2500	0.5000	0.5000	0.3333
Internal floor	0.7500	0.5000	0.5000	0.6667
External wall *	0.5833	0.4583	0.5833	1.0625

* for basic block 6m x 6m x 3m

We can use as a “functional unit” (in the comparison of different answers to a need for usable floor area) one m^2 of floor area including all other building elements needed per m^2 floor area. Using this “ratio” not only are the quantity of inputs needed for the construction controlled, but also the present value of the costs per m^2 of floor for maintaining, demolishing, reusing and disposal. All of them are influenced by the layout and thus by the “ratio”. Different technical solutions for elements such as external walls, roofs and groundfloors will lead to other heat losses per metre square of those elements. The costs for heating per m^2 of floor area are linked to the cost per element via the “ratios”.

There is no direct link between the land use and the master plan: in fact it is possible to provide a very compact building on a very big plot. But it is impossible to reduce a plot more than the “footprint” of the building. Land use is not only important in the sense that land is a unique resource, but also because land-use-patterns determine energy consumption for transport.

9 Conclusions

The major advantage of building systems based on pre-stressed concrete floor-, roof- and beam elements is the reduction of the mass of concrete and steel used per m^2 of floor area (efficient form for bending forces, factory controlled concrete quality, high steel quality).For larger spans the advantages of pre-stressing are more significant. An often overlooked effect of using larger spans is that the same structure can easily be adapted to accommodate changing needs. This leads to a reduction of energy consumption for demolishing and recycling materials as well as to a reduction of the waste fraction.

Linked to the adaptability is the layout of the master-plan. Another layout has an effect upon the quantity of external wall, roof, groundfloor and other elements per metre square of usable floor area. In a more complete LCC-analysis, usable floor area should be used as a "functional unit" for comparison. Doing so also effects related to maintenance, repair, energy losses and other costs-in-use of elements such as external walls, roofs, groundfloors are linked to a square metre usable floor.

RECYCLING WASTE AS BUILDING MATERIALS: AN INTERNET DATABASE

V. M. John
Department of Construction Civil Engineering, Escola Politecnica, University of São Paulo (PCC/USP), São Paulo, Brazil
J. A. Tinker
Department of Civil Engineering, University of Leeds, Leeds, UK

Abstract
Environmental concern is expected to have serious implications for affect the construction industry in the years to come. The construction industry, including building materials production, is probably the greatest consumer of natural resources, using between 17 to 50 % of those available. Recycling wastes both from construction and other industries is one important alternative to reduce the impact of construction activities on the environment.

However there are some constraints in using recycled waste as building materials , due to lack of information, research and development technology. Market and technology differences between countries make some recycling technologies successful in some instances but not in others.

An methodology outline for guiding research and development of building materials from recycled waste is presented in this paper and it's main steps are summarized.

Waste characterization is the first step of the study. The selection of possible applications for the waste must consider both the technical and market aspects. Laboratory research must be based on a scientific approach and performance concept. Durability evaluation is an important phase of the study and the service life of any new material will affect not only its economical feasibility but also its environmental impact.

A web site including a database about recycling waste as building material has been build and is available on the Internet. The database includeswaste and some basic information aboutthem, references and reports with researchers names. It is possible to everybody feed the database with new information. The address of the web site is http://www.recycle.pcc.usp.br.
Keywords: Recycling, methodology, database, Internet, sustainable development

1 Introduction

Environmental consciousness is considered as being one of the most important trends in the construction industry [1].

The construction industry, including building material production, is probably the greatest consumer of natural resources, using from 17 to 50 % of the extracted „resources, as water, wood, minerals and fossil fuels [2]. These figures are probably greater in poorer countries. The consumption of natural rock for aggregates to make concrete, asphalt, and road base ranges between 1 to 7.7 tones/year/inhabitant [3]. One author estimate that building construction uses about 66 % of the virgin wood, a potentially sustainable material [4] but only 20 % of the tropical forests that supply most of hardwood are managed in a sustainable way [3]. Some of the materials consumed on a large scale are subject to shortage in the near future. These include copper and zinc, which have estimated reserves for about 60 years [5].

The construction industry is also one of the biggest waste generator in the economy. In developed countries like USA and Germany, the amount of waste generated by the construction industry is comparable to municipal solid waste generation [4]. In the big cities of poorer countries like São Paulo, the waste generated by construction and demolition activities is 2.3 times greater than the municipal solid waste [6]. Almost one third of this construction waste is illegally placed outside of landfill, polluting the environment, obstructing rivers, and promoting floods during the raining seasons. For each tonne of steel produced about 700 kg of waste are generated, including about 300 kg of blast furnace slag.

The construction industry also generates air pollution ranging from CO_2 during limestone burning to airborne particulate material during site operations.

Reducing the environmental impact of the construction industry is a complex situation and certainly will include the environmental motif "Reuse, Reduce and Recycle". Re-using building components and reducing the consumption of energy and raw materials, including making the building more durable, will play an important role. But no matter how much the industry succeeds in reducing the natural materials consumption, making and maintaining buildings, roads, bridges will always consume large amount of materials and recycling waste produced by different industrial sectors seems to be vital.

2 Main recycling constraints

The construction industry has a long history on recycling. Recycling granulated blast furnace slag as a hydraulic binder, for example, started at the beginning of the 19th Century and in the beginning of the 20th Century the Portland slag cements were on the market and covered by standards [7]. Despite of the technical and environmental advantages of this kind of cement, it is not permitted to mix Portland cement with slag in some countries, like Argentina.

These differences in recycling policies between countries are not exception but a rule. Colliery spoil from coal extraction is recycled in China and the UK [3] but not in Brazil. This happens because recycling waste has some constraints.

2.1 Market differences

Differences in building materials market between countries or regions are frequently important. These differences can make one recycling technology economically viable in one region but not in other one. It occurs specially because the environmental impact of recycling is not considered at all in most of countries.

2.2 Lack of suitable research methodology

Standards and regulations, including those that are related to solid waste disposal and classification severely restrict recycling possibilities [9]. Most solid waste regulations are concerned about waste disposal and contain no rules that facilitate recycling. Standard leaching tests, for example, are developed to control groundwater contamination by a landfill, which can concentrate huge amount of dangerous waste. It clearly doesn't apply to a waste widespread over a large area, like when a waste is recycled as building material. In addition, it does not take into account the decisive influence of the size, shape, water absorption, and evaporation that causes leaching in real materials as well as the influence of the environment.

The main problem here is probably the lack of a consolidated and widely accepted systematic methodology to guide research and development and environmental risk evaluation for recycling technology. On the other hand , technical standards for the building industry almost enforce the use of traditional materials and components. Technical Approval's schemes, must also rely on a systematic methodology for environmental risk evaluation, could be a good solution to this problem. In addition, eco-label schemes can made good recycled products even more attractive to consumers.

2.3 Construction technologies

Differences between indigenous construction technologies also have a similar effect on the development of any recycling market.

2.4 Lack of information

Lack of reliable information about both successful and unsuccessful recycling technologies and expertise also plays an important role. Most waste producers have little association with the building industry and for this reason, they are not able to foresee possible applications. If they do succeed in detecting an application, they often take a long time seeking researchers with proper experience in develop new building material from recycled waste. Lack of information also affects research activities. The lack of knowledge about potentially recyclable waste can partially explain the concentration of research on blast furnace slag and fly ash. A web-site can contribute to widespread information about waste and recycling waste as building materials.

2.5 Recycling strategy

A poor recycling strategy can also contribute to keep some waste out of the recycling process. Most industries try to sell waste as waste, and as such, the consumer of the waste have to have the knowledge of recycling. This strategy works for some simple recycling technologies that are easy to develop or for those tremendously profitable. However, in most cases no potential consumer wants to bear the risk of financially supporting the research and development of a recycling technology for a product that belongs to someone else. The high cost of waste deposition and possible profits of recycling can however persuade a waste producer to invest in research and development.

3 Recycling research and development methodology

A recycling research and development project is always a comprehensive and multi-disciplinary study. A proposed outline of a methodology is presented.

3.1 Waste characterization

The first step in any research and development project must be the characterization of the waste, including any production parameter and a comprehensive physical and chemical analysis which considers it's variability with the time and environmental risk.

3.2 Selection of possible application

The next and the single most important step is selection of possible applications must consider both the technical and market aspects. From the technical point of view there is frequently more than one possibility for recycling. The selection of the most suitable alternative depends upon market evaluation, which must be based on a comprehensive knowledge of both the construction market and construction technology as well as a good estimation of the economic feasibility of each alternative.

Developing a cheap material may not lead to success in the market. For example, blast furnace slag activated with lime or sodium hydroxide was on the European and even North American market until the end of the 1940's. Even though this cement was cheaper than Ordinary Portland Cement, it vanished from the market because of it's poor performance regarding frost resistance and low initial strength [7]. Finding an application where the new product has a better performance than any other alternative already in the market is the most important thing.

Economical feasibility must be evaluated by comparing the cost of waste disposal in an authorized landfill against the cost of recycling.

3.3 Product research and development

It starts with very basic research and goes on to a complete performance evaluation, which includes durability and environmental impact. Development of the process of production, including the appropriate quality control tests, must also be covered.

The research must be conducted on a scientific basis in order to ensure complete knowledge about the new material properties. The evaluation of the new product must be carried on by considering its fitness for the purpose. It could be based on CIB W 60 [10] methodology and IS0 624 1.

Indoor air quality must be carefully considered when studying wastes containing volatile organic components. The use of standards developed specifically for traditional but similar material or components is not adequate and can give the wrong results. Tests must elucidate the main degradation factors, degradation mechanisms and the effect of these processes on the performance.

Not all recycling is environment friendly and therefore environmental impact has to be evaluated on cradle-to-grave basis.

3.4 Technology transfer

Unfortunately, few research programs dealing with recycling have been designed to facilitate the transfer of developed technology to the market and for this reason, most of them never reach the production stage.

Technology transfer must be planned from the very first phase of the research. Successful joint research and development projects will include a research institution, the waste producer and a company that expects to manufacture the new material. Of course, selecting the appropriate application for the waste is also critical.

Wide dissemination of research results to building entrepreneurs and consumers is also helpful to create good expectations in the market before the product is actually ready to be sold.

After the development is completed is important that the researchers give continued support to the producer to ensure the product get a technical approval and the proper environmental certificates.

4 Diffusion information using an Internet database

As mentioned previously, dissemination of information on potentially recyclable waste, research expertise and any research results could not only help other researchers but the society in general.

It has been the aim of this research programme to develop a database that is accessible through Internet by a plain Web connection. This database include:

1. Internet data sources and web-sites;
2. Potentially recyclable waste as building materials and their main characteristics
3. Waste recycling alternatives, both proved or possible;
4. References of papers and reports;
5. Researchers names, including the addresses if available.

The database is a relational one, built over a SQL server. It is fully indexed using a controlled vocabulary, making it easy and reliable in any search. It is possible feed the database with new information which will be available at the web site as soon as its consistency is checked.

The web site also includes short reports and texts and its address is http://www.recycle.pcc.usp.br.

5 Final remarks

Environmental concern is expected to deeply affect the construction industry in the years to come. Recycling wastes both from construction and from other industries is one important alternative to reduce the impact on the environment.

There are many constraints which make it difficult to develop a waste into a new material. These constraints include lack of information, lack of research methodology, poor recycling strategies from waste producers as well as differences in market and construction technologies between countries.

The development of a new product through waste recycling must include product characterization, careful evaluation of the market and technical acceptance of the recycling option, a scientific based research that includes the evaluation of the environmental impact of the recycling, as well as technology transfer.

Abstract
Absorbed water is the main deterioration factor of building materials, mainly for external wall surfaces. These surfaces can be protected by paints which may reduce the volume of absorbed water from external sources. At the same time, mould growth on coated external wall surfaces is also an important durability problem. A knowledge of the degradadion factors is important for increasing the service life of paintwork and for reducing maintenance costs. The rate of absorption and evaporation of water through the paint film affects the moisture content in the substrate. This property is also related to the time of wetness which affects the growth of fungus. In order to understand the water transport mechanism, the water absorption and evaporation of latex paints with different pigment/binder ratios was studied. The tests were done applying paints to mortar and concrete substrates. The results show that there is a correlation between paint composition and the rate of absorption and evaporation of water. Furthermore, the study also showed that acrylic latex paints provide a good barrier to water penetration. However, the substrate also has an effect on water transport mechanism. It was concluded that a functional substrate reduces the absorption and evaporation rates of paints, it is recommended to dry the substrates and protect them with acrylic paints. Improving the knowledge of the paints it is possible to increase the durability of the painted wall without adding toxic ingredients and doing so avoiding human and environmental hazards.
Keywords: humidity, latex paints, mould growth, permeability, service life, maintenance costs, degradation factors, time of wetness

1 Introduction

The external walls of buildings built in São Paulo are usually composed of mortar and concrete which are porous materials, and therefore permit water penetration from rain and wind. Absorbed water is the main deterioration factor of building materials. In order to prevent water penetration, the walls can be protected by paints that provide a polymer film barrier on the wall surfaces by reducing the volume of water transported through them. As such, coatings have an important role in limiting water penetration into the wall. As well, the availability of water in building materials is the key factor that leads to the growth of microorganisms. Microbial growth in external painted façades is considered to be one of the major and more significant maintenance problems in particular throughout the sub-tropical and tropical regions of the world [1,2]. Therefore, the presence of biological microorganisms is the most significant factor in the performance of paints in the regions when aesthetic performance is of prime importance. Usually these organisms are not destructive but they do produce disfiguring stains on wall surfaces.

Paints are formulated products designed to provide both a decorative finish and to protect the underlying substrate from environmental effects. They contain binders (resins), pigments, fillers, stabilizers, surfactants, solvents and thickners. The binder, sometimes called the vehicle, is essencial for film formation. The composition of the binder is of major importance to the film's properties, even though these properties are also modified to a considerable extent by the use of pigments. The pigments not only control color, gloss and hiding power, but also affect the strength and permeability of the paints [3].

It is necessary to consider the effect of the proportion of pigment in the paint in order to achieve a proper dispersion. This proportion is expressed as the pigment-binder ratio (P/B), usually calculated on a volume basis. For instance, the gloss decreases as the pigment-binder ratio increases but the relation is not a simple one and the changes are normally most rapid in the range from 0.9: **1** to **1.1: 1** [3]. An alternative way of expressing the same information is in terms of the pigment volume concentration (PVC) - the volume of pigment expressed as a percentage of the total volume of dry film (pigment volume + vehicle solids volume) [4]. The porosity of film is related to the type and content of pigment used. Films of paints with high PVC content present high porosity and consequently high permeability to water and water vapour.

This paper presents part of a research work dealing with mass transfer studies in order to improve the durability of building materials. It is an attempt relate to the volume of water transport through a latex film in relation to different pigment/binder ratios.

2 Experimental procedure

To evaluate the performance of paints in inhibiting the ingress of water in a substrate and to determine the drying process as well as understand the water transport mechanism through latex paints, 8 paints with a different PVC were applied on one mortar and two kinds of concrete substrates. The method used is based on the comparison of measurement of the water absorption by capillarity and evaporation over a length of time in painted and unpainted substrates.

2.1 Materials

2.1.1 Mortar

The mortar samples were prepared in laboratory, with CP II-E Brazilian Portland cement (ordinary Portland cement with addition of BFS up to 34% in weight), hydraulic lime and medium river sand, with a commonly used mix proportion (1:2:9, by volume). After casting, the mortar specimens were kept 7 days in a wet chamber having 95% relative humidity and then stored more than 30 days in a laboratory environment having 25 ^{o} ± 2 ^{o}C and 50 ± 5 % RH.

2.1.2 Concrete

Two differents concretes were used in these tests: one having a relatively high strength (40MPa and w/c 0.44) and the other with ordinary strength (20MPa and w/c 0.76). They were prepared using CP II-E Portland cement, coarse crushed aggregate (maximum size of 19 mm) and medium river sand. After casting, the concrete specimens were kept 7 days in wet a chamber having 95% relative humidity and then stored 21 days in a laboratory environment having 25 ^{o} ± 2 ^{o}C and 50 ± 5 % RH.

2.1.3 Paints

Latex paint products commercially available in São Paulo and commonly used in exterior building walls were collected for the study. The products consisted of pigmented latex, with PVAc and acrylic binder from different manufacturers, each having different gloss and matt finishes. The products were applied according to manufacturers' instructions: two coats were applied to all specimens and cured for two weeks. Table 1 shows the main characteristics of the emulsion paints and the pigment/binder ratio (g/g).

Table 1 - Characteristics of the paints

Product	Solid content (%)	Pigment content (%)	Binder content (%)	Pigment/binder ratio
Acrylic 1 (gloss)	50,2	24,3	26,0	0.9
Acrylic 2 (matt)	56,5	40,2	15,7	2.6
Acrylic 3 (gloss)	45,8	24,4	21,8	1,1
Acrylic 4 (matt)	49,3	37,6	11,7	3,2
PVAc 1 (matt)	50,7	36,1	14,6	2,5
PVAc 2 (matt)	40,4	31,2	9,24	3,4
PVAc 3 (matt)	51,9	45,6	6,32	7,2
PVAc 4 (matt)	49.1	33.8	15,2	2,2

2.2 Methods

2.2.1 Water absorption

The testing methods were based on the British Standard [5] with a few alterations to cope with the purpose of this research work – water transport mechanism study. Mortar and concrete specimens with 10cm x 10cm x 2cm were sealed with a silicone sealant on the 10cm x 2 cm dimensions faces. One set of these specimens was used as reference samples and another set had one of the unsealed faces painted. The 10cm x 10cm dimension surfaces of both the painted and the unpainted sets were faced down on deionized water, with those of the painted face placed painted side down. The gain of water was determined by weighing the specimens at predetermined time intervals. The measurement was done until the unpainted reference samples achieved complete saturation. The tests were done in an environment with 50-60% relative humidity and a temperature of 25°C. The results were plotted shown in terms of mass change as a function of time.

2.2.2 Evaporation of water

After the water absorption test, all specimens were partially immersed in water with the unpainted surface face down, until saturation of the substrates. Later, this face was sealed with aluminium foil and the specimens were allowed to dry with the unsealed surface exposed to an environment with 50-60% relative humidity and 25°C. The loss of water through the unsealed face was measured by weighing at predetermined time intervals, until a constant weight was reached.

3. Results and comments

3.1 Mortar substrates

The water absorption and evaporation characteristics of the mortar substrates was determined in relation to the eight latex paints. The relative change of water content in test specimens, unpainted and painted with PVAc latex and acrylic latex is shown in Figure1 to 4.

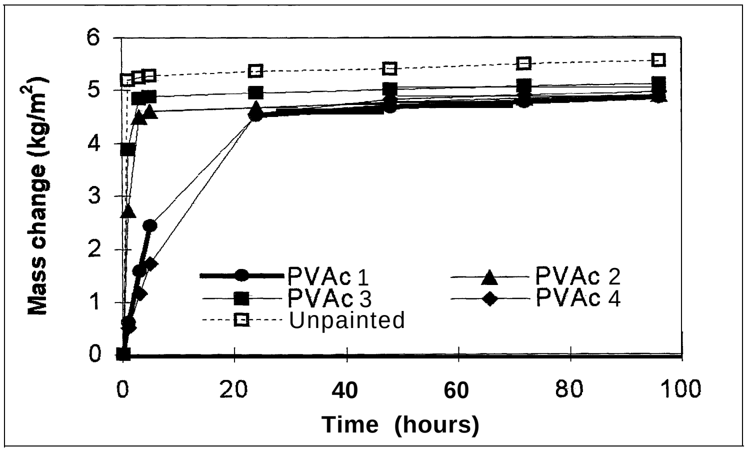

Figure 1 Water absorption of mortar, unpainted and painted with PVAc latex

The tests carried out in specimens painted with PVAc latex paints, with different pigment/bider ratios, showed similar performance. The water absoption after 96 hours immersion was reduced bv not more than 20% for all the painted surfaces when compared to the unpainted one.

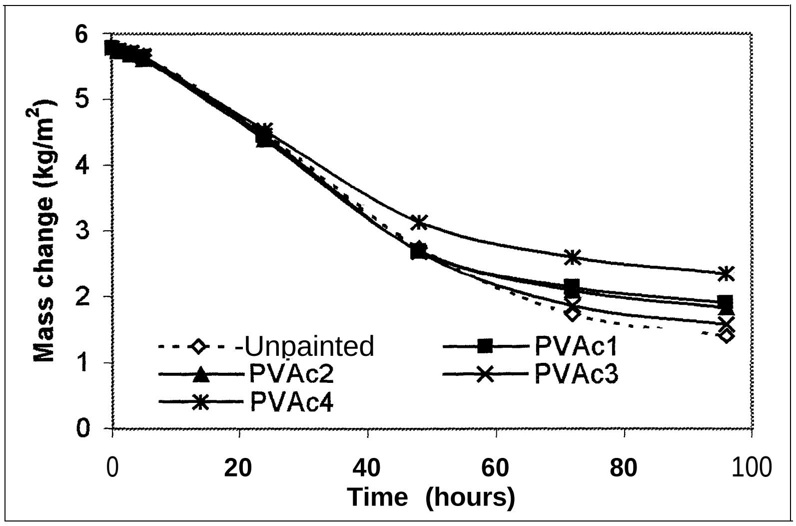

Figure 2 Water evaporation of mortar, unpainted and painted with PVAc latex

The evaporation rate after the same period showed a relative reduction of 10-26% after 96 hours of drying. In general, the effect of PVAc paint on water transport reduction was not significant. Moreover, as the paints are from different manufacturers the binder composition may be different and this most likely masks the possible effects of the P/B ratio on the transport properties of the paint. Therefore although products PVAc 1 and PVAc 4 provided relatively better results in relation to the other products, these are not clearly evident from the results.

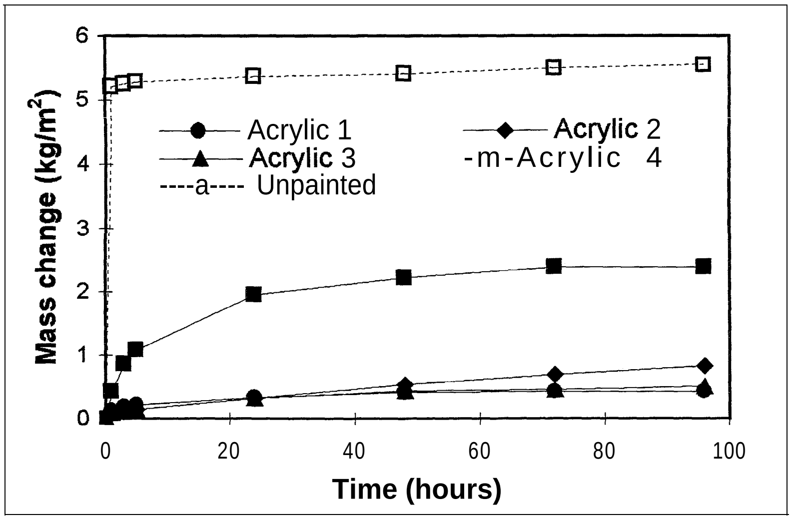

Figure 3 Water absorption of mortar, unpainted and painted with acrylic latex

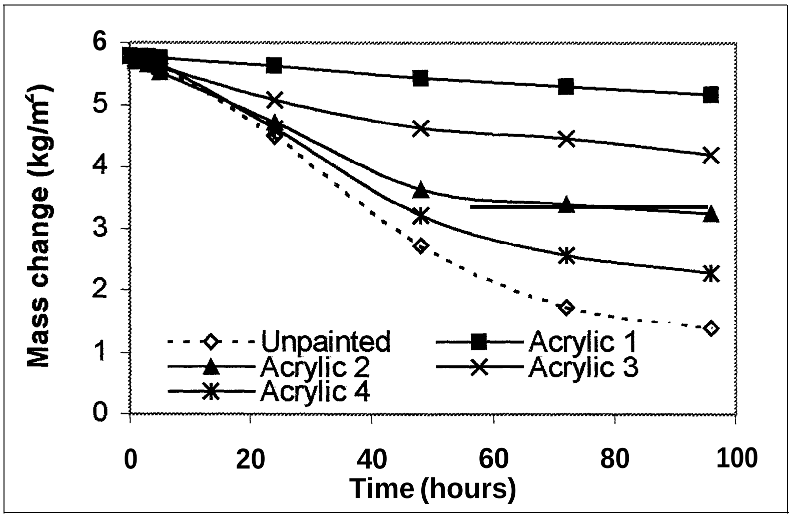

Figure 4 Water evaporation of mortar, unpainted and painted with acrylic latex

The same tests carried out on specimens painted with acrylic latex paints showed that **3** of them have a very similar performance and only the Acrylic 4 behaves differently. This is because the paint Acrylic 4 paint has a considerably lower binder content in comparison to the other products. The Acrylic **1, 2** and **3** products (low pigment/binder ratio) showed a relative reduction of 90% in water absorption. It is possible to conclude that these types of coatings provide an actual barrier to water penetration however, the evaporation process is retarded.

3.2 Concrete substrates

From the previous results, this part of the study was carried out with the two acrylic paints produced by the same manufacturer but having opposite performance. Figures 5 and **6** show the relative change of water content in test specimens, unpainted and painted with acrylic latex, gloss and matt finishes.

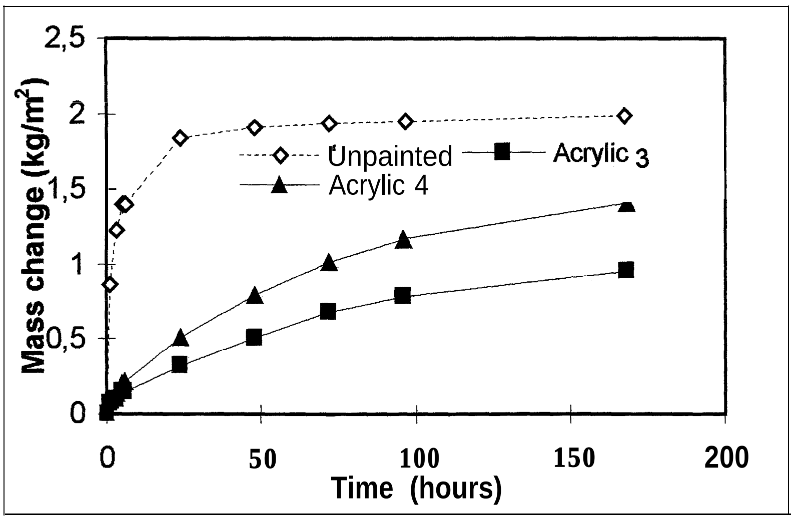

Figure 5 Water absorption, concrete (20MPa), unpainted and painted with acrylic latex

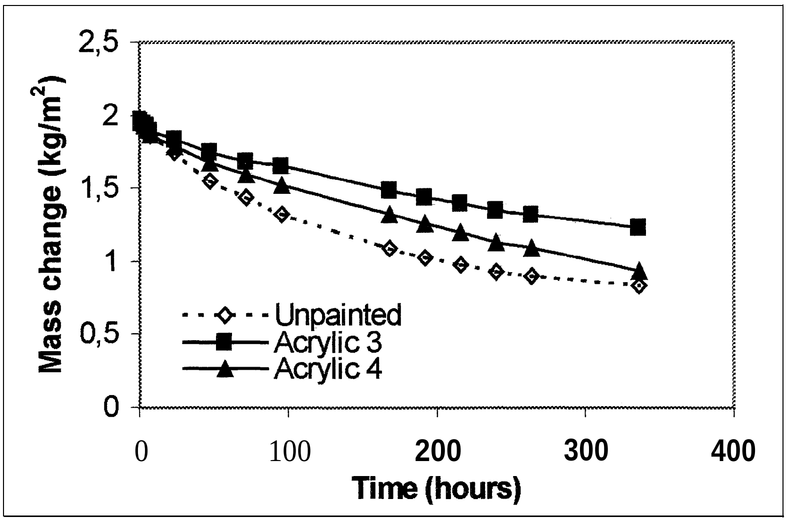

Figure 6 Water evaporation of concrete (20MPa), unpainted and painted with acrylic latex

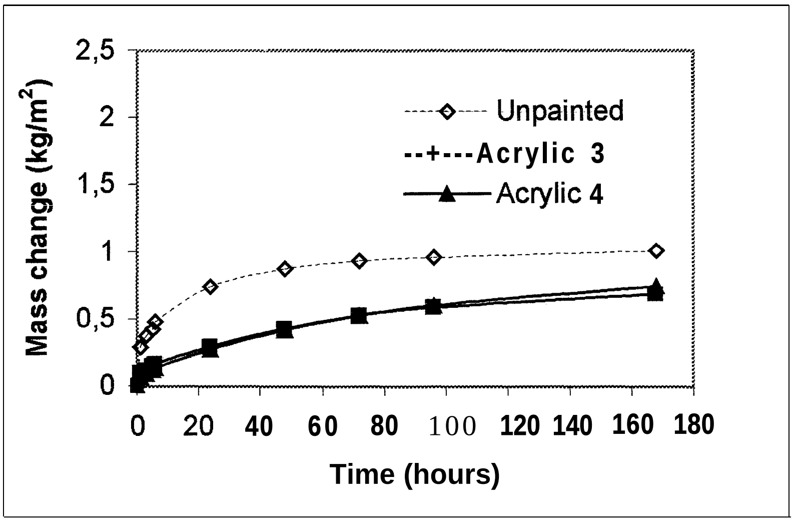

Figure 7 Water absorption of concrete(40MPa), unpainted and painted with acrylic latex

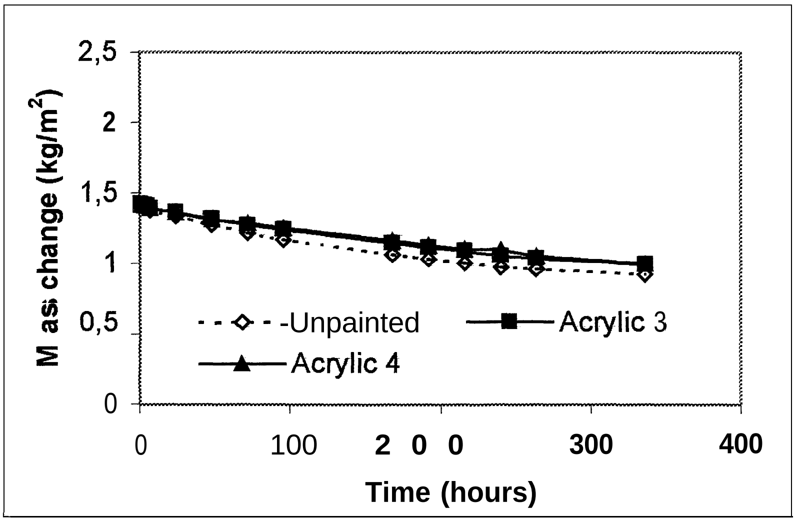

Figure 8 Water evaporation of concrete (40MPa), unpainted and painted with acrylic latex

The tests carried out on ordinary concrete (20 MPa) specimens painted with acrylic 3 latex paint (gloss finish and low pigment/resin ratio) showed a relative reduction of 50% in 168 hours of water absorption, but acrylic 4 (matt finish and high pigment/resin ratio) showed a relative reduction of only 30% in water absorption. These types of coatings provide a good barrier to water penetration although the evaporation process is also retarded. Therefore it appears that the binder content affects both the water absorption and evaporation rates.

The tests carried out on high strength concrete (40 MPa) specimens painted with acrylic latex showed that the substrate also has an effect on absorption and evaporation rates as the values are quite different from those obtained on specimens painted on ordinary concretes (20 MPa) (Figures 5 and 6).

4. Conclusions

As was expected, the pigment/binder ratios play a major role in the performance of the paints, as they affect the moisture content of the wall. However, there is no data available about the moisture content considered suitable for this purpose in international or Brazilian standards or codes, nor are results of published research. As claims from users are very frequent, the strategy adopted by producers has been the washing of painted surface with biocidal products and recoating the walls with a fungicidal quality paint. The major achievement of this paper is to demonstrate that with a better knowledge of paints it is possible to increase the durability of the paintwork without adding toxic ingredients and so doing, avoid human and environmental hazards.

It is possible to conclude that PVAc based paints present basically an aesthetic function, as the absorption process is rapid for painted mortar substrates and the drying process is slightly slower. The water is absorbed very easily and the residual water is not easily eliminated, creating good conditions for mould growth in rainy seasons.

Acrylic latex paints provide a good barrier to water penetration although the evaporation process is very retarded and the residual water is not easily eliminated. As, substrates with high water content present good conditions for biological microorganisms growth. These paints have to be applied only in very dried substrates to avoid creating good conditions for mould growth.

The substrate also ‘has an effect on the water transport mechanism. The concretes with low water/cement ratio itself present low absorption and evaporation rates. It is possible to conclude that a low permeable substrate does not need protection against water penetration. In summary, it is recommended to dry the substrates and protect then with acrylic paints.

Acknowlegments

The authors would like to thank the FAPESP - Fundação de Amparo a Pesquisa do Estado de São Paulo (State of São Paulo Foundation for Research Support) for funding this research work. The first two authors have FAPESP scholarships for their D. Eng. Degree studies.

A causal path model to evaluate the environmental impact of frame materials.

S. J. Allwinkle and A. W. Brown.
Building Performance Centre, Napier University, Edinburgh, Scotland.

Abstract
The previous decade has seen an increased emphasis placed upon assessing new construction projects in relation to the impact that they have upon the environment. The impact of construction projects upon the environment requires to be appraised both in relation to the product, in terms of Life Cycle Assessment (LCA) and in relation to the processes that are employed to produce it (Environmental Effect Assessment). In this regard, to properly understand the impact of construction projects upon the environment, it is necessary to analyse the resource consumption for the production of new buildings; to analyse the level of waste that is involved in the production process; to undertake Life Cycle Assessments for each component, product and material incorporated within buildings; and to analyse the deconstruction methods available for the disposal of construction assets at the end of their usable lifespans. The material used to construct the structural frame within commercial buildings is considered to be of importance in connection with understanding the impact that contemporary construction projects have upon the environment in relation to the aforementioned analysis.

Research work at Napier University has developed an approach to assess the significance of the frame material in relation to the environmental impact of building projects. This approach is based upon a causal path analysis that is considered to be particularly suitable for quantifying the relative importance of individual variables in an overall set of interrelated variables that are expected to influence a given dependent variable. The method is appropriate for testing intuitive ideas or beliefs concerning which variables are of most importance in determining an outcome in a statistically rigorous manner.

This paper presents the results of this research towards developing a full causal path model which will provide for a quantitative evaluation of the relative importance of alternative frame materials upon the overall environmental impact of building projects in connection with the assessment criteria detailed.
Keywords: Frame material, environmental assessment, causal path modelling.

1.0 Introduction

The UK market for framed building structures of two or more storeys is estimated at £1.5 billion per annum. Approximately £390 million of that figure is expended per annum on the construction of in- situ concrete frames. The remainder is expended on the construction of steel frames. Thus the share of the frame market presently held by steel construction is considerable. However, the concrete industry is presently challenging the present position by rigorously investigating its effectiveness and efficiency in order that it may compete with the steel industry in the area's where it is generally accepted that steel framed construction has major benefits; principally in relation to the speed of erection and the technical precision of frame assembly. To achieve its aims and to grow its market share, the concrete industry has involved itself in a £1.2 million research programme having as its principal aim the overall improvement of concrete frame performance [1]. The European Concrete Building (ECB) Programme (established by companies and trade associations working in the concrete industry and in its supply chains together with the UK's Building Research Establishment (BRE)) has provided the impetus for the above research programme, which aims to improve the quality of concrete design, to reengineer the concrete frame construction process and to improve structural performance.

Designers and concrete practitioners believe that the traditional design codes are too conservative and that, being based on individual elements, they do not appropriately appraise the inherent strength of a complete structure. As a result the above research programme sets out to rigorously investigate features such as thin plate floors, unobstructed soffits and pre- manufactured steel cross bracing and shearheads.

2.0 Requirement for an environmental appraisal

Clearly, the competition between the different frame materials as briefly described is presently based very much upon technical performance issues and upon on- site assembly processes which relate mostly to the time period which elapses between beginning work on the structural frame itself and allowing subsequent building assembly tasks to commence upon that frame. Such a basis for competition is not considered to be entirely inappropriate, since the efficiency of constructing the frame for buildings of two or more storey's is clearly of importance not only to the overall construction cost borne by the client organisation, but also to the overall construction time and, therefore, to the overall success of building project delivery from the client's perspective. However, it does mean that the primary basis of competition between steel and concrete frames is presently focused upon only technical and economic criteria. Little or no regard is paid to the differences which may exist between steel and concrete frames in relation to their overall impact upon the environment, throughout the life cycle of the construction project. With the exception of studies carried out to compare the in-use thermal performance of concrete and steel framed structures, little work has been undertaken to compare the environmental performance of the structural frame in relation to its role in the overall environmental impact produced by the building project process.

This study aims to address this deficiency and begins to address the process of applying environmental analyses in the complex case of the overall processes that are involved in the contemporary building project. The work is preliminary, however, a provisional causal path analysis model has been developed in an attempt to quantify the importance of the frame material in determining the overall impact of new construction projects upon the environment. Considering the demands which are now placed upon construction projects to be sustainable and environmentally sound, and considering the competition between the steel and concrete industries in relation to the future provision of structural frames, the present work is considered to be both appropriate and timely.

3.0 Environmental analysis

3.1 Basic environmental impact analysis

Environmental analysis techniques are relatively new and academic investigation of these is continuing towards developing agreed codes and standards that should be adhered to when undertaking environmental evaluations. Historically, the evaluation of products in relation to the impact that they have upon the environment has generally examined four main areas; namely, the energy use involved in their production, the air pollution involved, the water pollution and finally, the level of solid waste involved. Contemporary studies continue to examine these areas, however, the scope of environmental analyses has been extended. At the present time an appropriate environmental assessment may be considered to comprise an analysis of the environmental effects which are related to:-

- Resource consumption;
- Pollution (waste, emissions and discharges); and,
- Social and Welfare effects;

In attempting to realise the objectives of the present research, it is considered appropriate to investigate the environmental differences between steel and concrete framed structures in connection with the environmental effects of each over the whole life cycle of the contemporary building project.

In this regard *Life cycle assessment* (LCA) is of principal importance. LCA has been defined as a systematic inventory and a comprehensive assessment of the environmental effects (ie. resource consumption, Pollution and Welfare effects) of two or more alternative activities involving a defined product in a defined space and time including all steps and associated products involved throughout their life cycles [2].

In other words, a life cycle assessment is a comparative evaluation of *all* aspects of particular products, which must by definition must serve a specific function, as they relate to the environment (the products which are the subject of the assessment may be termed the *primary* products). Furthermore, it is an analysis of the environmental effects that are associated with all of the complementary products and processes which are introduced to a particular system by the selection of the primary product.

3.2 The inapplicability of existing analysis methods

The process of undertaking an environmental life cycle assessment is highly data intensive and rigorous and requires a series of relatively well defined steps and procedures to be followed. The products in question, the associated performance specifications and the functions require to be analysed to ensure that the investigator is undertaking consistent comparisons. However, the life cycle assessment process is not concerned with the comparison of particular products themselves but is rather concerned with the function that must be realised; the products are subsequently analysed in an attempt to determine which most appropriately (in terms of environmental effects) delivers the identified function. In conventional life cycle assessments, the function may be quantified in terms of *the functional unit of product.* Thereafter (in theory at least), the products being assessed in a given LCA should deliver 'equal amounts' of the identified functional unit in order that a valid comparison is realised. The environmental effects are then assessed in relation to the delivery of that function. This is relatively straightforward for a well defined product or service which has a clear function that is to be realised by its use. The most basic function of a structural frame may be described in terms of a requirement to transmit the loads in a building (quantified in kN per m^2) safely from the points where they occur, to the building foundation.

This is the most fundamental definition possible, however, obtaining a measure for the ***functional unit of product*** from this definition is not straightforward. First, the total loads to be supported by the frame are dependent upon the frame material. Therefore, a distinction must be made between the live loads and the dead loads; the latter being determined principally by the frame material. Second, the live loads to be supported by given frame are determined by the functional purpose of the building itself (rather than the frame). In other words, the live loads to be transmitted by the frame for a shop are substantially different from those for an office. Consequently, to validly assess which material is most appropriate for the structural frame in buildings generally, in relation to the environmental impact, a series of conventional LCA's are required in relation to different building types. Third, it is arguable whether or not a structural frame may be considered to be a ***product*** in itself. Rather, it is a sub- product of a building which is itself the usable product. This, of course, does not mean that an LCA using a functional unit of product defined in relation to the load per square metre to be transmitted safely to the foundations would be inappropriate. However, it is a fact that the material selected for the frame has so many substantive effects upon the design and construction processes and the completed building product itself that the product and sub- product analysis chains are vast and immensely complex, making the process of data gathering and analysis for a conventional LCA approach intractable and impractical. Many of the implications related to the selection of a particular frame material are not directly related to the fundamental function of the frame itself (as this has been defined), however, they do nevertheless have conceivable environmental effects which do require to be analysed in order that a comprehensive assessment is delivered. Figure 1 illustrates some examples of the complexity that is involved in relation to the effects of the chosen frame material (this is a simplified representation and by no means does figure 1 illustrate the overall complexity that is involved).

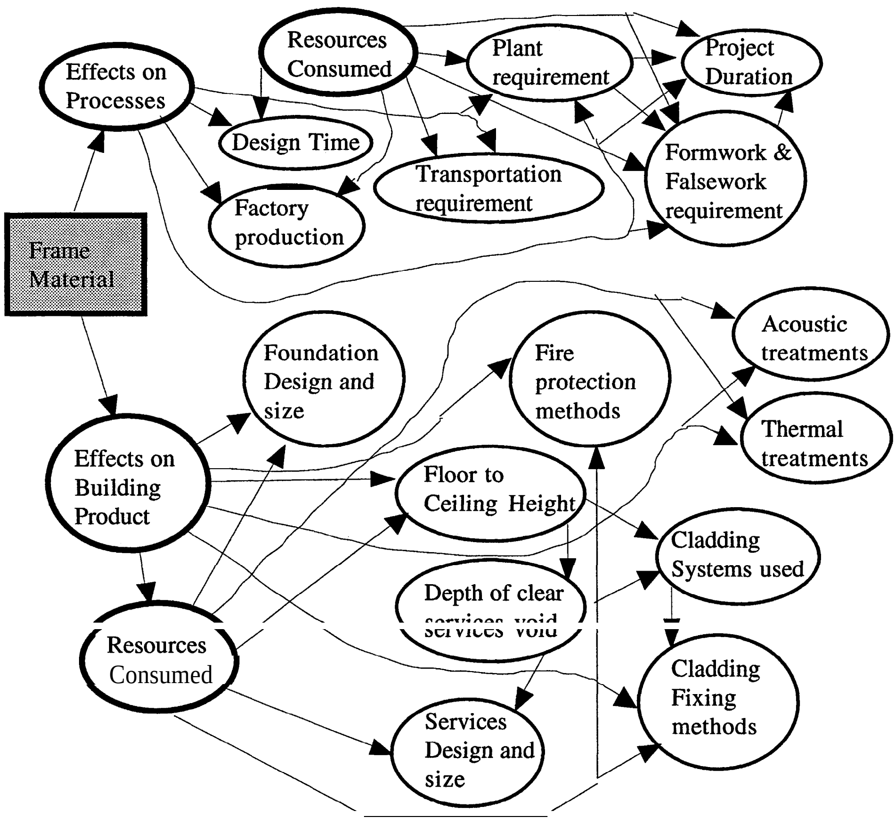

Figure 1 ***Simplified relationships between the frame material, the construction process and the building product.***

The relatively easy approach of analysing the environmental effects associated only with the materials; steel and concrete (in connection with the resources used to produce them, the pollution associated, and the social and welfare effects) would be wholly inadequate in any attempt to properly understand the true environmental impacts associated with the use of either a steel or a concrete frame considering that each frame type must include within it the use of ***both*** materials. Furthermore, as previously mentioned, the choice of frame material impacts many aspects of building project design, construction, use, maintenance and disposal, some of which are seemingly unconnected with the actual materials used.

An approach providing a comprehensive assessment of the total environmental effects of the frame material would be to view the building itself as the product, defining the functional unit of product in relation to the provision of square metres of usable space (the frame is, of course, very significant in realising this provision). This allows for an appropriate basis of comparison, that is the usable-building, and would capture analysis of all of the implications that the choice of a particular material for the frame has upon the overall fabric-and specification of a building together with the processes that are required for its construction and deconstruction. A more true analysis of the overall environmental effects of the frame material would thereby be realised. However, this approach would require an investigator to identify two very similar buildings having similar floor area's and very similar specifications (other than in relation to the structural frame). This in itself is an intractable task, however, obtaining the necessary data (even allowing for the use of 'qualified guessing') to undertake complete LCA's for two ***complete*** buildings (one having a steel frame and one having a concrete frame) is considered highly impractical and it is probable that such an analysis could not be completed in any valid manner (there are simply too many sub- products, components, materials and processes and sub- processes involved with each, to synthesise).

Therefore, it is proposed that an alternative, more practical approach to analysing the environmental performance of the frame material is required in order that concrete frames may be compared with steel frames in an appropriate manner.

4.0 Proposed analysis method

It is proposed that the evaluation problem that has been described can be practically approached using a causal path analysis method.

The causal path method provides a robust analvtical framework within which the strength of influence betweeninterrelated variable&an be measured and understood. The method has been widely applied in the social sciences to investigate postulated cause and effect relationships and in this context it is considered to be appropriate to the task of analysing the causal relationships which exist between a technological decision, that is the selection of structural frame material, and the subsequent impact of that decision upon environmental criteria [3]. Path analysis is an analytical tool which provides for the quantitative investigation of postulated causal influences between a set of interdependent variables [4][5]. The method provides a framework within which appropriate regressors and predictors may be statistically analysed and the output of that analysis understood. Furthermore it allows the formulation of intuitive ideas concerning which of the causal influences are significant. A path model is typically specified as a system of simultaneous regression equations which are usually assumed to be linear, additive and recursive [6]. Path coefficients, the standardised partial regression coefficients, are calculated from the regression equations. These provide an indication of the relative importance of a given explanatory variable upon the response variables. The coefficient is usually described in the form, $p_{i,j}$, where the subscript, j, refers to the response variable and, i, refers to the regressor whose direct effect upon the response is measured.

Normally, the path coefficient, pi,j, explains the proportion of the standard deviation observed in the response variable, j, for which the regressor variable, i, is directly responsible. The residual path coefficient measures the proportion of the standard deviation of j which is explained by unmeasured extraneous variables.

Prerequisite to the construction of any path diagram is the assumption that the explanatory variables and the response variables can be placed in a causal ordering. It follows that changes in the value of any explanatory variable can effect variables later in the causal chain but cannot effect variables earlier in the chain. The causal ordering cannot be decided by empirical analysis of data; it must be determined from prior theoretical knowledge. *A priori* knowledge is the starting point from which path diagrams showing the manner in which variables are expected to relate to one another are developed. The *a priori* structure provides the framework for the statistical analysis of data and also for the interpretation of the results. During the analysis the hypothesised structure of interrelationships may be altered in response to the data, or alternative hypotheses may be tested against the data. It follows that the more realistic the *a priori* path diagram is to the true situation, the more meaningful will be the results of the path analysis. The fundamental task in applying the path analysis method is the construction of a path diagram which reflects as closely as possible the true situation.

5.0 Defining an appropriate causal path model

The first task in developing the causal path model involves clearly stating the objectives of the evaluation and understanding its purpose. The aim of the present study is to understand the environmental impact of steel and concrete frames in the context of contemporary building and construction projects. As mentioned earlier, the frame, despite having a relatively clear functional purpose, cannot be properly viewed as a usable product. The building itself is the usable product to which the frame contributes. This is important since a building project will clearly have a significant environmental impact whether or not a concrete or a steel frame is used to support it. In other words, if a building project is to be undertaken, an environmental consequence is inevitable. Therefore, what is important is not so much the environmental impact of the frame material itself but rather how significant the influence of the structural material is in determining the overall environmental impact of the building project. Subsequently it is of importance to understand whether or not changing the frame material will reduce the overall environmental impact of the building project in a statistically significant manner. Therefore, it is hypothesised that the overall environmental impact of a complete building project will be influenced to some degree by the frame material. The purpose of the path analysis is to test this hypothesis in order to understand whether or not the influence of the frame material upon the overall environmental impact of the building is *significant* and subsequently to understand whether or not the overall environmental impact of building projects can be reduced by alternative frame solutions; specifically in relation to steel frame techniques and concrete frame techniques, bearing in mind that both require the use (to varying degrees) of *both* materials.

In order to construct a provisional path diagram, it is necessary to consider the frame material as the explanatory variable and the environmental impact of the building project as the dependent variable. The diagram must then address how the influence of the frame material upon the overall environmental impact of the building project may be transmitted. In this case it is hypothesised that the frame material will contribute to the overall environmental impact of a building project in a direct manner and also in an indirect manner as a result of the many processes, products and components that are influenced in building projects as a result of the selected frame method. This introduces intervening variables to the path diagram.

Intervening variables are those through which explanatory variables may be expected to exert an indirect influence upon the response variable. The identification of such variables, of course, must be based upon *a priori* theoretical knowledge. In providing a framework which allows for both the analysis of explanatory variables and intervening variables, path analysis allows the quantification of both the direct and the indirect effects of the explanatory variables upon the response.

6.0 Specification of provisional causal path model

A path diagram to investigate the nature of the influence of the frame material upon the overall environmental impact of building and construction projects may be most simply specified as illustrated in Figure 2.

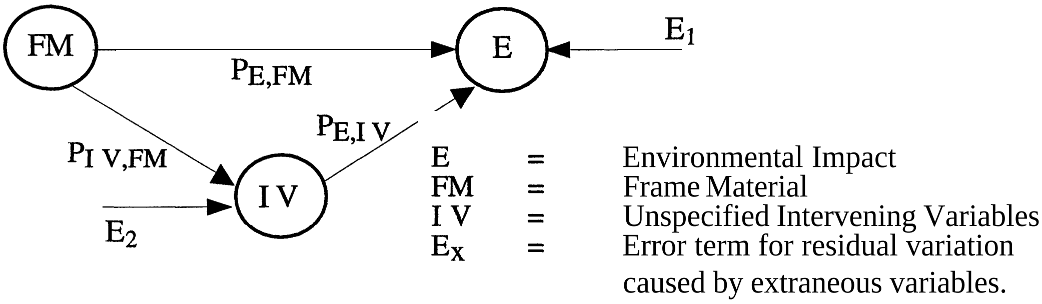

Figure 2 Simple causal path model to analyse influence of frame material upon the environmental impact of building projects.

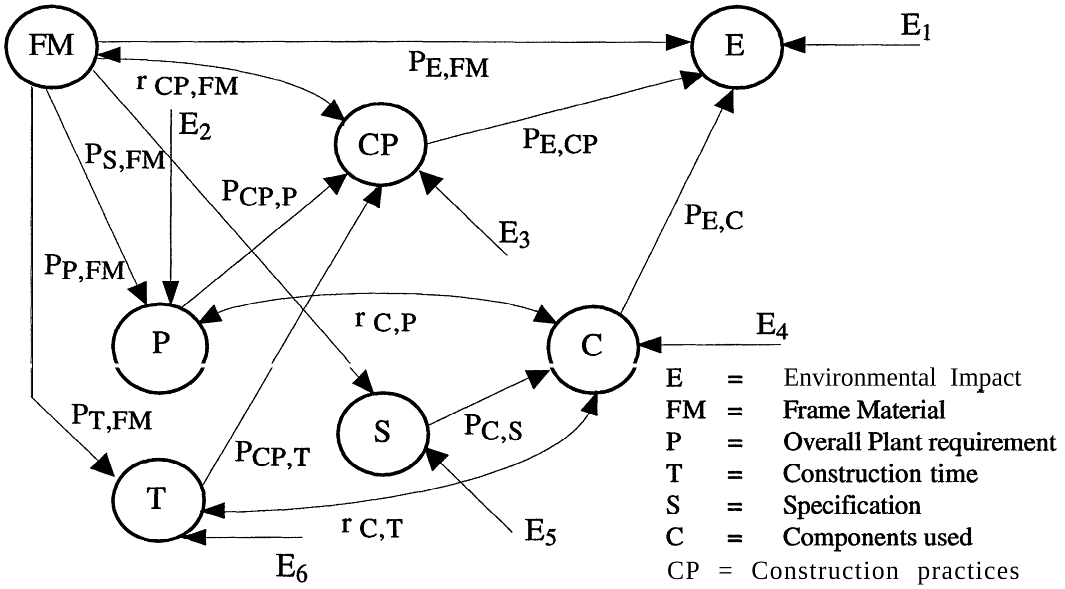
Figure 2 illustrates that the frame material (FM) is hypothesised to have a direct influence upon the size of the overall environmental impact of building projects (E) and an indirect influence through a series of intervening variables. However, importantly, the inclusion of the error terms (El and E2) indicates that there are other variables which are excluded from the system of the model that are nevertheless believed to influence the value, E. Therefore the output of the model is an indication of the importance of the frame material in determining E *relative* to other factors which will inevitably contribute to E. As the research develops, a number of variables presently excluded from the model can be introduced to improve the explanatory power of the model.

The number of likely intervening variables is considered likely to be large. However, the more parsimonious the model, the more useful will be the results. In other words it is desirable to minimise the number of variables that are included within the provisional causal path model. Nevertheless, grouping all intervening variables together in the manner described in Figure 2 is both impractical (in terms of deriving a valid aggregate measure) and inappropriate in terms of understanding how the frame materials influence upon the overall environmental impact is transmitted. Therefore, the process of identifying appropriate groupings of intervening variables is presently ongoing. The aim is to produce a practical causal path model which realistically analyses the implications that the frame material selection has upon the building project process and product in order that the importance of the frame material in determining the overall environmental impact of building projects may be more appropriately understood.

As a result the simplified causal path model illustrated in Figure 2 above has been developed and expanded as described in Figure 3. Work is presently focused upon devising valid and practical measurement systems for each of the variables (particularly for the dependent variable, E) that have been incorporated within the provisional model.



Model Specification:-

$E = F\{P_{E,FM}FM + P_{E,CP}CP + P_{E,C}C + P_{E,E1}E1\}$

$CP = F\{P_{CP,P}P + P_{CP,T}T + P_{CP,E3}E3\}$

$P = F\{P_{P,FM}FM + P_{P,E2}E2\}$ $T = F\{P_{T,FM}FM + P_{T,E6}E6\}$

$S = F\{P_{S,FM}FM + P_{S,E5}E5\}$ $C = F\{P_{C,S}S + P_{C,E4}E4\}$

Total influence of FM upon E (I):-

$I = P_{E,FM} + \{P_{E,CP} \times P_{CP,P} \times P_{P,FM}\} + \{P_{E,C} \times P_{C,S} \times {}_{S,FM}\} + \{P_{E,CP} \times P_{CP,T} \times P_{T,FM}\}$

Figure 3 Proposed provisional causal path model

7.0 Conclusion

Approaching the evaluation of the impact of the frame material upon the environment in the conventional LCA manner of investigating the differing environmental impacts of two or more alternative products in relation to the delivery of equal amounts of a functional unit of production is considered to be unworkable and inappropriate. Therefore, a causal path model is under development to simplify the analysis problem. The output of this model will be a quantitative statement of the importance of the frame material in determining the overall environmental impact of building projects and an improved understanding of the differences between steel and concrete framed structures.

The influence of finely ground ceramic waste materials on the properties of new mortars

M. Levy and P. Helene
Universidade de São Paulo, Departamento de Engenharia de Construção Civil PCC / USP

Abstract

The aim of this work is to analyze the influence that the addition of finely ground, hardened mortar and ceramic waste materials has on the properties of the mortars.

For this purpose, eight different mortars were produced using cement, ground waste material and natural sand.

The waste material used in this study was prepared in laboratory because of the difference in combinations frequently found between the two components when the waste is material collected at construction sites (hardened mortar and ceramic material).

The results obtained indicated that finely ground recycled waste materials are technically appropriate for use in mortar.

There is a large increase in the mechanical properties of mortars in function of the quantity of ceramic materials existing in their composition

Mortars that are produced with recycled materials present an economy of 30% in the use of cement, when compared with mortar produced with natural aggregates.

It is, however, important to carry out a complementary study to evaluate the behaviour and durability of this mortar as to time.

All the tests carried out according Brazilian standards.

KEY WORDS: Mortars, Waste material, Recycling

1 Introduction

Although building techniques and methods adopted in some regions of the country have evolved and the rendering of internal base plaster is widespread, the building process which utilizes internal and external rendering based in Portland cement, lime, clay, sand and other additions is still dominant in Brazil. Therefore, it is easy to see and comprehend that this building process will always generate an amount, no matter how small, of waste material that will not readily disappear .

The study was destined to contribute with data that will help in solving the problem of what to do with the large amounts of inorganic[1] material generated by civil construction by recycling it at the job site, in the production of mortars. This is particularly urgent as areas designated to receive this material are rare and the unlawful disposal of such material is prejudicial to the population and is an affront to environmental policies.

Therefore, in the SBTA I[2] an initial study has shown what influence the presence of finely ground waste material, such as ceramic blocks, concrete blocks and hardened mortars have on the performance of new mortars.

2 Objective

The results of the present study along with those of SBTA I, constitute part of a more comprehensive research whose objective is to determine in a technical fashion the influence that each component of the waste material has on the performance of mortars.

The researchers found it important for this study to detail the contribution of the pozzolanic activity of the ceramic waste in the properties of the mortars. This was due to results obtained which indicated an increase in resistance to the compression related to the addition of ceramic material.

Mixtures of finely crushed ceramic material and finely crushed hardened mortars were tried in different proportions and used as additions in the preparation of the new mortars which were then tested.

3 Methods and materials

For this study, four (4) mixtures of waste materials were prepared in the laboratory and each added to a mortar being tested. The study used two mix proportions resulting in eight (8) distinct mortars.

[1] The volume of construction waste material was about 2,000 ton/day just in the city of São Paulo. This volume of waste material from civil construction represent about 15% of the total amount of the urban nibbish estimated at about 12,000 ton/day [1].

[2] SBTA Brazilian Tecnological Symposium on Mortar

3.1 Materials

The materials used to elaborate this study were:

a) Medium sand, washed; used at our job sites to produce mortar.

b) Compost Portland Cement Type CP II-E- 32 equivalent to I (SM) ASTM C595.

c) Components present in the waste material:

c- 1) Ceramic blocks and clay bricks of different origin;

c-2) Mixed hardened mortars.

3.1.1 Collection and selection criteria

The materials were collected and ground at construction sites in the city of São Paulo.

Those sites used a rolling mill that not only recycled the waste generated at the site but also produced the mortars used at the job site.

The study made a separate collection of ceramic materials (classified as 1st quality and 2nd quality ceramic blocks and clay bricks) and mortar waste.

After a visual verification of the collected sample's homogeneity to avoid the presence of anything unwanted, the selected materials were ground in ANVI-500 type mills for about 30 (thirty) minutes at the sites. They were then in packed and transported to the drying process in the laboratory oven.

The criteria used to select the components of the waste for the experiment were:

Ceramic materials – only second quality ceramic blocks were chosen from the samples collected, because they presented the desired pozzolanicity[3] and also because they are currently the most widely used in the building processes in Brazil.

Mixed mortars – from different jobs sites were ground and mixed in a random way and then stored in the laboratory for more than 180 days to avoid the undesired influence of any finely ground cement that still not hydrated, could act as blending in the new mortar produced.

3.1.2 Characterization of the materials

The sieve analysis, as well as other physical characteristics, of the components used in the preparation of the recycled mortar used in this study is indicated in Table 1.

The components used in this experiment were ground for 30 min. They were then transported to the laboratory and stored for 180 days to avoid any undesired influence from parts of non-hydrated cement that after ground could act as blending in the newly produced mortar. Before being used the components were dried in oven at 105° C.

At the same time, Instituto de Pesquisas Tecnológicas IPT made a test to determine the pozzolanic activity of ceramic waste materials classified as 1st quality and 2nd quality ceramic blocks and clay bricks.

The chemical characteristics of the material used in preparing the waste as well as of the characteristics of the cement (CP II E-32) used in the preparation of the tested mortars are shown in the following, Table 2.

[3] Pozzolanic activity is the capacity of reaction of a given substance with CaO. in order that the pozzolanic activity presented by the substance is able to contribute with an increase in compression strength there must be a consumption of at least 330 mg of CaO / g of the sample in the Chapelle test. Only in this case can the material be considered as pozzolanic material[2].

Table 1 Physical characteristics of components used in the preparation of waste materials.

		Materials Cumulative Percentage Retained			
Characteristics	Standards	Ground ceramics	Ground mortar	Sand	Cement

Ceramic blocs 1ª quality	-	242	-
Ceramic blocs 2" quality *	-	454	-
Clav brick	-	565	-

* Material used for preparation of added (waste).

Table 3 shows unit weight in the loose state of the mortar samples prepared in laboratory.

Table 3 Unit weight of added (waste) prepared in laboratory.

Added	Unit weight in loose state (kg/m³)
c (100%)	1.145
Ca (66% ceramic : 34 % mortar)	1.222
cA (34% ceramic : 66% mortar)	1.300
A (100% mortar.)	1.378

3.1.3 Mix proportion of waste's components

The relative composition of mix proportion components was varied according to the proportions indicated in Table 4, while keeping the other variables of each mortar produced, constant. This was done to obtain a representative waste from the diverse stages of any given job.

[4] According test report IPT n. 829.785 de 14/set/95.

Table 4 Mix proportion additions by volume.

Manufacture added	Ceramic matermic material	Hardened mortar
C[5]	100%	0%
Ca	**66%**	**34%**
cA	**34%**	**66%**
A	**0%**	100%

3.2 Mortars

As a general rule, an effort was made to maintain the same characteristics of mortars used in jobs. To do this, the same mix proportion by volume as that normally used by construction companies was employed.

3.2.1 Mix proportion

In order to follow the rules set forth in item 3-2, the traces 1 3 : 8 and 1: 1.5: 6 in volume, were adopted. These were transformed into weight with the addition of the four (4) mixtures, previously prepared. The eight mortars indicated in Table 5 were produced.

Table 5 Relationship between mix proportion by volume and mass of test mortar.

Addition used for preparation of test mortar	Mix. Proportion by volume (Cement: Added: Send)	
	(1 : 3 : 8)	(1 : 1,5 : 6)
C	1 : 3,04: 10,290	1 : 1.520 : 7.715
Ca	**1 : 3.25: 10.290**	**1 : 1.623** . 7.715
cA	**1 : 3.45: 10.290**	**1 : 1.726 : 7.715**
A	**1 : 3.66: 10.290**	**1 :** 1.829 : 7.715

3.2.2 Molding of the specimens

A total of 264 specimens were molded. Ninety-six (96) cylinders of 50x 100 mm were used to determinate the compression strength; ninety-six (96) cylinders of 50x100 mm were used to determine the elastic modulus and seventy-two (72) prisms measuring 40x40xl60 mm were used to determine flexural strength.

3.2.3 Properties studied

The following properties were selected for investigation in this experiment:

a)For fresh mortar:

- *Unit weight*- was determined according to Brazilian standard NBR 7251/82 to permit to get the cement content employed in each mix proportion.
- *Water retention* - was determined in Biichner funnel in accordance with Brazilian standard NBR 9287/86, to evaluate the capacity, that finely ground ceramic material added to mortar has, in retaining molding water.
- *Content* of *cement*- was calculated by the equation $C_{(cement\ amount)} = \gamma_{Mortar} / M_{total}$
- *Flow* - the amount of water used was that necessary to get a flow of 3 10 ±10 mm as determined by the flow table according to Brazilian standard NBR 7215/81.

[5] According to the nomenclature adopted, the capital letter represents the material existent in a higher proportion in the mix, ceramic material or hardened mortar.

4.2.2 Content and flow

In the laboratory, during the preparation of mortar, a flow of 3 10 ± 10 was adopted. The mix proportions by weight of mortars, on average, are showed in Table 7.

Table 7 Mortar properties obtained from a flow of 3 10 ± 10 mm.

Mix. Proportion	1: 3: 8				1: 1,5: 6			
	C	Ca	cA	A	C	Ca	cA	A
Cement content (kg/m^3) (%)	109,0 (7,0)	107,5 (6,9)	105,0 (6,8)	103,1 (6,7)	157,9 (9,8)	156,0 (9,7)	152,0 9,6)	149,0 (9,5)
Waste content (m^3/m^3) (%)	0,289 (21,2)	0,283 (22,3)	0,279 (23,4)	0,270 (24,5)	0,209 (14,8)	0,207 (15,7)	0,202 (16,5)	0,197 (17,3)
Sand content (m^3/m^3) (%)	0,785 (71,8)	0,767 (70,8)	0,757 (69,8)	0,745 (68,8)	0,849 (75,4)	0,842 (74,6)	0,821 (73,9)	0,802 (73,2)
w/c Ratio	3,146	3,111	3,030	3,016	2,099	2,053	2,134	2,086
w/dry mat Ratio	0.219	0,214	0,206	0,203	0,219	0,199	0,204	0,198
Flow (mm)	305	311	312	308	322	325	335	330

4.2.3 Water retention

Figure 1 presents the different values of water retention for each one of the eight (8) mortars prepared. As can be seen, the best results were gotten by using waste material Ca, composed of 66% ceramic material and 34% hardened mortar. The values were slightly lower than those obtained by JOHN [5] which were 57% and 64% for conventional mortar (Cement : Lime : Sand) using a mix proportion volume 1:2:9 with a flow of about 300 mm dolomite lime and calcic lime.

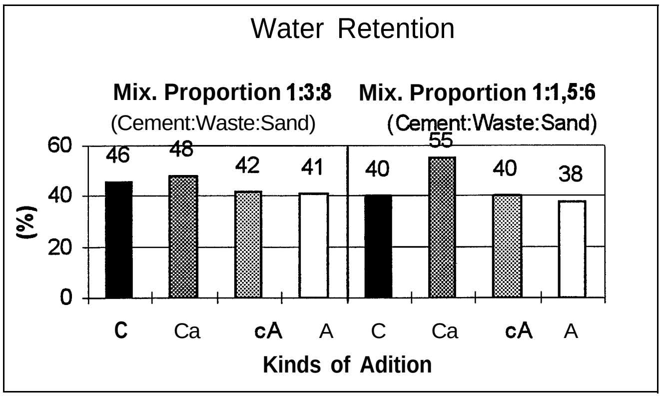

Figure 1 Variation of the water retention index

4.3 Results of hardened mortar.

4.3.1 Compressive and flexural strength

Figure 2 presents the values of compression strength after 7, 28 and 91 days according to the addition employed. Compressive strength increases by 2.5 times with a variation of cement content of no more than 5% and prepared with and without ceramic materials. This same tendency can also be observed for tensile strength as indicated in Figure 3

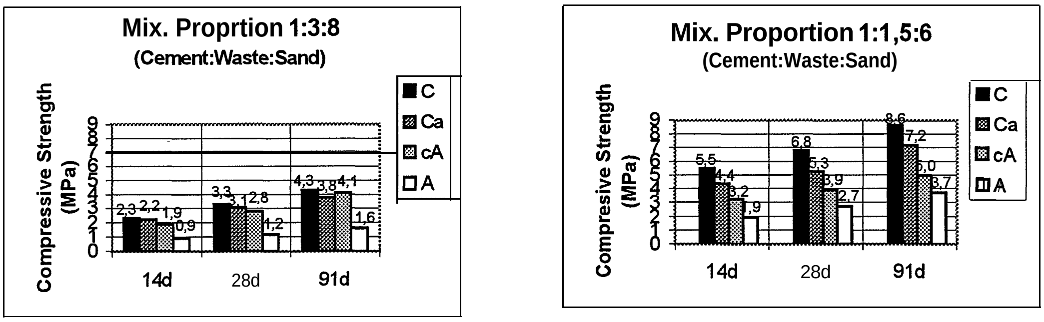

Figure 2 Compressive strength, mix proportion 1: 3 : 8 e 1: 1,5: 6

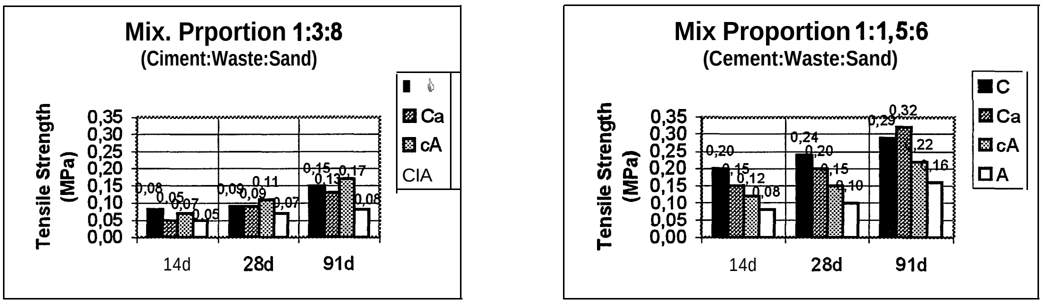

Figure 3 Tensile strength, mix proportion 1: 3 : 8 e 1: 1,5: 6

4.3.2 Elastic modulus

The normal values for mortars with a mix proportion of 1: 2: 9 were around 1 GPa at 28 days [5]. For those mortars with a mix proportion of 1:3 : 8 and produced with recycled material. the values at 28 davs were practically the same, who it is show in Figure 4 for some mortars tested.

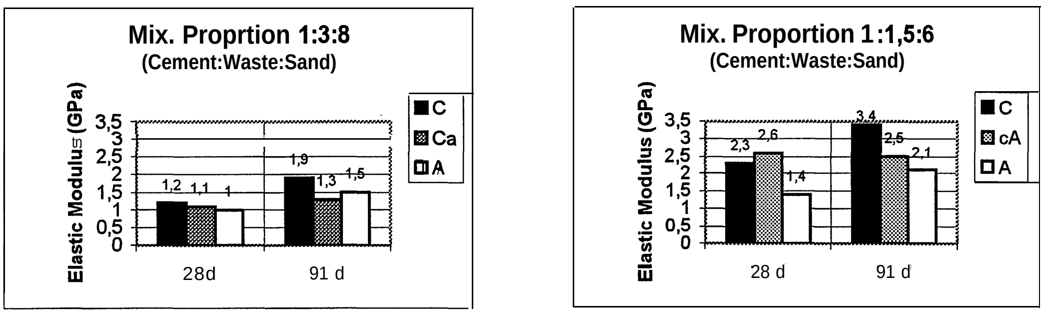

Figure 4 Elastic modulus evolution for mix. proportion 1: 3 : 8 e 1: 1,5: 6

5 Conclusions

The results have indicated that either a higher or lower amount of ceramic material or hardened mortar added to mixes, has an influence in its main proprieties.

Substituting with a higher proportion of one of the two waste materials presents a differentiated influence.

In general, a higher amount of ceramic material in the fresh mortar state, produced a mortar that is more compact (an increase in unit weight). At the same time, a higher presence of hardened mortar waste produces mortars that consume less cement, a difference of about (3 to 5%) as compared to mortars richer in ceramic waste materials.

A modest variation (3 to 5%) in the consumption of cement was detected for those mortars under study. This results in an increase of around 2,5 times in compression strength. This significant modification can be explained by the development of the binder potential of ceramic material present in the waste and due to a pozzolanic reaction with filler effect.

On the average, mortars produced with waste material present a reduction in cement consumption of about 30% when compared with data found in literature for similar mortars [6].

This work has shown that it is possible for studies and technological evaluations about recycling (not only of the materials tested here, but of many others for their low cost and immediate possibility of utilization) to change the value concept of what is called "waste", "refuse" and "debris", and in turn affect the laborious and precarious process toward their final destination.

Methodology to evaluate used foundry sand as concrete aggregate

Sbrighi Neto, C.; Tango, C.E.S.; Lotti, F.; Quarcioni, V.A.
IPT Technological Research Institute of São Paulo State – Brazil

Abstract
Nowadays used foundry sand becomes, more and more, an environmental problem because it is not easy to find a safety way to dispose it. This is due to the fact that during some metallurgic processes many times, it can incorporate heavy metals contaminations and the use of organic compounds(as phenolic resins, for example) which can migrate in variable proportions to residual sand.
To verify the possibility of reusing foundry sand as concrete aggregate IPT(Technological Research Institute of São Paulo State-Brazil) developed a methodology with the following steps:
-(1) used foundry sand samples technological characterizations;
- (2) production of concrete specimens based in selected mix proportions;
-(3) performance tests including physical- properties and mechanical strength
-(4) stability and immobility of the contaminants(heavy metals and organic compounds) through Brazilian Standard Test(NBR- 10 004 Solid residues) which involves lixiviation and solubilization procedures.
An example of application of the suggested methodology is presented with its mechanical and chemical test results and conclusions about its applicability for similar materials.
Keywords: Waste materials, used foundry sand, inertization, evaluation methodology.

1 Introduction

The scarcity of good quality aggregates near mostly of great cities induces a big effort to research alternative sources necessary to improve urban growth and infrastructure construction. At same time environmental reason promote need for protecting nature against predatory exploitation, through maintenance of the current explored mines, in acceptable level of production.
One of these alternatives is recycling industrial waste with potential applicability in function of its physical/mechanical characteristics. The used foundry sands have a good shape, strength, but, sometimes, do not show chemical stability because some kinds of contaminants can exhibit a hazardous behavior. These contaminants are mainly heavy metals and organic resins as phenolic ones (acid or basic type).
This paper proposes a methodology to evaluate the applicability of used foundry sand through inertization process with portland cement paste as a cover material which makes a barrier for solubilization or lixiviation of dangerous substances.
Besides aspects of public health it is necessary to consider economic aspects because costs of used sand disposal are so high in Brazil – near US$ 20-25/ton and in certain conditions it can be over US$ 60/ton.
The inertization by a Portland cement shield makes possible, if reached production of masonry blocks, structural concrete and some kinds of rendering mortars with safety and adequate technological properties. It becomes only an optimization exercise for the proportioning of concrete materials components.

2 Methodology

2.1 Fundamental principles

The proposed methodology is founded on some steps: representative sampling; run mechanical and chemical tests to verify stability and immobility of dangerous contaminants of sand in concrete specimen prepared with a specified compressive strength (30 MPa) and an accurate data interpretation.
This method try to represent structural concrete mixed in current proportions and its behavior when lixiviation and solubilization are increased to extreme conditions.
For used foundry sands from metallurgic processes without heavy metal or phenolic resins the evaluation have less difficulties but an accurate verification is requested.

2.2 Sampling

Real use conditions must be reproduced for running valid tests. It is very important to verify the waste homogeneity and divide it in lots with the same main characteristics according to the necessary. In our case these conditions are not easy to reach because waste materials are normally neglected, so this is generally a new concept to introduce in the procedures of technical staff who manages the waste. This spends attention and has serious consequences in case of differences between test samples and materials, which are really used as aggregates. Grain size distributions, or needing for milling, for example, are characteristics that influence utilization methods and concrete performance.
Each situation requires an analysis to define adequate sampling procedures.

2.3 Waste characterization

A previous characterization of wastes is made at the beginning of study, with a petrographic examination and X-ray fluorescence analysis, and eventually Chromatography or Infrared Spectroscopy if organic compounds are expected.

2.4 Mechanical performance concrete tests

Since concrete for masonry and pavement blocks is made using vibrating and compression, with demolding in the fresh state, cohesion and workability are important in this condition, and influence concrete properties after hardening. To simulate a concrete block-molding machine the specimens for tests are vibrated and pressed into standard conditions using an adapted device from a "VeBe" apparatus currently used for measuring dry concrete consistency.

Specimens are cylinders with 7.5 cm, diameter and 15 cm, height, , molded with a standard compression with a standard vibrating time. After humid chamber curing (relative humidity > 90%, temperature 22±2 °C) of 3, 7, or 28 days, specimens are tested in compressive strength by NBR 5739/9 ABNT method.

Compressive strength is the most important property of concrete, since it is not only a mechanical performance index, but it also is related with durability, impermeability, water absorption, etc. If there is some perturbation in hydration due to the residue, it is possible to detect it by observing perturbations on compressive strength-time relationship.

2.5 Standard concrete proportioning

The above test results permit to construct graphics relating compressive strength with concrete proportions. The interpolation in these graphics makes it possible to reach a concrete mixture proportion with. expected standard strength (e.g. 30 MPa, adopted in this study). The intention is to make standard mechanical performance concrete to be compared with other concretes with similar mechanical performance using the following tests.

When standard concrete is approved, graphics are also useful for concrete proportioning and cost analysis.

2.6 Stability and immobility tests on standard concrete

Standard mechanical performance concrete is previous and sufficiently ground for complete passing in the 9.5 mm sieve; ground sample is submitted to NBR 10005/87 and 10006/87 ABNT -procedures for, respectively, residue lixiviation, and solubilization. These procedures are standard simulations of weathering agents over pulverized concrete after, for instance, a building demolition in which residues were present as a part of the material.

Tolerances for some chemicals are shown in Table 1.

3 Practical examples

Two residue tests are presented as examples:
A residual sand originated by "Block Foundry" metallurgical process and other called "Ecolotec", with phenolic resin addition during industrial procedures, both used in manufacturing of cast components for automotive industry in São Paulo, Brazil.
A petrographic analysis showed two rounded grain sands with polished surface texture, where quartz is practically the only mineral specimen. X-ray fluorescence analysis showed no traces of Fe, Al, Na, and Mg, thus those were not quantified by specific tests.
"Block Foundry" residue presented Fineness Modulus 1.49, and "Ecolotec" residue, 1.85, according to NBR 7211 ABNT.
Cement of Brazilian type CP II-E 32 (Composed Portland Cement with less than 34% Blast Furnace Slag Addition) was used, with Blaine Fineness 353 m^2/kg and Standard Compressive Strength 38.2 MPa according to methods cited by Brazilian ABNT NBR 11578. As coarse aggregate a 9.5 mm maximum size crushed granite with 5.44 Fineness Modulus according to NBR 72 11 ABNT was used.
Experimental mixture proportions were made with the above materials, discriminated in table 2, using principles for designing concretes for masonry blocks (Tango, 1994).

Concrete mixture proportions (cement : fine aggregate : coarse aggregate, weight)		
Mixture proportion	"Foundry Block" sand residue	"Ecolotec" sand residue
"Poor"	1.00:2.82:5.18	1.00:3.11::4.89
"Medium"	1.00:1.89:4.11	1.00:2.08:3.92
"Rich"	1.00:0.96:3.04	1.00:2.05:2.95

Table 2 Experimental Concrete Mixture Proportions for Compressive Strength Tests

Compressive strength test results for the above concretes are graphically and analytically related with total aggregate cement proportions in figures 1 and 2.

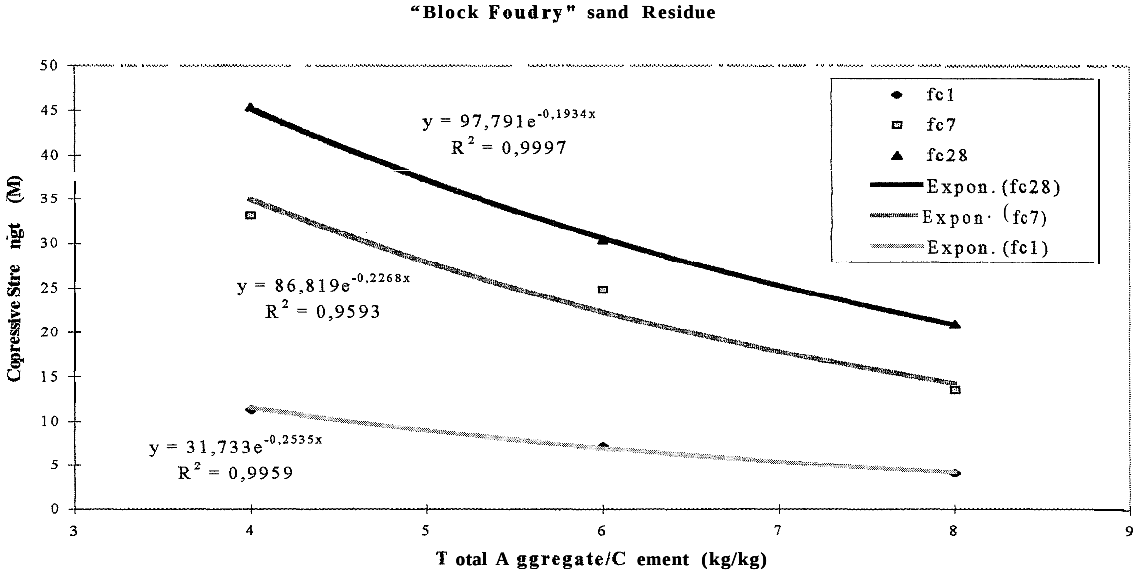

Figure 1 Aggregate-cement ratio versus compressive strength for concretes made with "Foundry Block" sand residue as fine aggregate. f_{c1}, f_{c7} and f_{c28} are compressive strengths at 1, 7 and 28 days..

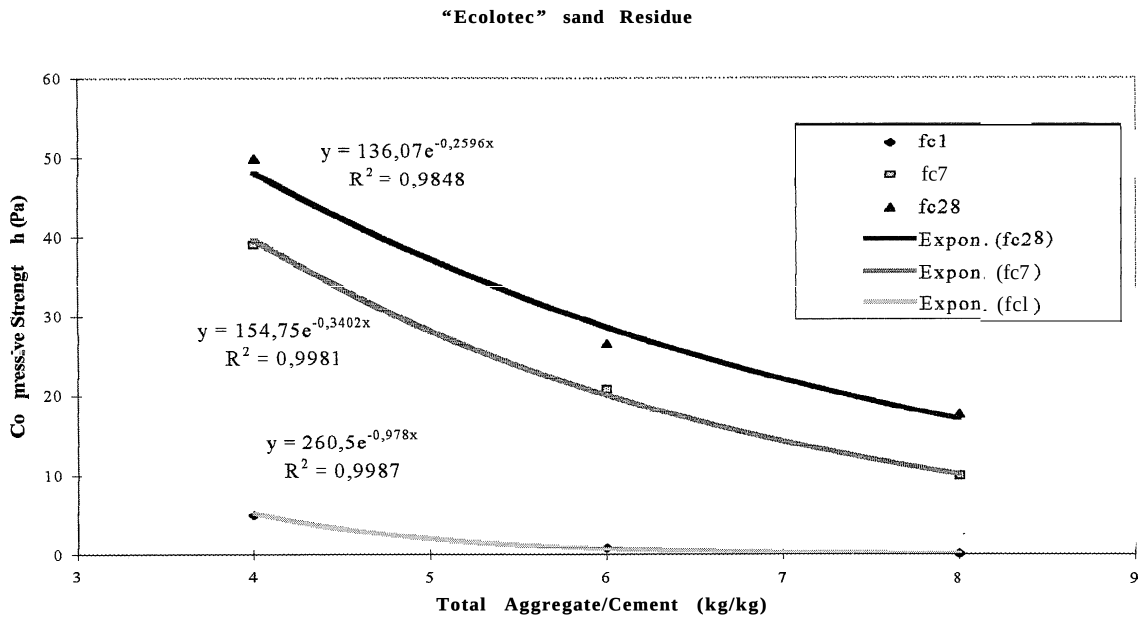

Figure 2 Aggregate-cement ratio versus compressive strength for concretes made with "Ecolotec" sand residue as fine aggregate. . f_{c1}, f_{c7} and f_{c28} are compressive strengths at 1, 7 and 28 days.

With the equations for 28 days shown in figures 1 and 2, and imposing the original concrete fineness modulus, it was possible to calculate the ideal mixture proportions for obtaining the standard compressive strength 30 MPa. The calculated mixture proportions were (cement : fine aggregate or residue : coarse aggregate):

1 .OO: 1.99:4.22 for "Foundry Block" sand residue;

1.00: 1.98:3.84 for "Ecolotec" sand residue.

With these standard mixture proportions, specimens were molded, moist cured up to 28 day age and ground passing 9.5 mm sieve for lixiviation and solubilization tests, which results are in table 3.

Determination	“Foundry Block” sand residue		“Ecolotec” sand residue

4 Discussion

Figures 1 and 2 show that there are differences between strength gains with time in concretes with “Block Foundry” and “Ecolotec” sand residues. The presence of phenol is the main difference between these concretes, probably the cause of strength retarding in 1 day age, with better relative strengths at later ages, for "Ecolotec" sand residue. Similar effect on strength is shown by other organic impurities, as sugar, into Portland cement concrete. Another possibility is an eventual degradation of phenolic compounds in cement paste alkaline environment during time, which would induce the lowering of retarding effect.

In table 3, comparing its results with table 1, it is easy to see that “Ecolotec” sand residue is not acceptable because of Ba and Phenol levels.

Therefore, chemical results in table 3 are affected by components originated not only by the used residues, but also by cement, coarse aggregate and water. Thus, it is important to compare these results with those from concrete made with original sand without metallurgical process influences. This was suggested for continuing the studies.

Some determinations as Al, Fe, Mg, Ba, and Na are in a very low level and can be strongly affected by portland cement chemical composition, and the limit standards for those and other elements maybe would be object of more discussion.

5 Conclusions

This methodology was applied to study several samples originated by many kinds of metallurgic process and ever showed a good applicability and sensibility to distinguish between dangerous and applicable ones.
The main proposition of this paper is to establish a standard level for compressive strength of concrete specimens, and in this manner to have a correspondence with structural requirements for concrete
Improvements in the methodology, for the next steps research in this field, would be summarized in three basic ideas:
To introduce previous characterization of original sand (without any use or metallurgic process influence);
To study the possibility for using monolithic or not completely ground samples;
To introduce tests for durability of reinforced concrete, including atmospheric carbonation, chloride permeability and others.

Efficient Hydrophobation of Concrete with Novel Silicone Products

W. Keller
Wacker-Chemie GmbH München, Munich, Germany
R. Hager
Wacker-Chemie GmbH München, Werk Burghausen, Burghausen, Germany

Abstract

The presented class of products is an important addition to the existing variety of silicone based formulations for use in building protection. Compared to most silicone masonry water repellents marketed so far – which are usually applied as liquid formulations – this new protection system has a higher viscosity.

The novel product line shows significant innovative features:

- *easy application* with airless spraying equipment or other means
- *„ over-head " application possible* (no dropping of product)
- *better working efficiency* by achieving a high impregnation depth with a one-step-application because of possible higher film thickness
- *optimum distribution of the product* on the construction material by achieving a constant film thickness – and thus constant quality of the impregnation
- *optimum control overpenetration depth* (product absorption) by adjusting the film thickness (> 5 mm penetration at up to 300 g/m^2)
- *no loss of active material* due to evaporation or low viscosity on vertical sites, thus providing minimization of environmental pollution
- much *higher content of active silicones* compared to regular emulsions
- *high penetration depth* better than pure silane compositions by longer contact time

Because of the combination of above mentioned product specifications this novel product is highly recommendable for water repellent treatment of construction materials, especially concrete. It was possible to verify the lab data by field trials on selected concrete structures.
These results as well as the hydrophobing effects and application methods of the above mentioned product line – as well as a general introduction into silicone masonry water repellents – will be dealt with in the presentation.

Keywords:
Concrete Protection, Creme, Hydrophobation, Silanes, Silicones, Siloxanes, Masonry Water Repellents

1. Introduction

One of the main physical properties of silicones is their pronounced water repellent effect on treated substrates. So shortly after industrial production had started some decades ago, silicones were used as impregnating agents, e.g. for textiles or building materials.

Today a variety of customized silicone products is used to protect buildings and building materials against moisture and subsequent physical, chemical, and biological deterioration. During the years, the change in building materials used, tougher performance requirements, and greatly enhanced environmental awareness were some of the driving forces for continous innovation in the field of silicone masonry water repellents.

One of the changes in product formulation which is still going on is the tendency to use water based rather than solvent based products. One further step will be a change of physical state. Up to now, ready-to-use silicone based masonry water repellents have always been liquid, now a new generation of pasty and solid products is being developed.

The use of pasty agents is especially interesting for protection of concrete structures, where a very dense material of relatively low water absorption is to be treated and a sufficient contact time is often not reached by using liquid products.

2. The importance of surface treatment in concrete protection

Reinforced concrete for many years had the image of a non-corroding, maintenance-free building material that was said to have a lifetime of some centuries. With such a common belief it was out of question why surface protection should be sensible – it was not. The disillusionment came in the 70s, when corrosion of many of the reinforced concrete structures became a public issue.

Damage of reinforced concrete is mainly caused by diffusion of carbondioxide into the concrete and subsequent carbonation of the containing lime, as well as absorption of pollutants like chloride ions. A crucial role in deterioration plays the penetration of water into the concrete by which the speed of corrosion is multiplied. The following points have to be considered:

- Preventive protection of non-corroded concrete
- Establishment of a lasting corrosion protection
- Protection of new concrete replacing old, deteriorated concrete
- Increase of chemical and mechanical resistance of the concrete mixture

A simple classification of surface protection systems, which is technically sensible as well, is the classification by thickness of the protecting layer:

- hydrophobing impregnation, which has no measurable “thickness”
  – water repellent + (if needed) oil repellent and/or strengthening
- socalled “sealings” (about 50 µm thick), which can not fill pores totally
  – strengthening effect and partly clogging of pores
- filmforming coatings (some 100 µm thick)
  – clogging of pores, CO_2-diffusion hindered, reduction of water uptake

3. Molecular basis of silicone masonry water repellents

Most of today's silicone masonry water repellents are based on polymeric silicone resins as the basic chemical structure. Since the monomeric silane building blocks to these resins are trifunctional alkyltrialkoxysilanes $RSi(OR')_3$, the resulting resin can be considered as an organomodified quartz ($RSiO_{3/2}$ instead of $SiO_{4/2}$). Thereby the water repelling effect is caused by the hydrophobicity of the alkyl group R.

Because quartz – or more general silicate – is the binder of most natural and artificial stones and masonry, the resemblance between silicone resins and quartz is the reason why silicone resins are so suitable to be used on building substrates, particularly in terms of durability and service life.

Silicone masonry water repellents, in contrast to filmforming organic polymers, do not seal the surface pores of masonry. They only modify the pores of the substrate in such a way that liquid water absorption is suppressed, while the pores remain open and water vapour permeability is not affected. Chemically spoken, covalent Si-0-Si bonds are formed between the SiOH groups of the substrate pores and the SiOR of the silicone, thus rendering the pores water repellent but leaving them water vapour permeable.

In the beginning of silicone masonry water repellents, solutions of polymeric methylsilicone resins in aromatic solvents were used. Since fully cured resins of high molecular weight are not soluble any more, lower molecular weight precursors have been used for that purpose.

On many low porous substrates like concrete, the penetration depth of silicone resin solutions or their precursors is not sufficient to meet current performance requirements. On these substrates the silicone resins have to be replaced by agents with even lower molecular weight, which are monomeric alkyltrialkoxysilanes or oligomeric alkylalkoxysiloxanes $R_xSi_x(OR')_y$.

After application to the masonry structure, all the mentioned agents will react with water or humidity to the cured silicone resins, which are anchored to the substrate by stable covalent Si-O-Si bonds while alcohol is liberated as by-product.

Modern silicone masonry water repellents are preferably mixtures of alkylalkoxysilanes and oligomeric siloxanes. The alkoxy groups OR' are either methoxy or ethoxy groups. The organic groups R are methyl or longer chain hydrocarbon substituents like octyl groups. Long chain substituents impart alkaline stability to the hydrophobing agents, since thermodynamical and kinetical effects prohibit decomposition of the cured resins by alkaline chemicals or substrates.

Until the mid 80s, silicone masonry water repellents were mainly used as solutions in organic solvents. There were only two exceptions: undiluted 100% products and water based siliconates – both for special applications.

Since solvents only act as a transport medium, after having fulfilled this function, they are simply emitted into the atmosphere. For this reason and due to increased public awareness in terms of ecology and health, there is only one implication for masonry water repellents as well as for paints:

Replace organic solvents by water wherever possible!

4. Aqueous silicone masonry water repellents

Besides the siliconate approach mentioned above which is by now well known for almost 40 years, basically there are two ways of dissolving and dispersing organosilicone substances in water:

- Producing silicone emulsions
- Introducing hydrophilic functional groups into polysiloxanes to get selfemulsifying systems

These two modern approaches to water based masonry water repellents will now be delt with in more detail.

4.1 Emulsion approach

Silicone emulsions for masonry protection have been used successfully in mainly three application:

- Silicone resin emulsions as binders in silicone resin emulsion paint
- Emulsions of special linear polysiloxanes as additives in masonry paints
- Emulsions of low molecular alkylalkoxysilanes and -siloxanes as penetrating water repellents and primers

4.1.1 Silicone resin emulsion paint

Silicone resin emulsion paint is regarded as the most modern of currently available facade coating systems [1]. Coatings with silicone resin emulsion paint are water vapour permeable like mineral paints but at the same time are also water repellent like filmforming dispersion paints. These unique properties result from the main binder component, an emulsion of a solid silicone resin. Since solid products can hardly be emulsified, the silicone resin either has to be dissolved in organic solvents or the emulsifying process has to be done with a liquid precursor of the – finally solid – resin. Of course, the solvent-free approach is more desirable due to ecological factors.

4.1.2 Silicone additives

Silicone additives are added to coating materials, mineral paints, dispersion paints, plasters, etc. in small quantities in order to change the coating's properties permanently – especially to improve water resistance while obtaining high water vapour permeability. Modern additives are solvent-free emulsions of functional reactive polysiloxanes. The following chemical structure is an example of such a high-performance siloxane:

$$H_2N(CH_2)_2NH(CH_2)_3Si(OCH_3)_2O[Si(CH_3)_2O]_nSi(OCH_3)_2(CH_2)_3NH(CH_2)_2NH_2$$

In many cases only 1% of the additive is required to reduce the water uptake by more than 90%, e.g. from 5 kg/m² down to 0.5 kg/m² (after 24h).

4.1.3 Masonry water repellents

For a long time it was thought impossible to create storage stable water based masonry water repellents. One of the main demands for masonry water repellents is that they have to be well penetating into the stone. If other parameters are kept constant, the penetration of a liquid into a building material is better when the viscosity is lower. In contrast to homogenous solvent based products where the viscosity of the whole solution is relevant, in emulsions only the viscosity of the oil phase – i.e. the silicone – is important [2]. Of course, to get good penetration results, low molecular weight alkylalkoxysilanes and -siloxanes have to be chosen. The problem, however, is that these agents hydrolyze and polymerize in water, thereby forming larger and larger molecules up to solid silicone resins. Consequently their penetration behaviour turns worse and worse with time.

In the mid 80s it was found that the hydrolysation speed of alkoxysilanes can be slowed down if silanes $RSi(OR')_3$ with longer chain organic substituents R (e.g. octyl or isooctyl) are used. The same effect results of the use of ethoxy instead of methoxy substituents as groups OR‘ [3]. Emulsions made of the mentioned silanes are storage stable for several months. Their main disadvantage is that the formation of the final water repellent polysiloxane in the masonry structure takes a rather long time. This problem could be solved by formulating an emulsion containing not only silane but also oligomeric and polymeric siloxanes [4].

Similar to solvent based products, such emulsions are:

- Storage stable over more than one year (before and after dilution)
- Well penetrating into mineral substrates
- Stable against alkalinity
- Suitable for all mineral substrates, concrete as well as natural stone

4.2 Selfemulsifying microemulsion approach

The storage stability problems with water sensitive alkylalkoxysilanes and -siloxanes when brought into contact with water via emulsifying were the reason for another development. Some years ago, Wacker-Chemie GmbH introduced a technology of water based silicone masonry water repellents – the so-called Silicone Microemulsion Concentrates – abbreviated and registered as WACKER SMK® technology [5].

Silicone Microemulsion Concentrates in terms of WACKER SMK® are low viscous, clear, anhydrous, and solvent-free liquids based on alkylalkoxysilanes and -siloxanes which – simply upon being poured into water – spontaneously form extremely fine particle (1 O-80 nm) silicone microemulsions.

It is well known that microemulsions of so small particle size require 10 times more emulsifier than common emulsions with particle sizes of 500-1000 nm, In addition, a co-emulsifier is necessary to achieve microemulsions.

Following this thought, conventional emulsifiers are unsuitable for use in masonry water repellent microemulsions because emulsifiers in the high amounts necessary prevent the development of the desired water repellency.

The concept behind silicone microemulsions of WACKER SMK® is therefore that emulsifier and coemulsifier are at the same time active ingredients and lose their emulsifying activity after being used.

WACKER SMK®s are diluted to form microemulsions by simply being poured into water. This should be done directly before application to the substrate since contact with water causes the reactive components to begin reacting within the microemulsion droplets. After activation, the silicone microemulsions gradually lose their effectiveness, e.g. their ability to penetrate into dense building materials.

Main advantages of the WACKER SMK® technology are:

- Solvent free products of 100% active ingredients
- Storage stability of the concentrates over years
- Easy to use
- Concentrated form (lower storage, transport, packing costs, and duty)
- Environmentally friendly (diluted with water)

Table 1 shows a comparison of performance between a solvent based allround impregnant (WACKER 290), a WACKER SMK® type product (WACKER SMK® 13 1 1), and a silane/siloxane emulsion (WACKER BS 1001) as described in the preceeding chapter. All products were used in a concentration of 10% actives on three substrates: lime sandstone, brick, and concrete.

It can be concluded that there are some differences in performance between the three product types, but all penetrate well into the substrate and reduce the capillary water absorption sufficiently.

Product	Substrate	Impregnant uptake [g/m²]	Penetration depth [mm]	Water uptake 24 h [g/m²]
	Lime sandstone	0	0	2.6
Untreated	Brick	0	0	5.0
	Concrete	0	0	1.2
	Lime sandstone	550	6-9	0.16
WACKER 290	Brick	2185	> 35	0.04
	Concrete	210	2-4	0.15
	Lime sandstone	540	5-8	0.18
WACKER SMK 13 11	Brick	1654	> 35	0.11
	Concrete	150	1-2	0.24
	Lime sandstone	530	4-6	0.19
WACKER BS 1001	Brick	1020	> 35	0.59
	Concrete	167	2-3	0.22

Table 1: Performance of solvent diluted (WACKER 290), emulsion (WACKER BS 100 1) and microemulsion based (WACKER SMK® 13 11) masonry water repellent.

5. Novel pasty silicone masonry water repellents

Silicone based water repellents in the past have always been liquids. The disadvantage of liquids is that excess material is running down at vertical surfaces and subsequently penetrating into the ground, thereby polluting the environment.

Another point is safety reasons, e.g. if the water repellent agent has to be applied by flooding „over head“, the applicator can hardly avoid to be contaminated with chemical substances (solvents plus actives).

Most interesting in these terms is the impregnation of reinforced concrete, particularly road constructions and bridges. In the past undiluted alkylalkoxysilanes $RSi(OR')_3$ were often used for this purpose. Since high performance concrete is a rather dense substrate, only highly concentrated (up to undiluted) and low viscous products penetrate sufficiently. Once chosen, even these products have to be applied at least two times in order to achieve a penetration depth of some millimeters and a coverage rate of at least 100 g/m^2. In addition, monomeric undiluted silanes are the most volatile of all silicone products and so lots of active material is lost by evaporation into the atmosphere [6].

Therefore the challenge was to develop a product line with the following characteristics:

- Excellent penetration even into high grade concrete
- Only one application step to obtain a sufficient coverage rate
- No volatility problems
- Good beading effect
- Water based and solvent free

These reqirements could be met by changing the physical state of the silicone masonry water repellents from liquid to pasty.

The first attempt to realize this was to combine silanes or siloxanes with thickening agents as bentonite or montmorillonite [7]. A main disadvantage of such products is that the thickener remains on the surface, thereby affecting the appearance and having to be removed later. Another drawback is the fact that the volatility problems with such a product are even worse than with the pure silanes because the agent is applied in a thick layer and the volatile components have plenty of time to evaporate instead of penetrating into the concrete.

Very recently pasty products have been developed which are not subject to these disadvantages. Their formulation principle is totally different from those mentioned above. Their pasty consistency is not achieved by using a thickening agent, it is achieved by a special emulsification process which is stopped at the stage of a high viscous phase and renders a storage stable product. As silicone active ingredients preferably mixtures of alkylalkoxysilanes and -siloxanes are used. By variation of the silane: siloxane ratio „tailor-made“ impregnants for different substrates can be formulated. The actives content normally ranges above 80% while the rest of the product is water.

These products are preferably applied via spraying with a modified airless equipment. This way, very easily layers up to 0.5 mm thickness can be achieved without loosing any material on vertical substrates. Witin a few hours the silicone penetrates complety leaving no visible remainings on the surface.

For demonstrating the performance of the new pasty products, a formulation was chosen which contained 80% actives and a silane/siloxane ratio of 9:1 (WACKER BS 69001). Concrete cubes (grade B35, 10 cm edge length) were covered horizontally with a 0.4 respectively 0.8 mm layer of WACKER BS 69001.

For comparison, well established liquid products were tested which were applied on to the concrete cubes by 5 minutes immersion (coverage rate approx. 100 g/m^2). All treated cubes were stored at ambient conditions for 2 weeks, immersed in water for 7 days, and then the water uptake was determined.

From the experiment's results it could be concluded that the pasty product penetrates tremendously well (at 0.8 mm layer 3 times better than the 100% silane) and at the same time is the only product in the test series which reduces the water uptake over 7 days by more than 90%. The penetration of the diluted products – especially the silane emulsions -- is extremely poor compared to the performance of WACKER BS 69001. As a consequence the water uptake reduction of these products is significantly lower.

Although water beading is sometimes considered as an „eye catch effect" (which might be true to some extent), a lack of beading effect is usually correlated with a lack of water repellency. For that reason water beading is important, even on concrete structures. In the formulation of the pasty product this fact was taken into account by chosing a silane/siloxane mixture as active ingredient and not a pure silane. Therefore, in contrast to pure silanes which evaporate from the surface near area, WACKER BS 69001 provides good water beading as soon as the emulsifier residues on the top of the surface are washed out.

6. Summary and prospect

Although it may sound a bit strange, several ways have been developed in order to formulate *water* sensitive *water* repellents into *water*. Meanwhile silicone emulsions and microemulsions are available for almost all applications where some years ago exclusively solvent diluted products were used.

Sometimes not only organic solvents but also active ingredients have to be considered as a problem in terms of ecology and health. An example are the undiluted, volatile alkylalkoxysilanes which are currently used for concrete protection. Due to their volatility, not neglectible amounts of these chemicals are emitted to the atmosphere during application.

In order to offer an alternative, pasty products were developed that penetrate into concrete orders of magnitude better than silanes. As water based formulations, these solid-free pastes – or cremes, as they are sometimes called – are much more acceptable regarding environment nd health.

This latest development is a good example that even the physical state of well established products is not invariable. The future of silicone based water repellents will be full of suspense – won't it?

Life cycle assessment for the evaluation of environmental impacts of construction materials

M. Öberg, M.Sc.
Cementa AB, R&D, Danderyd, Sweden

Abstract

The general focus on environmental aspects of human activities has triggered a growing environmental awareness in the building industry. Life Cycle Assessment (LCA) is a tool for the actors on the market to address the environmental dimension.

This report refers to a series of LCA-studies on building materials and components with the focus on concrete that have been undertaken 1994-97 within a project initiated by the Nordic Cement industry. (Environmental adaptation of concrete)

Emissions to air and water and use of raw materials and energy have been inventoried from the extraction of raw materials, over building process and user phase to the destruction of the building and final disposal of materials.

The inventory results have been evaluated with three different evaluation models.

A computer model has been developed and introduced to enable the use of LCA in day to day planning of environmental process improvement and product development.

The conclusions of the study from a methodological point of view;

- LCA is an adequate tool to map environmental effects of building materials.
- The inventory phase (LCI) provides a good base for the product environmental information that is being increasingly requested by the market.
- The evaluation models should be selected carefully and need some further elaboration to match the specific conditions applying to buildings regarding e.g. a long life cycle.

The conclusion from the specific case studies;

- High quality data on the environmental aspects of the production of cement and concrete have been provided.
- The differences with regard to environmental characteristics between construction materials, when only production phase is considered, 'Cradle to gate', is small and in many cases insignificant as compared to the user-phase.
- For products or materials with long expected lift-time the focus should be put on the user-phase performance. The user-phase usually accounts for over 80 % of the environmental loads. Careful urban development is a key factor for sustainability.
- For 'Green procurement' of buildings concrete is a good choice regarding components with long expected lifetime for example building frames, civil engineering works etc., were features like low need of maintenance or high heat-capacity in houses are essential. Shorter life cycles of enhances production and recycling aspects.

Keywords: LCA, Life Cycle Assessment, Sustainable buildings

1 Introduction

Within the Nordic project 'Environmental adaptation of Concrete', initiated by the Nordic cement industry, an LCA calculation model has been developed which has been used in several product studies.
The project has been financed by the cement industry in Finland, Norway and Sweden, TEKES in Finland and the Nordic Industrial Fund.
Different expert teams within the LCA field have been involved; Stiftelsen Östfoldsforskning, Norway, Chalmers Industriteknik and Chalmers Technical University, department of Technical Environmental Planning, Sweden and VTT, Finland.

This report gives an overview of the different studies that has been conducted so far.

2 Scope

The scope of the product studies has been to
- make an adoption of the general LCA-computer model on the specific product to be used in sustainable product development,
- get a rough comparison on environmental performance with alternative materials (Benchmarking) and to
- develop a base for environmental product information.

Aspects like work environment and indoor health are not included in this study as there are not any scientific models available to connect such parameters with the exterior environmental aspects normaly dealt with in LCA.

3 Methods

The inventory and evaluation of data and the adaptation of the computer model for the specific product has been conducted by different expert teams within the LCA field in Finland, Norway and Sweden.
The data is aggregated with the LCAiT (LCA inventory tool) software developed by Chalmers Industriteknik, Sweden and the evaluation is performed with the Microsoft Excel programme.
The evaluation has been conducted with three different evaluation models; The effect-category method - CML (Leiden, Holland. Adapted to Swedish environmental goals), Environmental Priority Strategies in product design - EPS (Steen/Ryding, Sweden) and The Ecological Scarcity Method - BUWAL (Switzerland. Adapted to Norwegian and Swedish conditions).
In order to supply data and make a critical review of the work a reference group has been connected to each study. The reference group has consisted of representatives from the specific product group concerned. For example in the study of road surface materials the reference group have consisted by representatives from the asphalt and ready mixed concrete industries as well as contractors and road authorities.

4 Results

4.0 General

From the LCA a lot of different aspects can be quantified and presented according to the use in the particular case. In each study the functional unit is described and the inventory data reflecting its environmental characteristics is displayed, for example energy use and emissions to air. This information provide the base for environmental product information.

The evaluations conducted with the three evaluation models mentioned above, are presented graphically to visualise the significant environmental effects.

It should be nothed that the evaluation models sometimes give different environmental ranking when comparing alternative constructions.

4.1 Cement and concrete. Cradle to gate [1]

The first product study comprised the production of cement and concrete. The production processes for all seven cement plants of Finncement in Finland, Norcem in Norway and Cementa in Sweden where examined in detail from the limestone quarry to the transport to customer.

The database was integrated in a computer model which today is used operationally as a decision making instrument in the environmental improvement schemes for the cement production and also in all product developments.

To illustrate the operative use of the LCA-data model the effect of the improvement plans 1996 to 1999 for the Swedish plants is presented in diagram 1. The diagram also shows that emissions of C02, NOx and SO2 and the use of fossil fuel are the major contributors to the environmental impact of cement production.

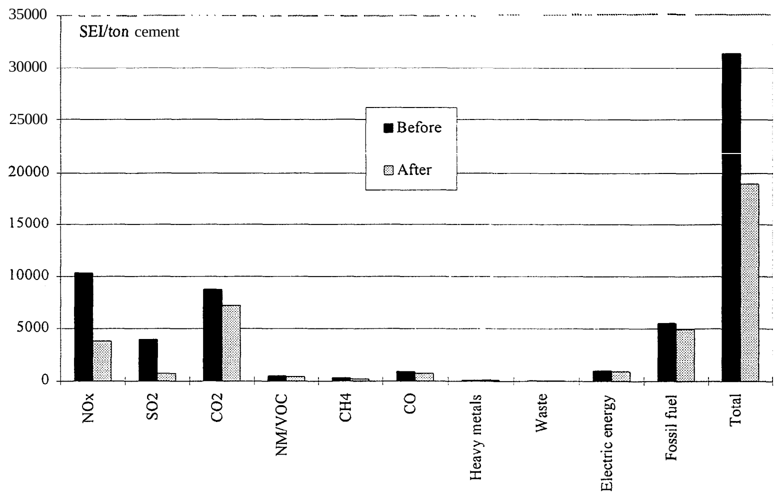

Diagram 1. Evaluated environmental effects of improvement scheme 1996 to 1999. Mean values for Swedish cement plants. Effect category method. Note that all the following presentations are based on cement data prior to the improvement scheme.

The cement content in concrete varies between 10 and 20 % by mass and the environmental characteristics of the production of concrete is closely related to the production of cement as can be seen in figure 5 below.

From the LCA a lot of different aspects can be quantified and presented according to the use in the particular case. In each study the functional unit is described and the inventory data reflecting its environmental characteristics is displayed, for example energy use and emissions to air. This information provide the base for environmental product information.

The evaluations conducted with the three evaluation models mentioned above, are presented graphically to visualise the significant environmental effects.

It should be nothed that the evaluation models sometimes give different environmental ranking when comparing alternative constructions.

4.1 Cement and concrete. Cradle to gate [1]

The first product study comprised the production of cement and concrete. The production processes for all seven cement plants of Finncement in Finland, Norcem in Norway and Cementa in Sweden where examined in detail from the limestone quarry to the transport to customer.

The database was integrated in a computer model which today is used operationally as a decision making instrument in the environmental improvement schemes for the cement production and also in all product developments.

To illustrate the operative use of the LCA-data model the effect of the improvement plans 1996 to 1999 for the Swedish plants is presented in diagram 1. The diagram also shows that emissions of C02, NOx and SO2 and the use of fossil fuel are the major contributors to the environmental impact of cement production.

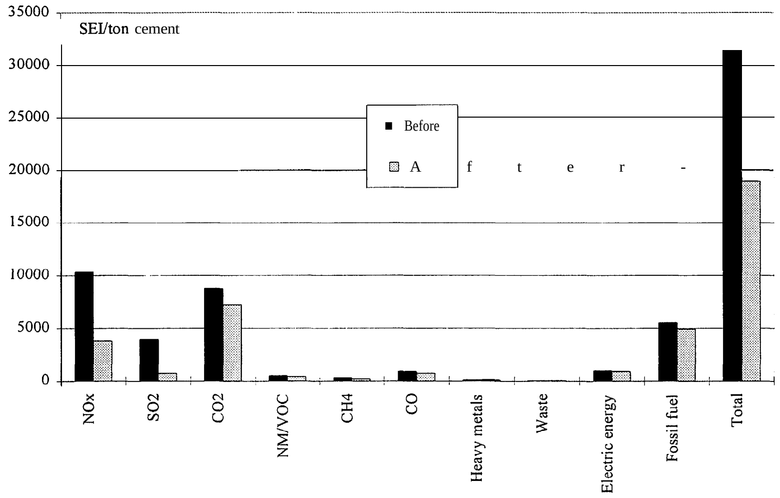

Diagram 1. Evaluated environmental effects of improvement scheme 1996 to 1999. Mean values for Swedish cement plants. Effect category method. Note that all the following presentations are based on cement data prior to the improvement scheme.

The cement content in concrete varies between 10 and 20 % by mass and the environmental characteristics of the production of concrete is closely related to the production of cement as can be seen in figure 5 below.

4.2 Asphalt and concrete paving. Cradle to grave [2]

The object of the study was to assess the environmental impact of road pavements including maintenance. In order to establish relations to other user phase impacts the fuel consumption of vehicles and the energy use for lighting of the road was also quantified. The functional unit was defined as one km of a motorway close to Tampere in Finland with a traffic of 20.000 vehicles per day and a life span of 50 years.

Regarding the production of the pavement the inventory results for the most significant environmental aspects are presented in diagram 2. As can be seen the material characteristics differ significantly without giving any clear indication on which material is environmentally favourable. Applying the different evaluation models on this inventory data give no consistent answer. Using the Eco-Scarcity model asphalt is advantageous whereas using the EPS or the Effect Category methods concrete is preferred.

Regarding the entire life cycle including traffic and lighting the environmental effect of producing the pavement becomes negligible. See diagram 3

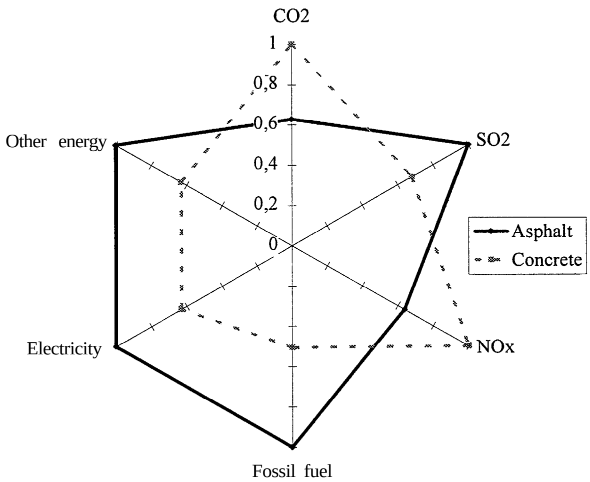

Diagram 2. Environmental characteristics of asphalt and concrete pavements.

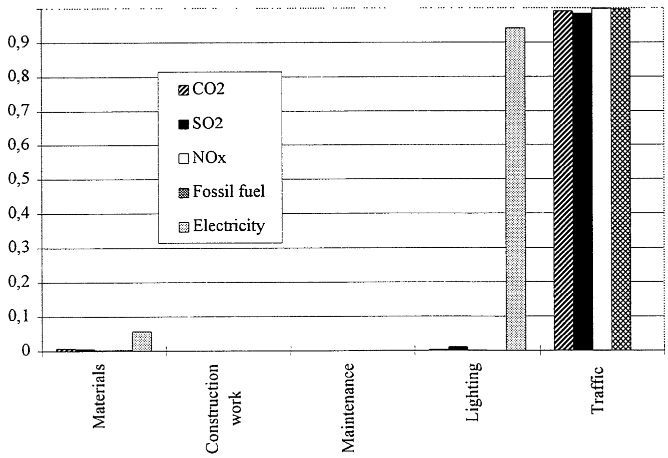

Diagram 3. Relative impact of the environmental burdens of paving and user phase of motorway during 50 years.

4.3 Concrete sewage water pipe. Cradle to grave [3]

In this study the total life cycle of a one km long concrete sewage water pipe line was inventoried and analysed. Data for unreinforced concrete pipes with a given diameter from three different concrete pipe producers in Sweden were gathered and specific data on excavation and other construction works were collected from the city of Gothenburg.

In diagram 4 below the distribution of environmental load according to the three chosen evaluation methods and also gross energy use is displayed.

As could be expected the cement production is a substantial contributor to the environmental load but the most interesting aspect is that the transfer of filling materials by far carries the environmental burden for the pipe line. Thus the environmental performance would benefit from techniques were the excavation is minimised.

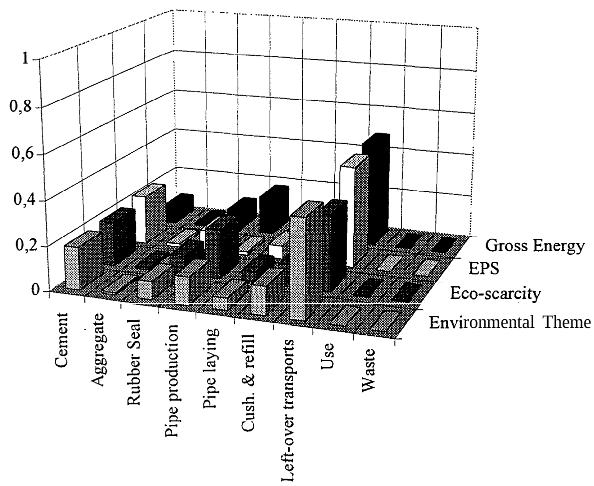

Diagram 4. Summary of the evaluation of the environmental impact of a concrete sewage water pipe line.

4.4 Building frames of concrete, steel and timber. Cradle to grave [4]

The scope of the frame study was to map the external environmental effects of building frames over the whole life-cycle. The following building frames for multi storey office or residential buildings in the Nordic countries were analysed;

In situ cast concrete, precast concrete, steel frame and hollow core slabs, in situ cast concrete with precast floor plates, steel frame with in situ cast concrete on precast floor plates, steel frame with ligth deck and timber frame.

In order to limit the amount of input data a segment of a frame was studied. See figure 1. The environmental load was related to 1 m2. of floor area during 50 years service life. The location of the building was defined to central Sweden in order to get comparative transport distances for components and materials.

Relevant portions of facades and interior walls areas were included.

Surface materials like paint, wall paper, carpets and installations were excluded.

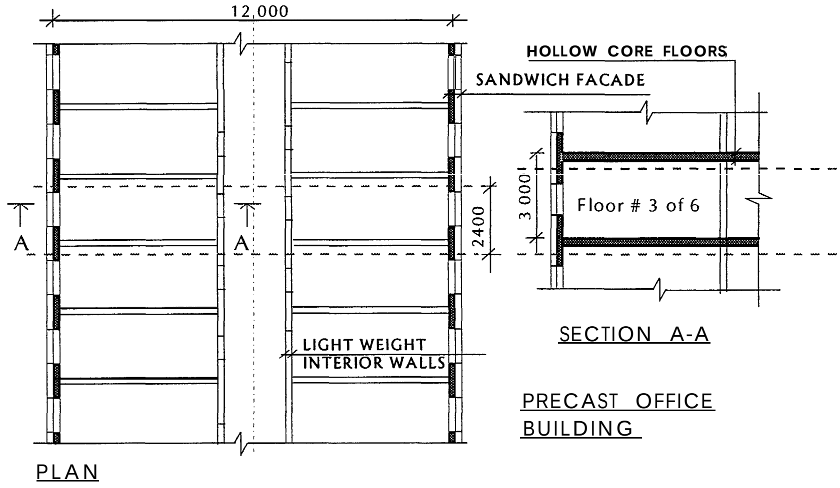

Figure 1. Definition of functional unit for building frame.

For the precast concrete as well as ready mix production specific plants was inventoried. For steel production general data for the Swedish steel industry with specific data for transportation distances have been used. For other materials like plasterboards and insulation general data from manufacturers have been collected.
General environmental databases are used for environmental data on transportation.
Environmental loads from the building site are related to the use of energy and generated waste.
For the service life general statistical data on the use of energy for heating and how this energy is supplied is used. A general overwiev of the positive effect of heat capacity in heavy buildings is presented but no evaluation of the behaviour of the different frame types in this study with respect to heat capacity was made.
The destruction phase adds to the environmental loads by the use of fossil fuel for demolition and transportation of waste material.
The LCA provides an effective tool for product improvement. In diagram 5 the distribution of one environmental parameter, - the energy use for a concrete floor, is displayed.

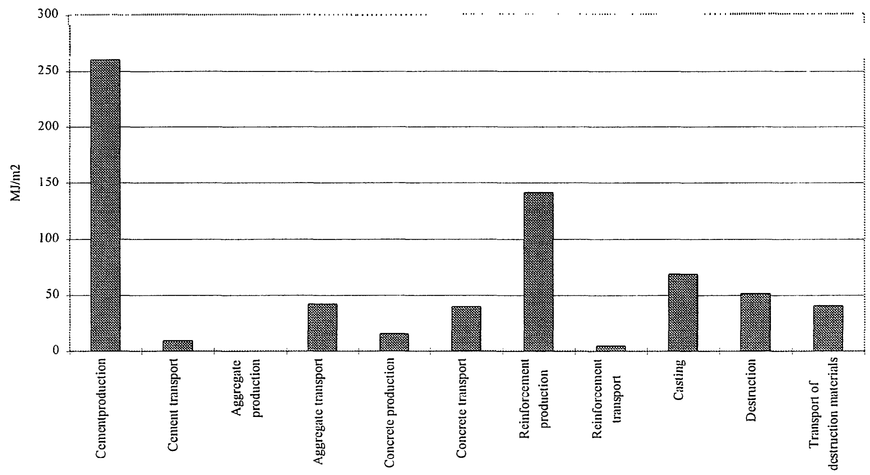

Diagram 5. Energy use for one m2. in situ cast concrete floor, H=200, over the whole life cycle. Energy for heating of the building during the user phase is not included.

The distribution of environmental loads evaluated with three different evaluation methods over the whole life cycle is presented in diagram 6

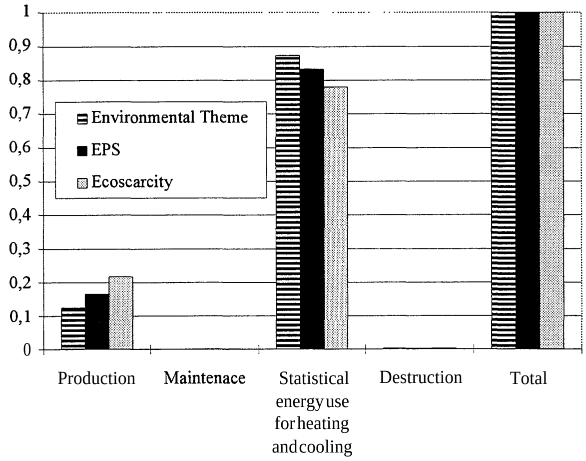

Diagram 6. Distribution of environmental loads of precast concrete frame over the life-cycle according to three different evaluation models.

A comparison between different frame types with four different frame types is presented in diagram 7.

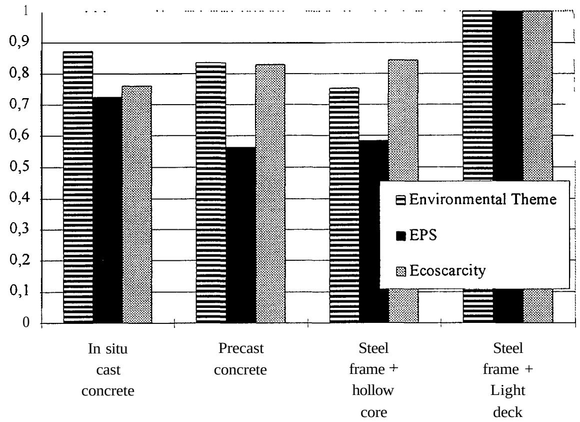

Diagram 7. Comparison of environmental load for the production of some of the frame types according to three different evaluation models.

The following conclusions can be drawn from the LCA-study on building frames;

- The difference in environmental impact from the production of the precast, in situ concrete and combined steel/concrete frames is small whereas the extreme light weight frames deviates more.
- Raw materials used are abundantly available with the exception of the fossil fuel.
- For the production phase the production of cement and steel are main contributors.
- The recycling possibilities of materials are important.
- Over the entire life cycle the user phase gives the highest environmental loads and the energy use for heating of the building is the dominating parameter.
- Because of the importance of the energy for heating (and cooling) during the user phase qualities like heat capacity are important.

- The environmental load from maintenance of a concrete or steel building frame is negligible.
- The impact of destruction is small and is related to the use of fossil fuels by transportation
- Some evaluation models give high response on waste which stresses the importance of minimising production waste and to recycle demolition waste e.g. as filling material.

5 Conclusions

LCA metodology is an adequate tool to map environmental effects of building materials and structures. The evaluation models should however be selected carefully and need some further elaboration to match the specific conditions applying to buildings regarding e.g. a long life cycle. Quite often applying different evaluation models will give disparate ranking between alternative constructions. Compare diagram 7, above.
High quality data on the environmental aspects of the production of cement and concrete have been generated.
The differences with regard to environmental characteristics between construction materials, when only production phase is considered, 'Cradle to gate', is small and in many cases insignificant as compared to the user-phase.
For products or materials with long expected lift-time the focus should be put on the user-phase performance. The user-phase usually accounts for over 80 % of the environmental loads. Careful urban development is a key factor for sustainability.
In the existing evaluation models little or no attention is given to the positive environmental value for the society, of building activities in the sense of providing buildings and infrastructure.
For the green procurement of buildings concrete is a good choice regarding components with long expected lifetime for example building frames, civil engineering works etc., were features like low need of maintenance or heat-capacity in houses are essential. Shorter life cycles of enhances production, destruction and recirceling aspects.

Presentation of Eco-Quantum, the LCA-based computer tool for the quantitative determination of the environmental impact of buildings

J. Kortman, H. van Ewijk
IVAM Environmental Research Amsterdam, The Netherlands
J. Mak, D. Anink, M. Knapen
W/E consultants sustainable building, Gouda, The Netherlands

Abstract
The Dutch government and building industry have agreed that life cycle assessment (LCA) should be the basis for the determination of environmental effects of (building) products. In order to provide architects and project developers with an instrument to measure the environmental performance of buildings, the Dutch government and other organisations financed the development of Eco-Quantum (EQ).

EQ is a computer tool on the basis of LCA which calculates the environmental effects during the entire life cycle of the building: from the moment the raw materials are extracted, via production, building and use, to the final demolition or reuse. This includes the impact of energy and water use, the maintenance during the use phase, the differences in the durability of parts or construction needs, like adhesives and nails. EQ also takes into account the possibility for selective demolition or renovation. The method can be used for both dwellings and non-domestic buildings.

Two types of computer tools are developed and will be presented at the conference: EQ-domestic and EQ-research. EQ-domestic is a tool for architects. With this instrument architects are able to quickly include environmental consequences of material, water and energy use in their designs of domestic buildings. So Eco-Quantum can be used to communicate on issues related to sustainable building between various partners, like project developers and designers. EQ-research is the tool for developing innovative designs for sustainable buildings and offices.

Keywords: Eco-Quantum, computer tool, building design, life cycle assessment, quantitative, environmental impact

1. Introduction

The life cycle of a building is responsible for a considerable part of the environmental effects caused by human activities. It is therefore important to dispose of instruments which show the environmental consequences of decisions of a building design. Two types of computer tools are developed in the Netherlands which enable architects and project developers to measure the environmental performance of complete buildings on the basis of LCA. They are named Eco-Quantum Domestic and Eco-Quantum Research. With Eco-Quantum Domestic architects are able to quickly identify environmental consequences of material choices and water and energy consumption in their designs of domestic buildings. Eco-Quantum-Research is the tool for in depth analysing of the environmental performance of buildings and developing innovative designs for sustainable houses and offices.

The Dutch government and building industry have agreed that life cycle assessment (LCA) should be the basis for the determination of environmental effects of buildings and building products. In order to provide architects and project developers with an instrument to measure the environmental performance of buildings, the Steering Committee for Experiments in Public Housing, the Dutch Building Research Foundation, the Association of Dutch Architects and the Dutch government financed the development of Eco-Quantum.

Until recently, only LCA's of building components and materials were carried out. But, a building is more than adding the various components, for example the life cycle of a building is important. Therefore IVAM Environmental Research and W/E consultants sustainable building developed Eco-Quantum, a computer tool on the basis of LCA which calculates the environmental effects during the entire life cycle of a complete building: from the moment the raw materials are extracted, via production, building and use, to the final demolition or reuse [1, 2, 3]. This includes the impact of energy and water use, the maintenance during the use phase, the differences in the durability of parts or construction needs, like adhesives and nails. EQ also takes into account the possibility for selective demolition or renovation.

2. General lay out of Eco-Quantum

Eco-Quantum consists of 3 related programmes, Eco-Quantum Research, Eco-Quantum Domestic and SimaPro. Databases are another part of Eco-Quantum. The two most important databases are: the database Components and the database Environmental Profiles.

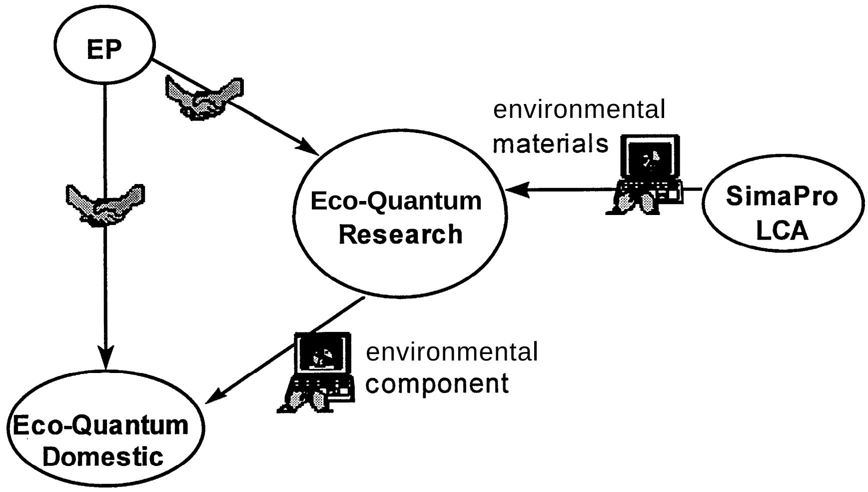
In figure 1 the general lay out of Eco-Quantum is presented. Eco-Quantum Domestic and Eco-Quantum Research are provided with information from a stand-alone version of the Dutch LCA programme SimaPro 4 [4] and the Dutch Environmental Performance Standard (EP). SimaPro calculates split environmental profiles per kilogram building materials and for processes related to the production of energy and water, transportation and waste processing. These environmental profiles are the input to the database Environmental profiles in Eco-Quantum Research. The Dutch Energy Performance standard is applied to determine the energy consumption during the use of the building.

Architects provide the input of the design: materials and quantities of the building components of the design, together with figures about energy and water consumption. Eco-Quantum translates this in kilogram materials and water flows and MJ energy. For this Eco-Quantum comprises of an extensive database components which consists of materialised components of the building, with information about life span, materials needs, maintenance and waste scenarios.

In order to calculate the environmental performance of a building the environmental information from the database Environmental profiles is connected to the material, water and energy flows of the building. By doing this the environmental interventions related to the total life cycle of the building are accumulated. Furthermore the environmental interventions are converted on the basis of characterisation factors of the LCA methodology of Heijungs et ***al.*** [5] into 11 environmental effectscores such as raw material depletion, ecotoxicity and greenhouse effect. In a following step these 11 effectscores are converted into four environmental indicators: raw material depletion, emissions, energy consumption and waste according to the Dutch project “Environmental Ratings in the construction industry set up by the Council for the Construction Industry (see figure 3).

Various outputs can be presented in de from of environmental indicators, environmental profiles and material flows.

Figure 1 Subsystems Eco-Quantum



Eco-Quantum

3. EQ domestic

Performing LCA of complete buildings is normally a complex and time consuming task. Environmental requirements are added to an enormous amount of design requirements which architects have to consider for designing a building. If an instrument does not consider this complex task and the time constraints of architects, it won't be used in a design process.

Against this background EQ domestic is developed as a practical computer programme which enables architects to quickly reveal the environmental performance of a housing project. In order to do so environmental information about standardised building components is prepared in Eco-Quantum Research for Eco-Quantum Domestic in the form of environmental profiles of components (see figure 1).

If the specifications of a building design are available it is possible to determine the environmental impacts in about a half an hour. The environmental profiles of standardised components in Eco-Quantum Domestic serve as an aid to the architect. The user can indentify the most important causes of the environmental impacts, make changes in the design of the building and evaluate the alternative solutions.

The user performs the following steps in EQ domestic:

- **enter information about the building project**

In order to calculate the environmental performance of a housing project the user opens a new project en describes it by filling in the name and other general information. It is expected that various design variants will be developed. Therefore the user also gives each variant of the project a unique name. Eco-Quantum connects to each variant a tree structure which consists of 4 levels: the complete building, 8 building parts, 24 building elements and about 60 building components. The structure of the tree follows the structure of the Dutch NL/SfB Building element method.

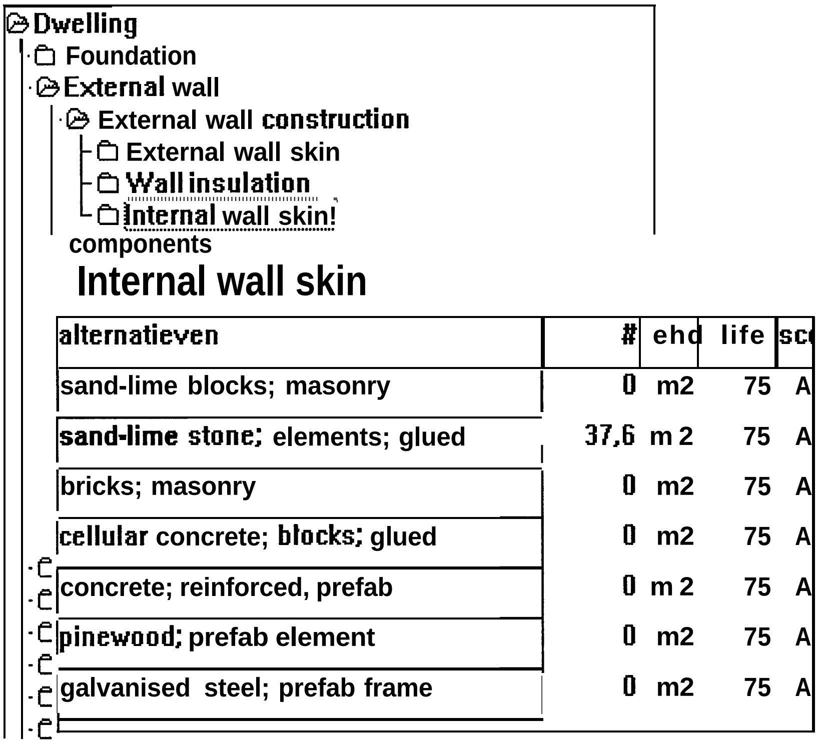
- **enter the design data of the project**

In Eco-Quantum Domestic the input of a design is as limited as possible. In figure 2 an input screen is presented. In the upper part of the figure a small part of the tree is shown following the four levels:

- building
- 8 building parts, e.g. external wall
- buildings elements: only one building element is folded out: e.g. external wall construction
- buildings components: only one component is folded out: e.g. internal wall skin

The architect folds out one element (in this case external wall construction) and selects one component (in this case the inner side of the cavity wall, the internal wall skin). In the lower part of the screen the architects enters the necessary design information in the form of the amount of walls (37,7 m2). Furthermore the architect can change the life span (here 75 years) and choose between demolition scenario A (current situation) and B (optimised situation). After finishing the input for this component Eco-Quantum Domestic automatically goes to the following component. Besides this information both the information about energy consumption and water consumption of the specific design is entered in the programme.

Figure 2. Input screen and part of the tree



- **calculate the environmental profile of the building**

On the basis of these inputs the programme calculates the environmental performance of the building. First, Eco-Quantum relates the environmental profiles to the corresponding material, energy and water flows. By doing so the environmental interventions related to the total life cycle of the building are accumulated in the form of raw materials, energy input, waste and emissions. Second, the environmental interventions are converted on the basis of characterisation factors of the LCA methodology [5] into 11 environmental effect scores such as raw material depletion, ecotoxicity and greenhouse effect. In the following step these 11 effect scores are automatically converted into four environmental indicators: raw material depletion (exhaustions of resources), emissions, energy consumption and waste according to the Dutch Environmental Rating methodology (see figure 3).

- **presentation of results**

The user can choose between various kinds of output depending on the question to answer. The three possibilities are:

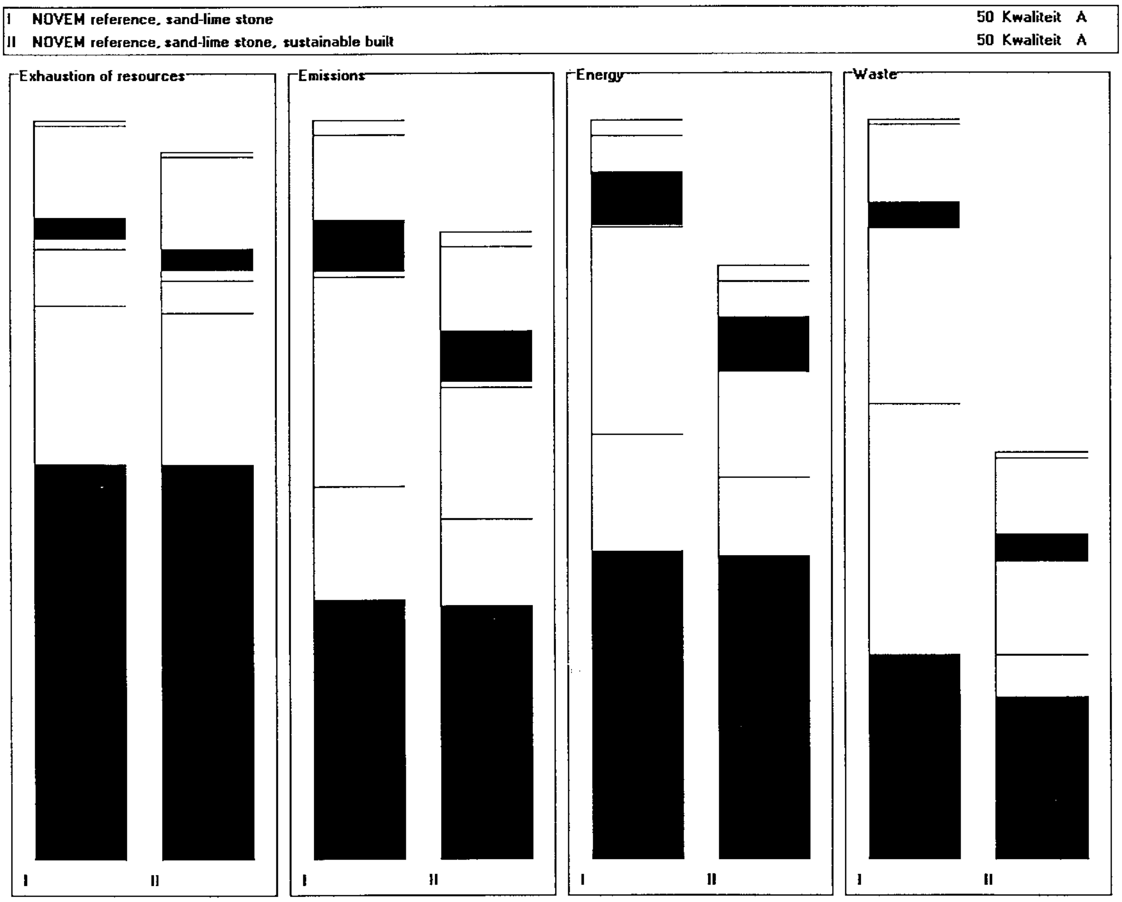
1. an overview of materials streams
2. 11 effect scores, according to the life cycle analysis of Heijungs.
3. 4 environmental indicators, according to the “Environmental ratings in the constructions industry” (exhaustion of resources, emissions, energy and waste)

If an architect wants to detect the causes of the environmental burden of the design it is possible to give a division of the environmental impacts over the stages of the life cycle of the parts, elements and components of the building.

- **optimise the environmental profile of a design**

The user can environmentally optimise the design in various ways. The components and constuctions at which the largest environmental benefit can be obtained are indicated. So the user can optimise these with the material alternatives offered. So the environmental burden can be reduced mostly. The user can also select alternative building components and constructions and see what the impact is on the environment. Of course, installation concepts for reducing energy and water consumption can also be changed, just like the life span, and the use of secondary materials and recyclable products.
Eco-Quantum Domestic enables the architect to easily change the input and quickly calculate the new environmental profile and compare the original design with the optimised one (see figure 3).

Figure 3 Output: comparing the original and the optimised design



- **compare the environmental performance of various designs**

In figure 3 the environmental profile of a standard sand lime brick house is compared to an optimised sand lime brick house. In the latter the improvement options from the Dutch manual for sustainable building: Nationaal pakket Woningbouw (National Package Sustainable Housing) [6] are implemented. Examples are energy saving installations, better insulation, less use of scare materials and wood from not-sustainable managed woods.

4. EQ research

Eco-Quantum Research is the instrument for in depth research of the environmental impacts for all types of buildings by researchers, consultants and large design offices. An important difference is that in Eco-Quantum Research users can enter new building components whereas Eco-Quantum Domestic works with fixed standardised building components. This makes Eco-Quantum Research a tool which is suited for all building types. The environmental impact of any building type can be calculated with it, like schools, hospitals and other health buildings, offices and other industry buildings. This can on the other hand make EQ Research a more time consuming instrument. A user can, but is not obliged to, add self made building components. If the user wants add components, he of she has to enter the design data himself, for example material consumption per square meter, building waste, time span and waste scenario.

5. Concluding remarks

Both the prototypes of Eco-Quantum Domestic and Eco-Quantum Research will be presented by W/E consultants sustainable building and IVAM Environmental Research at the conference in order to enable participants to see the details of the programme.

Eco-Quantum makes it possible to communicate on the environmental impact of buildings during the design of a building. By presenting quantitative results in a relatively simple way, architects can improve the environmental quality of a building themselves. Other qualities of a building are of course at the same time considered. And Eco-Quantum enables them to communicate with their initiators and future owners.

Abstract
The service life of external building materials largely depends on the severity of the micro climate and the properties of the material itself. The rainwater is the most effective environmental agent, particularly on porous building materials, either as a harmful agent itself or as a means of several degradation mechanisms resulting from the combined attack with other weathering agents. Thus the moisture characteristics of the material play an important role in determining its durability.

As most of the damages are related to water, measures must be taken against the ingress of water into the structure. The use of surface treatments for the protection of porous building materials against rainwater extends the service life of the component. The silicon-based water repellants are increasingly used due to their hydrophobic properties.

In order to evaluate the performance of the hydrophobed porous building materials, some laboratory tests have been carried out on autoclaved aerated concrete (AAC) specimens, rendered with different combinations of plasters and hydrophobed with silicon compounds. Common properties, such as capillary water absorption and vapour permeability were tested. This paper reviews degradation mechanisms related to rainwater and the general properties of surface treatments. Brief results on moisture characteristics of plastered AAC with and without water repellants are presented.
Keywords: Autoclaved aerated concrete, surface treatments, water repellants, degradation, moisture properties

1 Introduction

A large number of buildings have various problems due to exposure to wind-driven rain and water vapour from the inside. Failures of facades can be seen both on existing old and new buildings. Agents originating from the atmosphere are most relevant for the ageing process of the materials used in the exterior envelope of the buildings. External walls are deteriorated by the atmospheric agents in scale of components and materials, especially on facades exposed to wind-driven rain. The severity of damage is increased by the combined attack of the weathering elements like solar radiation, rain, air constituents and contaminants and freeze-thaw cycles.

When porous building materials are subjected to rain, an inward transport of water occurs. Water penetrates through the capillaries, cracks and joints by wind and capillary suction forces directed into the building enclosure. The absorption rate depends on the pore structure of the substrate and the hydraulic properties of the surface. The rate of drying after wetting is also dependent on the porosity of the material and the ambient temperature, relative humidity and wind velocity.

In fact, the wetting of the walls is due not only to rain but also to condensation phenomena. Vapour permeable waterproofs should be applied to vapour permeable substrates in order to allow vapour to pass through the coating to the outside of the building. Otherwise, vapour condenses at the interface of the nonpermeable layer, causing deterioration. Therefore, the continuity of the moisture transport through the different layers of the wall, that is, the vapour permeability of the whole wall system, plays an important role in proper material selection.

The use of surface treatments for the protection of porous building materials against water ingress is expected to extend the service life of the walls by raising their performance. However, surface treatments should not affect the vapour transmission as not to cause condensation in the wall structure.

2 Degradation mechanisms related to rainwater

Rainwater is the major destructive atmospheric agent for most external building materials. The amount of water hitting a wall depends on the intensity of driving rain, which in turn is directly proportional to the amount of rainfall and the wind velocity during rain.

Volume changes, as expansion on exposure to moisture and contraction during drying out, result in cracking or surface crazing of porous building materials. The flow of water over surfaces or splashing back of water against surfaces from rainfall causes change in appearance of facades, such as staining.

Water transports salts within the wall structure and deposits them on the surface of the porous material by evaporation. This phenomenon is known as efflorescence. The crystallisation of soluble salts within the pores beneath the exposed surface within the structure is referred to as ‘cryptoflorescence’. The white deposits of soluble salts on surfaces can lead to change of appearance as well as give rise to deleterious effects by the reversible uptake of water. Cryptoflorescence may cause loss of adhesion of external wall finishings such as renderings and surface coatings and leads to embrittlement and crumbling of the surface material as a result of crystallisation pressure [1]. Formation of these crystals can trap moisture in masonry pores, which cause spalling during freeze-thaw cycles. Additionally, if cryptoflorescence is severe enough, it prevents the natural moisture transport properties of the masonry wall.

When porous building materials are exposed to low temperatures, the water in the capillary pores freezes and stresses produced lead to deterioration. The frost resistance of the material is mainly influenced by the water content and the pore structure of the material. For the deterioration mechanism the influence of water content is related to a value known as 'critical water content', below which materials are resistant to frost action. Therefore the permeability of a material plays an important role in frost action. The most common frost damage, such as cracking and spalling, is caused by progressive expansion from repeated freeze-thaw cycles. By preventing water penetration, substrates will also be protected from the damaging effects of freeze-thaw cycles.

Ultraviolet radiation received on the surfaces of buildings causes degradation particularly when it acts in conjunction with oxygen, water, heat or a combination of these agents. Loss of appearance, fading, yellowing, and erosion are common UV failure modes. UV also contributes to the loss of protection properties such as water repellency.

Sulphates and nitrates in the air form sulphuric and nitric acids by reacting with rainwater (acid rain), which acids are transported deep into the porous material via wet deposition and capillary suction. They attack the calcium compounds of the substrate, causing deterioration.

Fine particles of atmospheric dirt settle at building surfaces and the contaminated rain falls at and runs off the same surfaces. The flow of water may wash the particles out but usually redeposit them, the outcome depending on direction and rate of the flow. Porous materials trap the particles in their pores [2].

In addition to the deterioration effects of water, the high moisture content declines the thermal performance of the wall, bringing significant energy losses.

3 Surface Treatments

Surface treatments are used as a preventive measure for improving the performance of porous building materials against external degradation agents. As most of the damages are related to water, the protection is usually intended to reduce the absorption of water in the material.

Surface treatments can be classified in four main groups according to their protective action [3] :

- penetrant / pore liners
- penetrant / pore blockers
- sealers and coatings
- cementitious coatings

3.1 Pore-liners

These treatments line the pore surfaces of the substrate by a chemically bonded water-repellent hydrocarbon molecule [4]. As they do not block the pores, the effect on the vapour permeability of the wall is negligible. As the surface treatment is colourless, it makes very little change on the appearance of the facade.

By penetrating the substrate, the material itself is shaded and thus highly protected from the UV radiation. Accordingly, a long term durability is achieved. The performance of the pore-liners largely depends on properties of the substrate, such as porosity and moisture content and on the amount of material applied.

Silanes, siloxanes and silicon compounds are examples of this type.

3.2 Pore-blockers

These treatments penetrate into the substrate and clog the pores. In this way water is repelled along with any dissolved salts, acids and other aggressive agents. This treatment is also known as the crystal growth method. The crystalline reaction products bind to the water molecules and increase in volume.

The vapour transmission is greatly restricted by the blockage of the pores. Improper application can cause water uptake by capillary action. Pore-blockers have no effect on the appearance of the surface. They are usually used for hardening of the surface and as a primer before the main coating.

The most common examples are silicates, silicofluorids and some kinds of epoxy and acrylic resins.

3.3 Sealers and coatings

By forming a pinhole-free, continuous film layer on the surface, sealers and coatings prevent the water ingress but obstruct also the vapour diffusion. Owing to their penetration into the substrate to some degree, sealers have a good adhesion to the substrate and are often used as primers. Film forming surface coatings can be pigmented when colour is desired.

Epoxy resins, polyurethanes, acrylics, linseed oil, alkyds, vinyls, chlorinated rubber, styrene-butadiene, cement based stone paints and bitumens are the typical examples of sealers and coatings.

3.4 Cementitious coatings

These are cement-based products containing finely graded siliceous aggregates. Chemical additives impart integral water repellency and improve the adhesion of the coatings to the substrate. Since cementitious coatings are water-repellent, they are highly resistant to freeze-thaw cycles. The performance against weathering is excellent, while the resistance to acid rain and other contaminants is poor.

These products are also vapour permeable, allowing transmission of vapour. Cementitious coatings adhere well to the substrate and are considered as an integral part of the substrate. But they do not function if cracking or substrate movement occurs.

The coatings completely change the original appearance of the facade. Pigments are added to colour and various textures are available, either by coarseness of aggregate or by application methods [5].

4 Silicon-based water repellants

Silicon-based water repellants are considered as the best protective agents against aforementioned facade failures. They are colourless, low viscous, capillary active liquids which act by forming a hydrophobic zone against water. The effect of water repellants is based on their low surface tension. They are claimed to satisfy requirements as [6]:

- excellent water repellency
- high vapour permeability
- good adhesion
- excellent durability (resistance to weathering, e.g. UV)
- solvent-free (environmentally friendly)
- no change in appearance.

Silanes and siloxanes have the best performance characteristics and long-term durability among the silicon compounds. They have t-structured molecules containing three silicon functional groups and one organofunctional group. While siliconates also belong to this group, they are no longer used for protecting facades. The reason is that a white layer is formed on oversaturated areas, which is hard to remove [7].

The hydrophobicity is provided by the organofunctional (alkyl) groups of the compound. The penetration depth into the substrate is determined by silicon functional (alkoxy) groups and affects the long-term durability of the repellant. By penetrating the substrate, the alkyl group is protected against UV radiation. Factors influencing depth of penetration include the porosity (particularly on the surface), moisture content of the substrate, molecular size and amount of water repellant agent applied [4]. The molecular size of silanes (10-15 A) and siloxanes (25-75 A) is small enough to permit the compounds to enter the pore structure of concrete (20-200 A).

The water-repellent hydrocarbon molecule (alkyl group) chemically bonded to the substrate, reduces the surface tension of the substrate. Different alkyl groups reduce the water absorption to various levels. The water absorption rate is represented by the water absorption coefficient of the surface coating, A [$kg/m^2h^{0,5}$]. This coefficient describes the water absorption of a wall when a film of water occurs at the surface. The behaviour of water when in contact with the surface of the material is governed by its surface tension which is measured by the contact angle.

5 Experiments

In order to study the performance of porous building materials against weathering, the moisture characteristics of hydrophobed plastered autoclaved aerated concrete (AAC) were tested. The hydrophobic properties of the sample components, i.e. capillary water absorption and vapour permeability were taken as performance parameters.

5.1 Materials

Tests were carried out on ten AAC specimens, rendered with five different plaster systems with and without silicon. Two different water-repellent products were used; as an additive in the plaster and as a treatment at the surface of the AAC. The water repellant used as an additive is a powder consisting of a silicon resin on a carrier matrix and forms pores in the plaster. The plaster gets flexible and thus has a low tendency to crack. The water repellant used as surface treatment is an aqueous silane/siloxane emulsion. It is solvent-free and water thinnable.

The plaster systems used are (in general) as following:

A1: Two layered thin plaster, (4 mm); primer and a sprayed topcoat
A2: Two layered thin plaster, (4 mm); primer with silicon additive and a sprayed topcoat with silicon additive
B1: Three layered plaster (17 mm); primer, lime-cement undercoat and a sprayed topcoat
B2: Three layered plaster (17 mm); primer with silicon additive, lime-cement undercoat with silicon additive and a sprayed topcoat with silicon additive
C1: Four layered coating (17 mm); primer, lime-cement undercoat, acrylic primer and a acrylic plaster as topcoat
C2: Four layered coating (17 mm); primer with silicon additive, lime-cement undercoat with silicon additive, acrylic primer and a acrylic plaster as topcoat
D1: Monosystem plaster (18 mm)
D2: Monosystem plaster (18 mm); (AAC surface treated with silicon)
E1: Three layered coating (15 mm); hydraulic lime primer, hydraulic undercoat and a cement-dolomite paint
E2: Three layered coating (15 mm); (AAC surface treated with silicon), hydraulic lime primer, hydraulic undercoat and a cement-dolomite paint.

5.2 Tests

Specimens in dimensions of 150*150*70 mm^3 were used in the capillary absorption test. The faces of the samples, except the surface to be immersed, were sealed water and vapour-tight. The samples were immersed in 1-3 mm of water (Figure 1). The samples were weighed at the start of the test before immersion and at various time intervals. The water level was kept constant during the experiment.

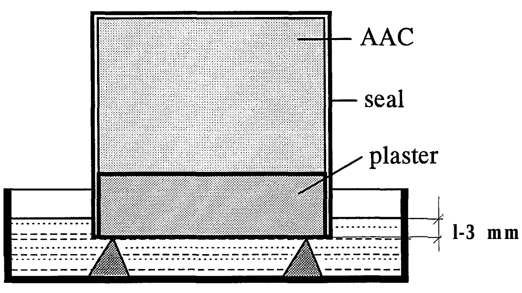

Figure 1 Capillarity test set-up

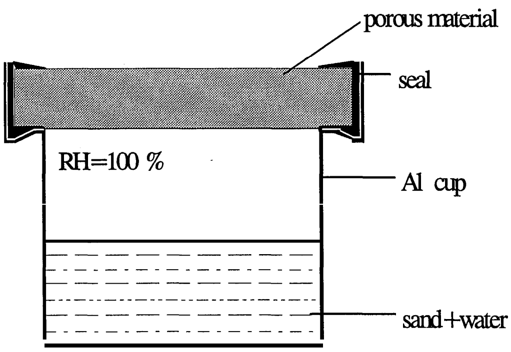

Figure 2 Wet cup method

The vapour permeability tests were carried out in accordance with the wet cup method. Cylindrical specimens with a diameter of 90 mm were placed in aluminium cups containing sand and water (Figure 2). The edges were then sealed so that only the upper and the lower surfaces were exposed. The cups were stored in the climate chamber at 20^0C and 65 % relative humidity. Changes in the mass of water in the cups were determined by weighing at certain time intervals.

5.3 Results

In Table 1, the samples are identified according to the existence and type of the water-repellent material. The water absorption rates at 24 hours and the reduction gained by water repellants are given in Table 2.

Table 1 Summary of specimens

	samples without repellant	samples with repellant
repellant as additive	Al	A2
	B1	B2
	Cl	c2
repellant as surface treatment	D1	D2
	El	E2

Table 2 Summary of best performance

samples	Water Absorption Rate [kg/m²$h^{0,5}$] without repellant	with repellant	Reduction %
A	2,12	1,18	44
B	1,67	0,25	85
C	0,99	0,22	78
D	1,90	0,67	65
E	2,15	0,55	74

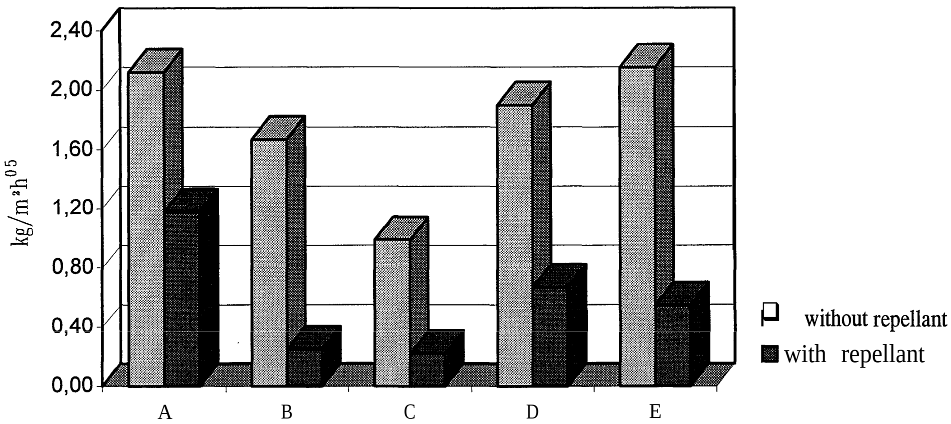

Figure 3 The water absorption rates for 24 hours

Samples B2 and C2 have the best performance among the plaster systems as can be seen from the diagram in Figure 3. The capillary water absorption curves are given in Figure 4 for both short and long periods. Unlike. the hydrophobed plaster systems B2 and C2 (though, the same water-repellent additive was used), the water absorption of the specimen A2 is significantly higher in the long period. The most likely explanation to this is the specific pore structure of the plaster and also its thickness.

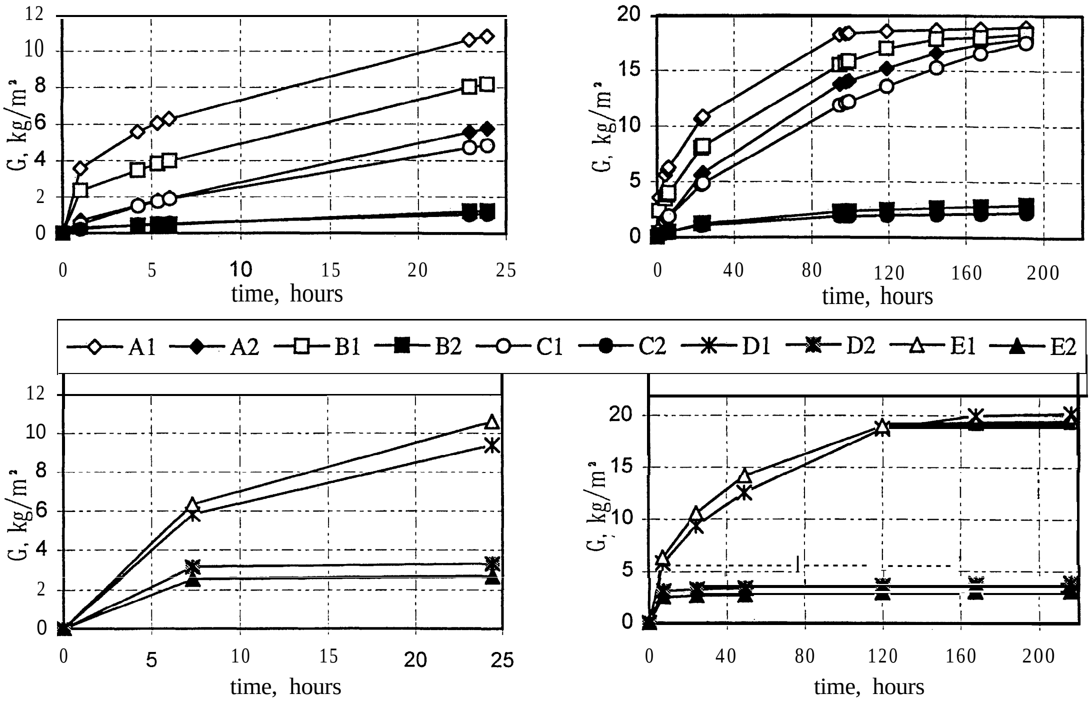

Figure 4 The capillary water absorption of the specimens

Diffusion resistances (the vapour diffusion resistance-equivalent air layer thickness, s_d), of the sample coatings are summarised in Table 3 and given as a diagram in Figure **6.** The results indicate that the water-repellent products used do not have a considerable effect on the vapour permeability of the sample components.

Table 3 The water vapour diffusion resistance-equivalent air layer thickness, s_d [m] values of the specimens

samples	without repellant	with repellant
A	0,141	0,122
B	0,307	0,334
C	0,439	0,357
D	0,151	0,215
E	0,175	0,198

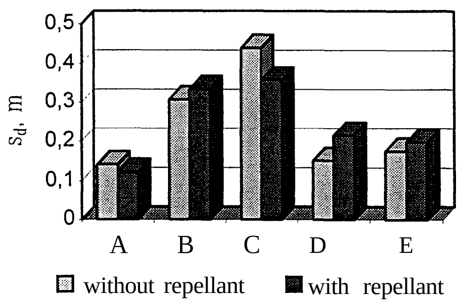

Figure 6 The s_d values of the specimens

6 Concluding Remarks

The test results indicate that the application of a water repellant on the surface of AAC, under the plaster, is not as effective as the water repellant applied as additive in the plaster. Hence, repellant as a surface treatment between the layers, may act as a barrier and cause accumulation of water at the interface, leading to deterioration. The application of repellant at the top surface of the plaster would perform better only if the surface remains free of later cracks or spallings. This is even verified by the outcomes of the experiments which are still going on to investigate the performance of water repellants as surface treatment on the plaster.

According to Künzel [8]; an exterior rendering can be termed 'water-repellent' (managing heavy driving rain conditions) only if it meets the requirements:

$A < 0{,}5\ kg/m^2h^{0,5}$ and $s_d < 2$ m;

and 'water-retarding'(managing medium driving rain conditions) if:

$A < 2\ kg/m^2h^{0,5}$ and $s_d < 2$ m.

The comparison of the test results indicate that:

- Only hydrophobed plaster systems B and C meet above requirements to be termed water-repellent
- All the plaster systems, hydrophobed or not, meet the requirements to be termed water-retarding
- All the plaster systems, hydrophobed or not, fulfil the above requirements for water vapour transmission.

The results obtained from the tests confirm the hydrophobic effect of water repellants on porous building materials. However, (in this case) the performance of repellants depends on the properties of the plaster system, its layers and its thickness. They also perform different depending on their application as additive or surface treatment. In order to make broader assessments, tests are continued with the samples treated with silicons on the top surface. Moreover, additional tests are planned to investigate the long-term performance of the water repellants on porous materials.

Abstract

A new type of water-based emulsion paints by using fluoropolymer have been on the market recently in Japan. These water-based paints are expected to decrease air pollution and also to keep such high durability as organic solvent type of paints.

This paper outlines the results of a series of performance evaluation tests for the new paints and other standardized paints such as solvent type of fluoropolymer paints, solvent type of polyurethane paints, and acrylic emulsion paints for comparison. A sunshine carbon arc type of irradiation test, outdoor exposure tests and corrosion tests for steel protective coating systems were carried out in the study. Moreover, repainting works with the new water-based paints and with other paints for exterior finishing systems were performed.

Through the sunshine carbon irradiation test and the corrosion tests, it was confirmed that the water-based fluoropolymer paints possessed competitive durability with solvent type of fluoropolymer paints which are more durable than solvent type of polyurethane paints. The outdoor exposure tests and periodical inspection for repainted exterior finishing have been continued for a few years. The fluoropolymer emulsion paints have shown good durability in the both tests. Finally, the draft of standard specifications of coating work with the fluoropolymer emulsion paints was obtained for both new painting works and repair painting works through this study.

Keywords: Air pollution, durability, fluoropolymer, paint, repaint, standard specification, water-based emulsion.

1 Introduction

According to the report [1] of Environment Protection Agency in Japan, about 30% of the total amount of organic carbons which were emitted into the air due to human activities has been considered to come from painting works. Different from coating in controlled manufacturing factories, it is difficult to collect organic solvents evaporated in the air, because painting works in construction are usually carried out in outdoor conditions.

For this reason, use of water-based paints has been recommended from the viewpoint of environment protection. This demand is becoming very strong recently. Paint manufacturers are intensively developing safer and more durable paints. Figure 1 shows fundamental methodologies for developing safer paints.

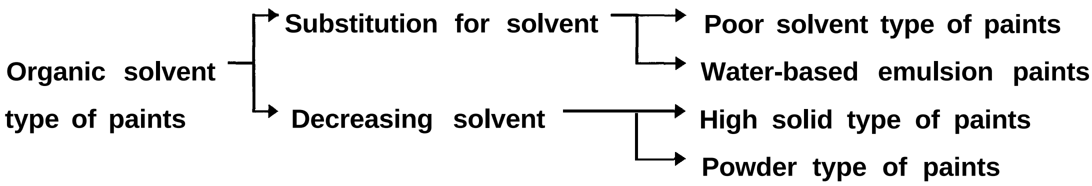

Figure 1 Basic methodology for developing environmentally safer paints.

Among the paints shown in Figure 1, poor solvent (mineral sprits, solvent with higher boiling point) type of paints, water-based paints and high solid type of paints have been on the market aiming at substituting for existing solvent type of paints used in construction works. Especially, water-based paints are considered to be suitable from the viewpoint of environment protection. However, water-based paints are generally less durable than organic solvent type of paints. Therefore, it is not so easy to replace water-based emulsion paints for existing solvent type of paints especially where high durability is required.

In this background, new type of emulsion paints by using fluoropolymer have been recently developed in Japan. As reported before[2][3], solvent type of fluoropolymer paints were already developed and have been prevailing in Japan. The durability level of these paints has been classified at the one of the highest ranks among the all types of paints on the market. The solvent type of fluoropolymer paints were already standardized in JIS K 5658[4] and JIS K 5659[5] for their materials qualities and the painting work specifications were also standardized in JASS18[6].

The newly developed emulsions consist of polymers whose molecular structures are similar with solvent type of fluoropolymer. One of the key points for imparting high durability to fluoropolymer emulsions is not to use usual emulsifiers. It is reported by the manufacturer that the durable fluoropolymer emulsion paints can be obtained by using macro-monomers compatible with both fluoropolymer and water as emulsifiers.

In this study, a series of tests including sunshine carbon arc irradiation test, outdoor exposure tests and corrosion tests have been conducted for the newly developed emulsion paints in order to evaluate their durability and applicability to construction work.

2 Experiment

2.1 Tested materials

The coating specifications listed in Table 1 and Table 2 were applied for cementitious substrate specimens and steel sheet specimens, respectively.

Table 1 Coating specification for cementitious substrates.

Coating system	Under coat	Top coat (dry film 40 μ m in thick)
System A	acrylic emulsion	water-based fluoropolymer emulsion
System B	epoxy primer	solvent type of fluoropolymer paint
System C	acrylic emulsion	water-based acrylic emulsion
System D	epoxy primer	solvent type of polyurethane paint

Substrate : fiber reinforced cement sheet (70mmx150mmx4mm).

Table 2 Coating specification for steel sheets.

Coating system	Under coat	Middle coat	Top coat (dry film 40 μ m in thick)
System E	anti-corrosive emulsion	none	water-based fluoropolymer emulsion
System F	anti-corrosive emulsion	acrylic emulsion	water-based fluoropolymer emulsion
System G	solvent type of anti-corrosive paint	none	water-based fluoropolymer emulsion
System H	solvent type of anti-corrosive paint	none	solvent type of polyurethane paint
System I	solvent type of anti-corrosive paint	none	solvent type of fluoropolymer paint

Substrate : cold rolled carbon steel sheet, ss400 (70mmx150mmx0.8mm)

2.2 Sunshine carbon arc irradiation

Sunshine carbon arc irradiation was performed according to IS0 4892-4[7]. The water spray cycle used was 18 min spraying with 102 min dry interval. The test was carried out until 5,000 hours for the cementitious board specimens and until 2,000 hours for the coated steel specimens.

2.3 Salt spray test and cyclic corrosion test

A neutral salt spray test was performed based on IS0 9227[8]. 28 cycles of treatment shown in Figure 2 was also done in the cyclic corrosion test after 60 hours of sunshine carbon arc irradiation. The both corrosion tests were performed for the coated steel specimens with intentional scratched marks.

↓

Drying with wind at 30℃ for 120 min

1 Cycle for 6 hours x 28 repetition

Figure 2 1 cycle of treatment for the cyclic corrosion test.

2.4 Outdoor exposure tests

Outdoor exposure tests have been conducted in the 4 locations (Sapporo, Tsukuba, Kawasaki and Okinawa) for the coated cementitious specimens and in the 2 locations (Tsukuba and Kawasaki) for the coated steel specimens. The specimens were mounted on the exposure racks facing the south at an angle of 30 degrees. The tests have been continued for a few years until now.

2.5 Test painting work for repairing

Repair painting was carried out for deteriorated textured coating on fiber reinforced cementitious boards. The deteriorated textured coating specimens (sized 180 cm x 90 cm) listed in Table 3 had been exposed for 14 years in Tsukuba. Extensive chalking and partial peeling and checking could be observed on the exposed specimens, however, bonding strength of the old layers to the substrate was not so low as initial bonding strength. The new coating systems in Table 3 were applied on these old coating layers after cleaning with water at the pressure of 15 MPa. The top coating layers in all the old textured coating systems were partially removed after such treatment and repainting work was conducted on the old coating layers including the partial old top coating layers.

Table 3 Repair coating specification for exposed textured coatings on the cementitious boards.

Coating system	Top coat of the old coating systems	New coating system	
		Under coat	Top coat
System J	solvent type polyurethane	water-based sealer	water-based fluoropolymer
System K	solvent type polyurethane	solvent type sealer	solvent type fluoropolymer
System L	water-based acrylic paint	water-based sealer	water-based fluoropolymer
System M	water-based acrylic paint	water-based sealer	water-based acrylic paint
System N	solvent type of acrylic paint	water-based sealer	water-based fluoropolymer
System 0	solvent type of acrylic paint	solvent type sealer	solvent type polyurethane

Preparation of old coatings: water cleaning with pressure at 15MPa

3 Results and Discussion

3.1 Acceleration test

Figure 3 shows the changes in gloss values at 60 degrees' reflection with carbon arc irradiation time for the coated cementitious boards. The results for the coated steel specimens showed similar behavior with Figure 3. As shown in the figure, it was confirmed that the water-based fluoropolymer paints kept about 90 % of their initial gloss up to 5,000 hours' irradiation and their resistance against ultraviolet light is competitive with that of the solvent type of fluoropolymer paints reported previously[2],[3]. This high durability is considered to be primarily due to strong bonding energy between C-F bonds. On the other hand, the controlled polyurethane paints and the acrylic paints lost their initial gloss remarkably with the irradiation time.

Table 4 shows the results of visual inspection after the salt spray test and the cyclic corrosion test. One of the important results was that System E did not possess enough corrosion protective performance. In System E, bonding performance to the substrate is considered to be insufficient due to insufficient performance of under coat.

To improve System E, addition of a process of middle coating with a water-based paint (System F) or use of a solvent type of paint as under coat (System G) is necessary.

System H and System I are rather popular as anti-corrosive coating specifications for heavy duty protection. Although the slight blistering could be observed in the cyclic corrosion test, the both systems showed good performance in total.

As to the anti-corrosive coating systems using water-based fluoropolymer paints, it can be said that such systems are as good as the coating systems using the polyurethane paints or solvent type of fluoropolymer paints if the under coating systems are sufficient. To improve the performance of under coats, addition of a middle coating process with a water-based paint or use of a solvent type paint for under coating is necessary.

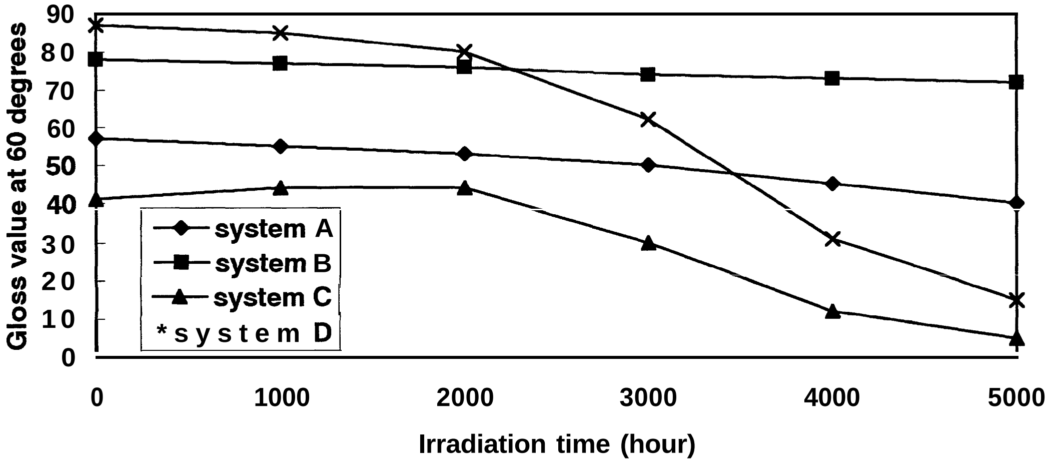

Figure 3 The changes in gloss values for the coated cementitious board specimens.

Table 4 Results of the salt spray test and the cyclic corrosion test.

Coating system	Cross-cut test before corrosion tests	Visual inspection after salt spray test	Visual inspection after cyclic corrosion test
System E	poor (10/25)	rusting within 120 hours	color change
System F	good (25/25)	no change more than 500 hours	no change
System G	good (25/25)	no change more than 500 hours	no change
System H	good (25/25)	no change more than 500 hours	slight blistering
System I	good (25/25)	no change more than 500 hours	slight blistering

3.2 Outdoor exposure test

Measurement of color difference and gloss has been performed periodically in the outdoor exposure tests. Figure 4 shows the changes in gloss retention after washing with water for the coated cementitious specimens exposed in Okinawa located in southern part of Japan. As shown in the figure, the specimens coated with the water-based fluoropolymer paints and the solvent type of fluoropolymer paints keep high gloss retention percentages. On the other hand, the specimens coated with the water-based acrylic emulsion paints and the solvent type of polyurethane paints are significantly losing their initial gloss. The outdoor exposure tests in other places showed similar results with the results obtained in Okinawa.

The results obtained in the outdoor exposure tests are consistent with the results obtained in the sunshine carbon arc irradiation test. The outdoor exposure tests are to be continued until the data after 10 years will be obtained.

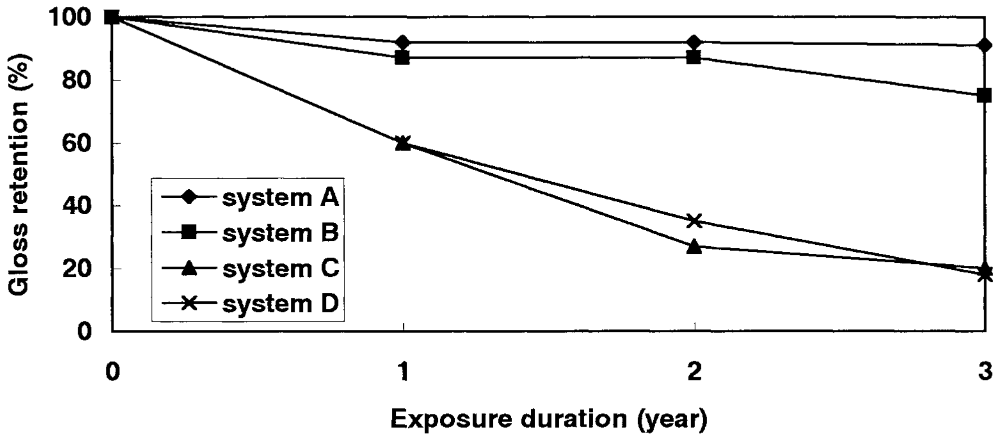

Figure 4 The changes in gloss retention after washing with water for the coated cementitious board specimens exposed in Okinawa area.

3.3 Applicability for repair coating

The repaired coating with the specifications listed in Table 3 was successfully conducted in every specification. The failures due to incompatibility with the existing coated layers such as delamination and swelling of the old coated layers could not be observed in and after repainting. The repainted specimens have shown no deterioration phenomena except for natural loss of the gloss until now. Moreover, adhesive strength to the old coated layers was confirmed to be sufficient by a pull-off test and a cross-cut test.

Generally speaking, water-based emulsion paints are preferable for repair coating to avoid swelling the old layers. On the other hand, adhesive performance to old coated layers are generally not so good as that of solvent type of paints. For this reason, the adhesive strength of the specimens are planned to be checked periodically in future.

4. Conclusion

A series of performance evaluation tests for newly developed fluoropolymer emulsion paints were conducted. It is considered that the durability of the water-based fluoropolymer paints is as high as that of organic solvent type of fluoropolymer paints.

Through these tests, a draft of useful coating specifications with water-based fluoropolymer paints could be obtained both for new construction and for repair works. The obtained draft of the specifications is helpful for application of the water-based fluoropolymer paints, although it will need to be reviewed based on the further data.

Returnable packaging for non-specific building materials

F. J.M. van Gassel
Eindhoven University of Technology, Faculty of Building and Architecture,
Department of Construction Engineering and Management,
Eindhoven, The Netherlands

Abstract
A certain amount of construction waste comes from disposable packaging and this waste is ecologically damaging, one solution would be to reduce the disposable by using returnable packaging for non-specific construction products. To find out if this solution is feasible a study has been carried out on the economical and ecological consequences.
A housing construction project was chosen to get insight into the sizes of the construction products and in the amount of packaging used in the construction products. Based on these results a transportation system has been developed. First an inventory was made of all the functions needed in the transportation system. For every function a solution is developed, and for the functions together, a principle design was chosen.
This study led us to design a synthetic crate with the floor dimensions of 400 by 600 and 400 mm height, and a lid which can be used as a small pallet. The crates are transported to the building site on EURO-pallets and are manually handled into the building by a specially designed handcart. The handcart has the functions of a pallet-cart, wheel barrow and sack car.
To manage these crates, lids and pallets a pool system was also designed. The principle of this system is that the pool organisation buys the crates and lends them to the packers with a deposit. The packer pay a fee to the pool organisation to can fill a crate. The transportation firm gets paid from the pool organisation for bringing back the empty crates to the packers. Based on this system, calculations are made on what the fee should be.
The use of the crate is economically and ecologically more interesting for construction products which use a high proportion of disposable packaging.
What important is in introducing a returnable crate is an efficient pool organisation. The packers must be the owners of the pool organisation.
The returnable crate is not only interesting for the environment, but it also has advantages for the working circumstances and the logistics between the producers and users of building materials.
Key words: Environment technology, packaging, return systems, transport equipment, waste prevention.

1 Introduction

The building of residential houses and non-resident buildings in 1993 in the Netherlands resulted in between 7,4 - 9,6 million ton waste [1]. Seven percent of this waste consists of disposable packaging materials [2]. The waste is transported from the building site to the recycling industry, dumping-ground or waste burning installations. The last two ways of getting rid off the waste are damaging to the environment.
The government says that there is a priority on what to do with the waste: first prevention, then re-use, burning and dumping. The government stated also that in the future packaging material has to be re-used for 66% [3].
A returnable packaging for building materials could be a solution that is in line with the government policy: it avoids the use of disposable packaging and encourages re-cycling because returnable packages can be re-used.
The idea using a returnable packaging is not new, other industries and shops are already using it.
Is the returnable packaging for non-specific construction products economical and ecological feasible? To find out this question a study on the order of the Ministry of Housing and Environment had been carried out.
This article will show the method and the results of this study [4].

2 Housing project

To develop a returnable packaging for non-specific building materials, insight into the number and sizes of these materials is necessary. To get these sizes and the number of the building materials, a housing construction project was chosen to measure these data. The housing project consisted of 27 houses which will be sold to the residents.
Some materials were not measured. These are materials which are liquid or delivered in bulk, which have extreme weight and dimensions, and which are already mounted in prefab products. This leaves 288 materials with a volume of 1026 m^3.
All the data is put into a spreadsheet, so that selections and calculations can be made.

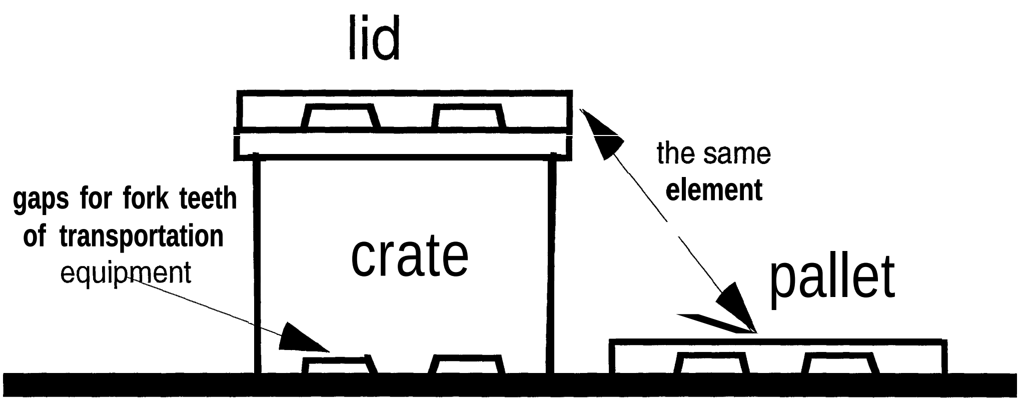

Figure 1 *Crate with lid.*

3 Transportation system

Based on these results a transportation system has been developed. First an inventory was made of all the functions needed in the transportation system. For every function a solution is developed, and for the functions together, a principle design was chosen.

This principle design is engineered to 'function models' of:

- A crate of re-cycled Poly Ethylene 400 by 600 mm ground floor and 450 mm inner height. The lid of the crate can be used as a small pallet. See Figure 1 for a sketch of the crate and lid. Eight crates can be transported to the building site on one EURO-pallet. The crates and lids can be stapled two layers height on the pallet in different ways. See Figure 2 for some possibilities. The empty crates can be nested to transport them with a minimum on volume.
- A handcart which can handle the crates from the EURO-pallet to the processing place in the building. The handcart has the functions of a pallet-cart, wheel barrow' and sack car. Figure 3 shows a 'function model' of this handcart.

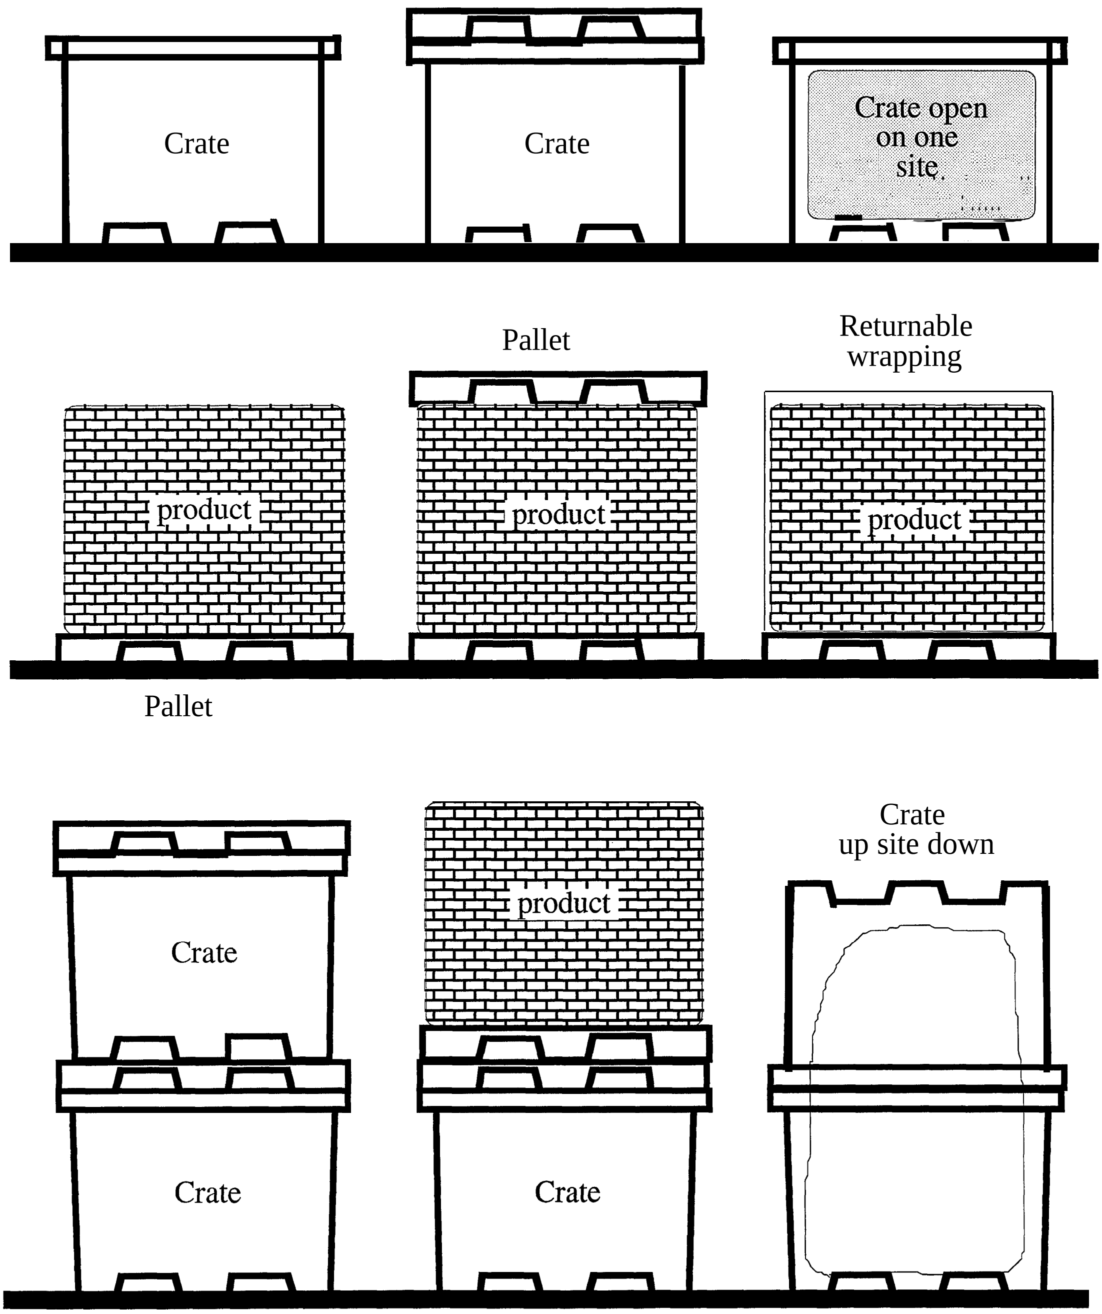

Figure 2 *Staple possibilities of the crate.*

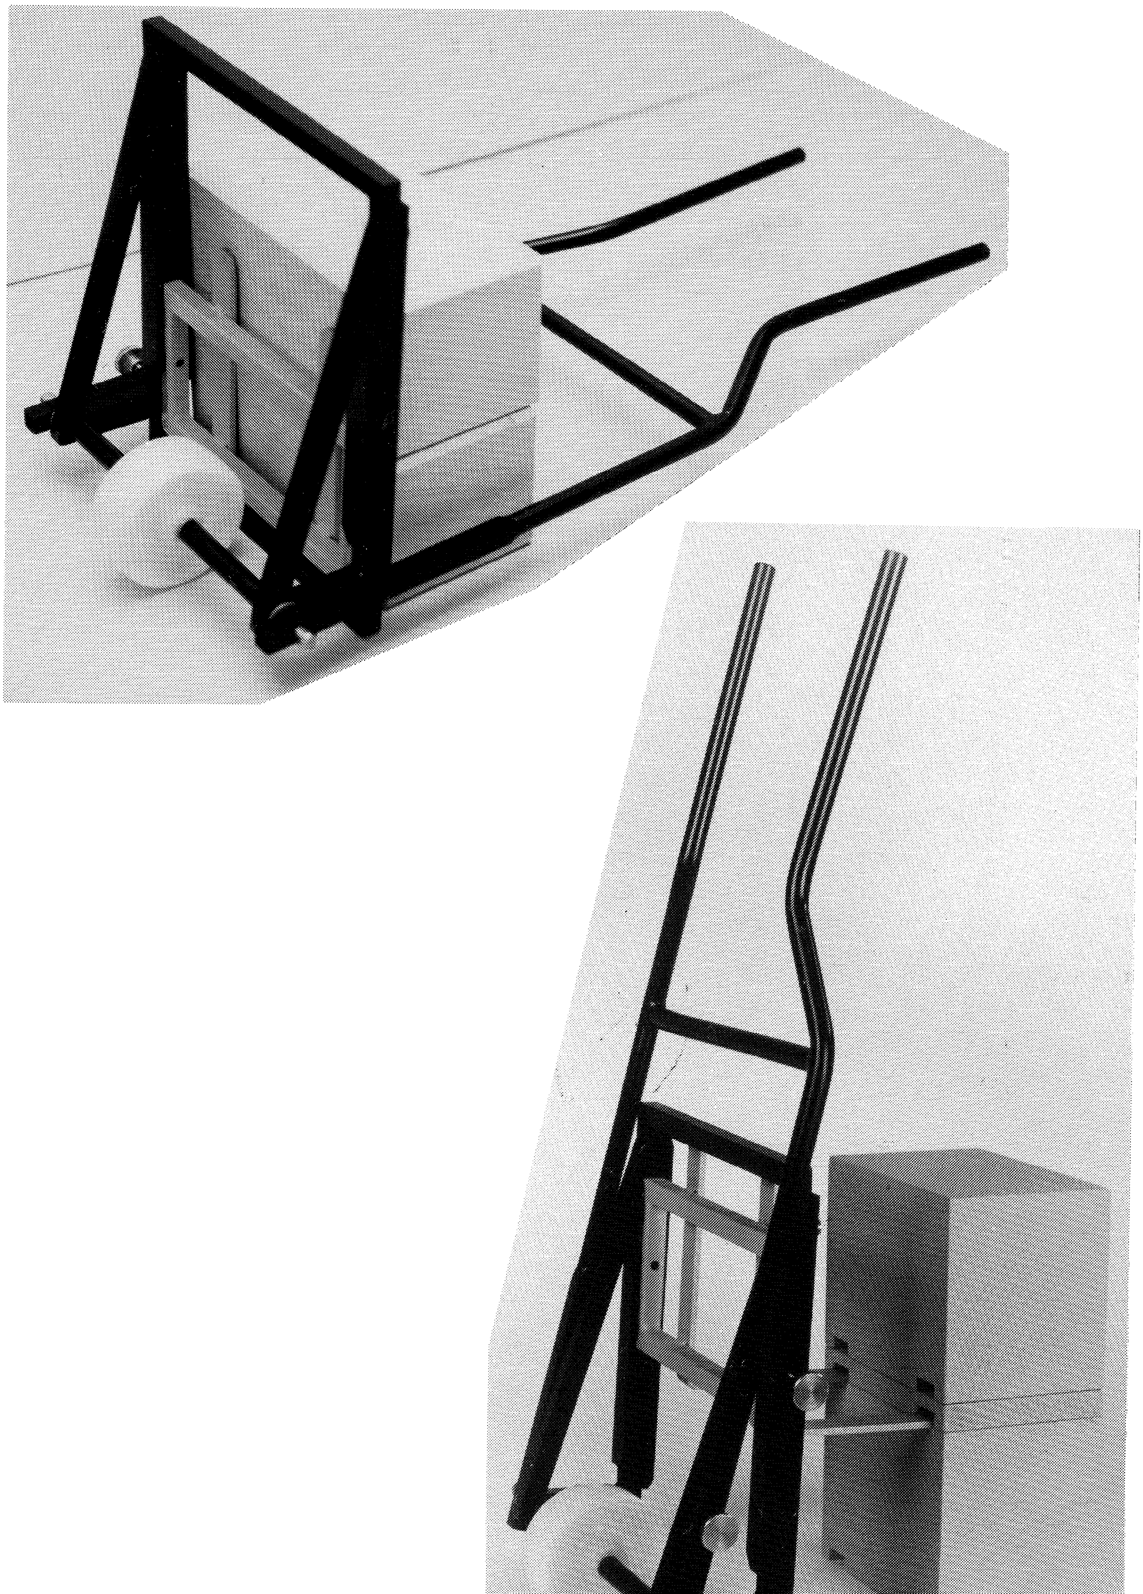

Figure 3 *Handcart as pallet-cart, wheel barrow and sack car.*

4 Pool system

To manage and to handle the return of the crates, a pool system is necessary. This system has the following partners:

- the producers of the crates, pallets and transportation equipment
- the producers of the building materials (packers)
- the transportation firms
- the trading firms of building materials (unpackers and packers)
- the contractors (unpackers)
- the pool organisation.

Every partner has a specific task and interest in the pool system. The packers are the owners of the pool system.
Two flows in the pool system are important: the money flow and the crate flow.
Figure 4 shows these flows.

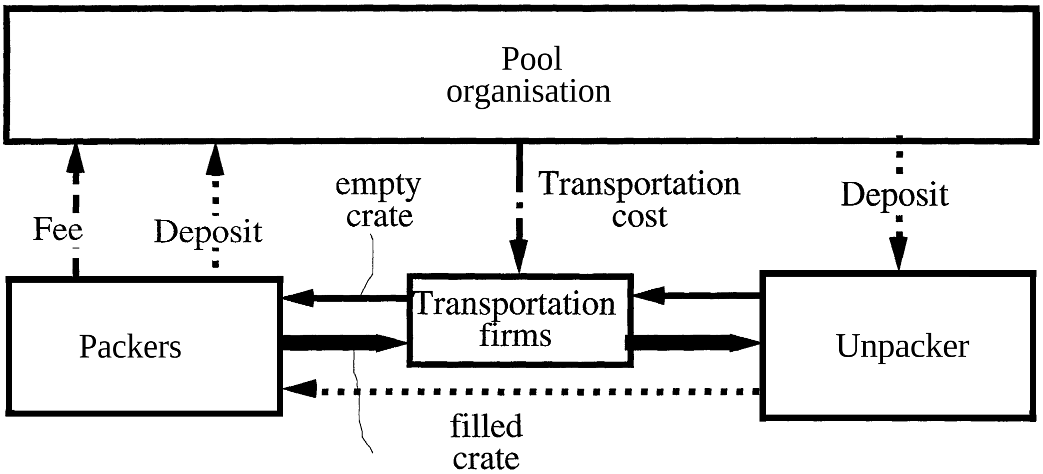

Figure 4 *The money flow and the crate flow.*

The principle of the system is that the pool organisation buys the crates and lends them to the packers with a deposit. The packer pay a fee to the pool organisation to can fill a crate. The transportation firm gets paid from the pool organisation for bringing back the empty crates to the packers. Based on this system, calculations are made on what the fee should be.
The calculation model has the following inputs:

- buying price of EURO-pallet
- buying price of crate with lid
- life of the pallet and crate with lid
- demolition cost
- maintenance cost
- interest
- deposit amount
- the number of filled crates on the pallet
- lost and damaged
- average transportation distance
- the number of empty crates on the pallet
- the number of pallets on the truck
- cost loading and unloading of pallets
- cost of administration and organisation pool
- the number of crates on stock by the packer
- stacking cost
- cleaning

5 Results

To find out if the developed transportation and pool system is economical and ecological feasible a study had carried out with the next results.
Some calculations have been made to study the economical feasible. The result is that the packer of the construction products pays a fee of HFL 1,22 per crate with lid to the pool organisation and has self about HFL 0,43 cost for storage and cleaning the crates.
Looking at the housing project we calculated that from the 175 products which can be packed in the crates 142 (8 1%) products give economical advantage to use the crate. In volume this is 33 m^3 on 672 m^3 (4,9%). The economical advantage for the contractor of the housing project is HFL 428 and for the packer HFL 1175. The advantage for the constructor increases as the cost to get rid off of the waste increases. The calculations stated that the use of the crate is no economically interesting by construction products which are delivered in great amounts and with limited disposable packaging. Such construction products are bricks and tiles.
The ecological feasibility is calculated with the Eco-indicator[5]. The result is that the value of the Eco-indicator for disposable packaging is 1,67 mPt and from the crate is 0,56 mPt. The lower this value, the better it is for the environment.

6 Discussion

In the building industry returnable packaging is already used; dry mortar in silos and window glasses in steel frames. EURO-pallets are also used on the construction sites but have problems with the paying of the deposit and the return transportation costs. The use of a returnable crate on the construction site is new. What important is in introducing a returnable crate is an efficient pool organisation. The packers must be the owners of the pool organisation. Also important is to normalise the transportation system for a broad acceptance.
The returnable crate is not only interesting for the environment, but it also has advantages for the working circumstances and the logistics between the producers and users of building materials.
To make the returnable crate successful in the short term it already can be used between the dealers of construction products and the contractors.

A Proposed Standard for Service Life of Buildings: Part 3 Auditing Systems

Kathryn Bourke
Building Performance Group, London, UK
Georg Soronis
Swedish Building Standards Institution, Stockholm, Sweden

Abstract
Durability and service life are vitally important and crucial issues to sustainable building development. This paper outlines the synopsis of Part 3 of the proposed ISO standard concerning auditing systems for service life planning of buildings. This work has been initiated by the ISO/TC 59/SC 14 "Design Life" and is a supporting document to the first part of the standard (Part I, General Principles). It describes a systematic procedure to audit durability and service life in planning design and maintenance of a building. The auditing systems will enable the client to review all ownership implications concerning durability and service life in the proposed building design. Finally, it gives a base for the research needed to formulate supporting documents needed for the implementation of this standard.
Keywords: Auditing systems, durability, service life, standards.

1 Introduction

It is a well known fact that the construction industry and the built environment are main consumers of resources – materials and energy. The stock of buildings and infrastructures is growing in all countries and built environment normally constitutes more than one half of their real capital. Construction represents up to one quarter of the GNP in many countries of the world.

Recent attention worldwide has highlighted the need for the constructions industry to cut its costs significantly and to improve its effectiveness. For example in the UK a figure of 30 % has been proposed by a joint government/industry review. Such savings can only be achieved by significant improvements in current practice . One major improvement would be the ability to design buildings for a specified design life [1].

The European Construction Products Directive in force in the EU sets out six essential requirements for works which must be satisfied during an economically reasonable working life [2], [3], [4]. Technical specifications for building products prepared by CEN and EOTA must contain provisions for assessing the products service life.

The international standards organization (ISO) in co-operation with the European Committeee for Standardization (CEN) has focused this area and in 1993 initiated the IS0 TC59/SC3/WG9 group which aims to the development of international standards and guidelines for the service life planning of buildings. This group is now upgraded to an own subcommittee ISO/TC59/SC14, Design Life.

The proposed IS0 standard [5], [6] contains five parts addressing:

- Part 1: General Principles
- Part 2: Service life prediction methods
- Part 3: Auditing systems
- Part 4: Data formating
- Part 5: Life cycle costing and maintenance

The different parts of the standard are expected to be completed for submission as Draft International Standard (DIS) as follows:
Part 1 in 31 March 1998
Part 2 in 31 October 1998
Part 3 in 31 March 1999
Part 4 in 31 March 1999
Part 5 in 31 December 2000

2 Aims

The purpose of the work presented here is to:

- To outline a synopsis aiming to identify the level of the audit reviews to be undertaken for the service life profile and design approach as described in Part 1, General Principles, of the proposed standard for design life of buildings.

3 Synopsis of Part 3, Auditing systems

The following documents have been reviewed for this synopsis:

- Methodology for technical audit of building and component durability - draft 3, dated November 1997. Prepared by Building Performance Group Ltd. or the Defence Estates Office
- Initial notes on scope for Part 3 prepared by Dr. Wyatt of University of Brighton, dated 30 January 1996
- Rough draft synopsis of Part 3 prepared by Mr Cain of Defence Estates Office, dated 10 January 1997
- Durability Brief and Durability Audit prepared by Mr Marsh of BRE for Durability by Intent for Concrete programme, dated 26 November 1996
- Notes on scope of Part 3 by working group at meeting of TC59/SC3/WG9 on 28/29 May 1997

3.1 Introduction

- cross references to other parts of IS0 15686 introduction to contents of Part 3
- references to IS0 9000 / IS0 14000
- concepts in service life planning and auditing overview diagram(s)
- limitations of Part 3 / caveats as required indication of role of auditing Scope

3.2 General audit issues

- introduction to actors / roles
- explanation of stages in auditing
- introduction to reporting audits and audit levels training / skills / liabilities of auditors quality assurance and quality control of auditing

3.3 Auditing the brief - to include:

- parties
- need for record of client requirements for service life record of client requirements for service life suggested proforma
- explanation of headings within proforma
- guidance to auditors and others on changes in requirements guidance to auditors on reporting on clients requirements references to documents which may help in compiling clients requirements
- guidance for auditors on missing criteria within the record of clients requirements

3.4 Auditing the design phase

- overview of design phase audit
- references to Part 1
- structure of design audit (building type, elements, components) targeting design audit to high risk areas

- proforma for auditing design
- explanation of sections within proforma
- identification of component design lives and maintenance/construction requirements/ assumptions
- guidance to auditors on assessing service life of components guidance to auditors on relevant subjects such as environmental
- assessments, interfaces / assemblies, interpretation of data on service life, warranties etc.
- references to documents which may help in auditing design guidance to auditors on reporting design audit

3.5 Auditing the construction phase

- overview of construction phase audit references to Part 1 procurement review - to include references to IS0 9000 structure of construction audit
- targeting construction audit to high risk areas proforma for construction audit
- explanation of sections within proforma
- identification of construction below levels assumed in design audit changes in design or construction during the construction phase commissioning of building and building services
- references to documents which may help in auditing construction guidance to auditors on reporting construction audit

3.6 Reporting the audit

- introduction
- audit levels / scope of audit report
- advanced notices / early warnings during audit evidence of audit trail
- contents of audit reports at various levels / times interpretation of audit reports
- response to interim audit reports
- response to final audit report
- proforma for audit reports (written and graphical interpretations) brief section dealing with use of databases, expert systems etc.

4 Acknowledgements

The authors of this paper appreciates many helpful suggestions by and discussions with Dr. David Wyatt at the University of Brighton, UK who is the chairman of the drafting committee for Part 3 of the standard. Thanks are also due to Mr C. T. Cain, Ministry of Defence, UK who has supported this work closely. Finally, many thanks are due to Mr. A. Raphael Makenya for helping us with the editing of this work.

A discrete stochastic model for performance prediction of roofing systems

Z. Lounis, D. J. Vanier and M. A. Lacasse
Institute for Research in Construction, National Research Council, Ottawa, Canada

Abstract
A stochastic modeling of the performance of roofing components and systems is proposed using a discrete Markov chain that predicts the incremental deterioration of roofing components. The capability to predict the performance of roofing-components and systems throughout their service lives is essential and constitutes the first step towards the development of a comprehensive building envelope life-cycle asset management system. The proposed Markovian model allows the simultaneous consideration of the time-dependence and randomness of the performance of roofing components and systems taking into account the uncertainty and variability associated with material properties, environmental degradation factors, quality of workmanship, and maintenance conditions. Depending on the controlling explanatory variables, transition probability matrices are generated for roofing components and systems using in-field performance data obtained from inspections. This probabilistic model can then be coupled to an optimization algorithm for the development of a risk-based optimal maintenance management system for roofs at both project and network levels.
Keywords: Condition rating, deterioration, Markov chain, performance, roof system, roof components, service life, stochastic process.

1 Introduction

Low-slope and more specifically built-up roofing systems are and have been extensively used in the North American building industry. For example, the volume of work in built-up roofing constructed in 1995 in the USA rose to 18.35 billion dollars (US) of which 79.1 % was comprised of low-slope roofing [1]. Similar statistics regarding the extent of use of low-slope roofing were derived from a survey undertaken by the Canadian Roofing Contractors Association (CRCA); it indicated that well over 56% of the roofs constructed in 1993 were built-up-roofing (BUR) [2]. Premature roof failures are nonetheless common place and the associated costs of repair can be a substantial portion of the yearly maintenance budget, especially in large single-story industrial buildings. Preventative maintenance strategies for roofs are increasingly being used to help mitigate these harmful effects. Nevertheless, without well established methodologies for verifying the in-service performance and expected remaining service life of the roof, the risk of failure and the consequences of premature roof deterioration cannot be readily ascertained using the existing maintenance methods.

In an industry-wide survey of built-up roofing membranes, it was found that no type of roofing membrane had more than a 50% probability of lasting 20 years [3]. The main causes of roof failures are water ponding, untested new materials, membrane splitting, water vapor condensation within the roof due to insulation use, membrane blistering, and leakage or destruction of the insulation due to vapor barrier use [4].

The performance of a roof system and its components deteriorates with time due to aging effects such as aggressive environmental factors, excessive loads as well as poor workmanship and lack of maintenance. The uncertainty and variability associated with these deterioration factors result in considerable fluctuations of the performance and service life from the mean values. Therefore, a realistic predictive model of roofing system performance should be time-dependent and probabilistic.

In this paper, a stochastic modeling of the performance of roofing components and systems using a discrete Markov chain is proposed. A Markov chain is a discrete stochastic process that enables the simultaneous consideration of the time-dependence and uncertainty of the system performance. This approach has been widely applied to solve different time-dependent probabilistic problems [5,6,7]. This probabilistic performance prediction model for low-slope roofing systems and their components constitutes the first step towards the development of an effective building envelope life-cycle asset management system (BELCAM) [8]. The development of the BELCAM system includes the following phases: (i) Collection of roofing performance data from in-field inspections and grouping according to material and roof system type, geographical location, and building type; (ii) Generation of transition probability matrices and development of Markovian models; (iii) Assessment of the risk of failure for different roofing systems and building types, and; (iv) Development of a risk-based life-cycle roofing maintenance management system.

2 Performance of built-up roof components and systems

A modern built-up roof system has in general five basic components, namely a waterproofing membrane, thermal insulation, flashings, structural deck and possibly a vapor or air barrier [9-10]. There is a strong correlation between the performance of different components, which in turn has a direct impact on the performance of the entire roofing system and its risk of failure. Generally speaking, two types of roofing configurations can be identified depending on the location of the membrane, namely: (i) Conventional roofing system in which the membrane is at the top and is directly subjected to environmental stresses, and; (ii) Protected or inverted membrane roof system in which the membrane is protected from environmental stresses by the insulation. In the following section, a brief description of the degradation mechanisms of various components is given. The performance requirements of a roofing system can be summarized as follows [9-10]: (i) *Water tightness:* prevention of water leakage into the building; (ii) *Heat transfer control:* prevention or minimization of heat (or cooling) exchange between the interior and exterior; (iii) *Condensation control:* prevention of water vapor condensation within the roof system; (iv) *Load accommodation:* ability to sustain dead and live loads, and; *(v) Maintainability:* capability of economic repair.

2.1 Failure modes of roofing components

- *BUR waterproofing membrane:* The built-up roofing (BUR) membrane is predominant on low-slope roofs and is manufactured by adhering three or more felt plies to each other with hot bitumen. BUR membranes are reinforced with organic, asbestos or glass-fiber felts. The service life of BUR membranes increases with the number and strength of felt plies, and as mentioned earlier, no type of roofing membrane had more than a 50% probability of lasting 20 years [3]. It was also found that due to a considerable scatter in the life data of these roofing systems, a normal distribution was used to approximate their service life [3]. The main degradation factors are temperature, solar radiation, water and wind. The major modes of failure are blistering, splitting and ridging. Slippage, delamination, alligatoring and surface erosion are less widespread [4]. Blisters, and to a lesser extent splitting, are the most common distress affecting BUR membranes. Splitting is the most serious failure mode and occurs more frequently in cold climates, more often on large roof areas. The causes of splitting include thermal contraction, insulation movement, water absorption in felts, and deck deflection.
- *Thermal insulation:* It reduces heating and cooling costs and has become an indispensable component of roofing systems for occupied buildings given the rapid increase of energy costs. The thermal resistance of the insulation depends on the performance of the vapor barrier and membrane, and its effectiveness is seriously compromised by moisture. Notwithstanding its positive attributes, the insulation may increase the probability of membrane splitting and water vapor condensation within the roof system. The presence of moisture in the insulation is the result of either condensation or water penetration through defects in the membrane and flashing. Moisture reduces the thermal performance of insulation and this reduction is a function of the material type.
- *Flashings:* They seal the joints at vertical elements, curbs, chimneys, vents, expansion joints and wherever the membrane is either interrupted or terminated. Base flashings are a continuation of the BUR membrane at the upturned edges, while

counterflasings shield the exposed joints of the base flashings. Flashings are considered to be the most common source of roof leaks [4]. The basic failure modes of flashings include [4]: Sagging, ponding leakage, leakage around (through) the flashing, separation of flashing materials, diagonal wrinkling, and post-construction damage.

- *Vapor / air barriers:* A vapor barrier is used to prevent the water vapor condensation within the roof system. The air barrier is used to minimize air leakage through the roof system [9].
- *Structural deck:* It provides structural resistance to the sustained dead and live loads and transmits the loads to the roof framing. The failure modes of a roof deck include excessive deflection, cracking (concrete deck) under service loads and flexural and shear failures under ultimate loads.

2.2 Reliability of roofing systems

The roof system is a multi-component system with multiple failure modes that can be modelled as a hybrid system that is a combination of series and parallel subsystems. The probability of failure of each roofing component is time-variant and increases with time due to the time-dependent degradation of its performance. The probability of failure can be determined using systems reliability approach taking into account the correlation between different components and failure modes. In addition, the corresponding risk of failure of the roofing system could be evaluated once the consequences of failure are established. Two types of failures can be identified: (i) Envelope failure defined by the loss of the envelope main functions (loss of water tightness and energy control), and; (ii) Structural failure (outside the scope of this paper), defined by the deck failure that includes collapse and loss of serviceability. The risk of envelope failure should be kept below a certain threshold value, which depends on the value and vulnerability of the building contents under the roof, costs of repair and other incurred costs.

3 Existing approaches to roofing performance prediction

The prediction of the performance or service life of a roofing system and its components is a very complex problem as it depends on several factors including the loading, environment, quality and frequency of maintenance, quality of materials and workmanship. Despite the large number of publications related to durability and service life prediction of building materials and components, there is a lack of reliable and practical quantitative approaches to performance and service life prediction of materials, components and systems. Moreover, the existing systematic methods, including accelerated testing [11], have yet to be successfully applied to roofing systems.

Accelerated testing is carried out by imposing higher than normal stress levels on building components in order to increase the rate of degradation and thereby shorten the component life. The purpose of such testing is the generation of performance or lifetime data in a short period of time, thus overcoming the time and money constraints associated with field exposure tests. Such data are analyzed by fitting a degradation model to the data to estimate the relationship between performance, age and stress level. The principal objective is the determination of the relationship between failure time and stress magnitude (of degradation factor) in order to extrapolate to actual in-service stress magnitudes. The main accelerating stresses used to increase the deterioration process of BUR roofing membranes include temperature (60°C to 150°C), ultraviolet radiation, water and mechanical stress [10]. Although accelerated testing can be useful in ranking the performance of different roof materials or components, it suffers from many shortcomings [12, 13], which include: (i) Difficulty to simulate the degradation mechanisms of the various materials and their interaction; (ii) Difficulty to reproduce the stochastic nature of the degradation factors affecting the roof performance, and: (iii) Difficulty to correlate accelerated laboratory test results to the actual in-service results.

Given the time-dependence, large uncertainties and correlation of the performance of roofing components, a stochastic model is proposed in this initial research stage and is described in the following section. At a later stage when considerable performance data are collected, simplifications may be made to derive practical semi-probabilistic approaches to performance and service life prediction of roofing systems.

4 Markov chain modeling of roofing system performance

In this paper, a stochastic modelling of the performance of roofing components and systems is proposed using a discrete Markov chain. This model forecasts the future performance of roofing components and systems throughout their entire service lives. This performance prediction capability is essential for the development of an effective roofing maintenance management system. The Markovian prediction model represents an important class of stochastic processes with wide engineering applications (queuing, inventory and maintenance models) [5,6,7] This model takes into account the randomness of performance and its time-variance. The roof component (or system) performance is not a deterministic quantity but rather presents a large scatter, which is due to the variability of material properties, degradation factors, workmanship and maintenance conditions. The performance deterioration may be the result of excessive environmental conditions (temperature, water, moisture, wind), poor materials and workmanship and inadequate maintenance. In addition, there is in general a strong correlation between the performance of the different roofing components (membrane, insulation, flashing, vapor barrier, deck). The combination of the above may result in different and complex degradation mechanisms with cumulative damage effects. These irreversible damages accumulate until the component reaches a threshold performance level that defines failure of the component or system. The service life of the component or system is defined as the time corresponding to this minimum performance level.

In this paper, condition ratings are used as a quantitative measure of the performance of roofing components and systems. Seven integer ratings are adopted to estimate the performance of the membrane, insulation, flashing, and deck, with 7 and 1 representing the "excellent" condition and "failed" conditions, respectively as shown in Table 1. The use of condition ratings for the assessment of facility performance is very widespread given their practicality and cost-effectiveness as they allow the development of optimal maintenance management strategies. They constitute an integral part of various maintenance management systems used for different facilities, including bridges, pavements, and roofs [7,12]. The initial condition ratings of the roofing components are estimated from in-field inspection and evaluation of the **type,** quantity and severity of distresses, by a procedure similar to that used in "ROOFER' [12].

Table 1. Condition assessment of roof components and systems

Condition	Excellent	Very good	Good	Fair	Poor	Very poor	Failed
Deterioration	None	Negligible	Low	Medium	High	Major	Extensive
Rating	7	6	5	4	3	2	1

The Markov chain is a stochastic process whose state space is finite or countable, that may be described by: $\{S(t_m) = s_k, k = 1, 2, 3, 4, 5, 6, 7\}$, such that the probability of a future state of the system, $S(t_{n+1})$, at time t_{n+1} is governed solely by its present state $S(t_n)$ at time t_n, and not its entire history, i.e.:

$$P[S(t_{n+1}) = s_j \mid S(0) = s_k, S(t_1) = s_{k-1}, \ldots, S(t_n) = s_i] = P[S(t_{n+1}) = s_j \mid S(t_n) = s_i] = p_{ij} \quad (1)$$

The transition probability p_{ij} represents the likelihood that the condition of a roof system will change from state i at time t_n to state j at time t_{n+1}. Equation (1) indicates that the conditional probability distribution of any future state $S(t_{n+1})$ is independent of the previous states, $S(t=0)$, $S(t_1)$,..... $S(t_{n-1})$, and depends only on the present state $S(t_n)$. This assumption represents the first-order type of stochastic process correlation underlying the Markovian process [6]. The states 7, 6, 5, 4, 3, and 2 are called transient states, whereas state 1 is called an absorbing state, which is a state that cannot be vacated, once entered if no repair is made. The Markovian modeling of the performance requires only limited data on the condition of the roofing system (or components) at two or more points in time, in order to derive the probabilities of transition from one state to other states having lower condition ratings.

The performance of different roofing systems and components is dependent on several explanatory variables, including age, environmental conditions, material and system types, loading magnitude, workmanship quality and maintenance level. In order to validate the adopted Markov chain model, it is necessary to develop transition probability matrices for roofing components and systems according to their classification with regard to the above explanatory variables. A stationary stochastic process may be assumed which implies the time-invariance of the transition probability matrix. The transition time is generally taken as one year, but other time intervals can be chosen depending on the time between consecutive inspections. Given the adopted condition rating scale and short transition time, the probability of a roofing component decaying by more than one state in one year may be assumed negligible. As a result, the performance of a roofing system (or its components) of a certain class can be modeled using the following transition probability matrix:

$$\mathbf{P} = \begin{vmatrix} p_{77} & p_{76} & 0 & 0 & \ldots\ldots\ldots\ldots & 0 \\ 0 & p_{66} & p_{65} & 0 & \ldots\ldots\ldots\ldots & 0 \\ & & & & & \\ \cdot & \cdot & \cdot & \cdot & \bullet \; p_{22} & p_{21} \\ 0 & 0 & 0 & 0 & \ldots\ldots\ldots\ldots & 1 \end{vmatrix} \quad (2)$$

in which p_{ij} is the probability of transition from state i to state j in one step or transition time. Hence, the transition probability matrix is greatly simplified and consists only of two terms in each row, namely: p_{ii}, and p_{ij} ($p_{ij} = 1 - p_{ii}$), representing the probability of remaining at the same state and that of deteriorating by one state in one transition period, respectively. Each drop in the condition rating may correspond to a different degradation mechanism. The Markov chain modeling and the associated transition probabilities for a deterioration process are illustrated in Fig. 1, for a roofing component or system with the seven condition states defined in Table 1.

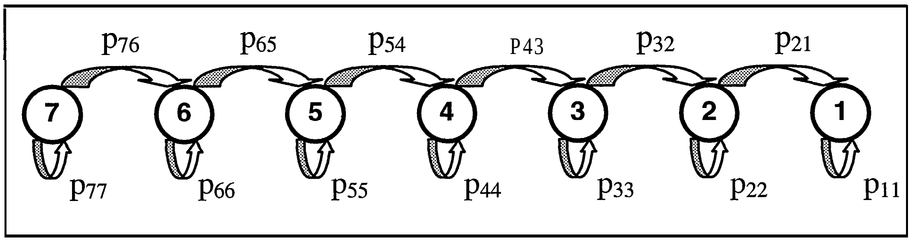

Figure 1 Markov chain modelling of roofing performance deterioration (with no repair)

Once the one-step transition probability matrix is generated, the future performance of a roofing component can be predicted using the n-step transition matrix as follows:

$$\mathbf{P}\{S(t_n)\} = \mathbf{P}\{S(0)\}\mathbf{P}^n \tag{3a}$$

which can be written in the following simplified form :

$$\mathbf{P}(n) = \mathbf{P}_o\mathbf{P}^n = [p,(n),\ p_6(n),\ldots,\ p_1(n)] \tag{3b}$$

in which $P\{S(t_n)\} = P(n)$ is the state probability matrix at time t_n after n transitions; $\mathbf{P}\{S(0)\} = \mathbf{P}_o = [p_7(0), p_6(0), \ldots, p_1(0)]$ is the initial state probability matrix; P is the transition probability matrix; and $p_k(n)$ and $p_k(0)$ are the probabilities that the component is in state k at times $t = t_n$ and $t = 0$ (initial condition), respectively.

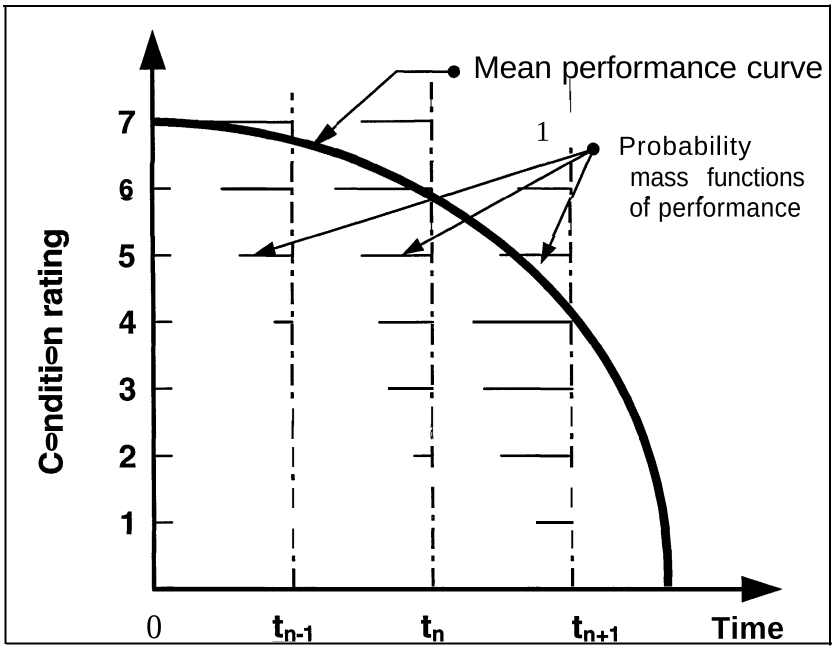

Figure 2 Markov chain prediction of roofing system performance

The probabilistic prediction of the performance using Eq. (3a) is illustrated in Figure 2, which indicates the evolution with time of the probability mass function of roofing performance. In general, at the start of the roof service life, the probability mass is close to condition rating 7; after aging and deterioration, this probability mass shifts from states having high condition ratings to those states with lower condition ratings. Ultimately, if no repairs are made, all the probability mass accumulates in the absorbing state with a condition rating 1. The transition probability matrix is determined as the solution of the following nonlinear programming problem, where the objective function is the minimization of the difference between the performance data obtained from in-field inspections and Markov chain predictions, i.e.:

$$\min \quad \sum_{k=1}^{7}\sum_{n=1}^{N}[p_k(n) - p_k^*(n)]^2 R(n) \qquad (4a)$$

$$\text{subject to:} \quad 0 < p_{ii} \le 1 \qquad (i = 1, 2, \ldots\ldots 7) \qquad (4b)$$

in which $p_k^*(n)$ = relative frequency of components in state k at age n from inspection data; $p_k(n)$ =Markov chain prediction of probability of being in state k at age n, obtained using Eq.(3b) as a function of p_{ii}, (i = 1, 2, ...,7); N= number of inspections or years of available data; and R(n) = number of components at age n.

The underlying assumption of the first-order Markov chain model referred to as the "Markovian property" is the dependence of the rate of deterioration on the current stress and cumulative damage and not on the entire stress history. The validity of this property will be checked through statistical inference testing. The transition probability matrix can be further updated using the Bayesian technique if additional performance measurements become available. The development of this Markovian model will be based on condition data of roofing components and systems collected throughout Canada using "ROOFER' [12] as a data acquisition system, in which many roofs, (grouped according to their age, material type, geographical location, and operating conditions) will be inspected at two or more points in time.

5 Conclusions

This paper illustrates the possibility of modeling the performance of roofing envelope systems using a discrete Markovian stochastic process that takes into account the time variance and randomness of this performance. The transition probability matrices for roof components and systems will be derived using in-field inspection data, for roofs grouped according to the controlling explanatory variables. This probabilistic modeling of performance enables a rational evaluation of the actual risk of roof failure that depends on the probability of failure of the entire roof system (membrane, insulation, flashing, and vapor barrier) and the consequences of this failure. The consequences of roof failure depend on the cost of repair, value and vulnerability of the building contents under the roof, and cost of disruption. This time-dependent probabilistic model constitutes the first phase towards the development of an effective risk-based roofing maintenance management system at either project- or network-levels that minimizes the life-cycle cost of the roof including the costs of maintenance, repair, replacement and failure.

Multicomponent cementitious binder from industrial by-products

M.Singh and M.Garg
Central Building Research Institute, Roorkee, India .

Abstract

Over hundred million tonnes of industrial by-products namely flyash, phosphogypsum, fluorogypsum and lime sludge are produced every year from various processes in India causing unwanted pollution and health-hazards. To save ecosystem, there is a strong need for effective and proper utilization of these by- products in the building sector. Keeping this in view, cementitious binders have been produced by blending fly ash with the calcined phosphogypsum or fluorogypsum and lime sludge. The cementitious binders produced using the ground fly ash ($400 m^2/kg$, Blaine) gave compressive strength of 25-27 MPa at 90 days. The strength was further enhanced on addition of cement.

The durability of cementitious binders has been studied by long term performance of the hardened binder in water and by wetting and drying cycles at 27° to 50°C. One cycle of wetting and drying comprised of heating the cubes for **16** hours at different temperatures followed by cooling for one hour and immersion in water for 7 hours. An increase in water absorption and porosity was observed with the increase in curing period. The formation of hydraulic products such as ettringite ($C_3A\ 3\ CaSO_4.32H_2O$), C-S-H and wollastonite which are responsible for hardening of the cementitious binders and their durability were identified by differential thermal analysis and scanning electron microscopy. The cementitious binders are eminently suitable for use in masonry mortars and concrete.

Keywords : Binder, flyash, phosphogypsum, ettringite, durability

1 Introduction

Over 100 million tonnes of waste material are produced as by- product from various agro-industrial processes in India per annum. These materials have degraded the environment and posing a threat to human and animal life. The utilization of by-products like fly ash, phosphogypsum, fluorogypsum, lime sludges and other materials are of paramount importance due to their enormous availability causing disposal and pollution problems. These materials have been used to small extent because of presence of certain undesirable impurities in them.

Extensive work has been carried out at Central Building Research Institute, Roorkee to develop a variety of building materials out of several solid industrial wastes. Some work on the utilization of these wastes has been reported elsewhere [1]. To save environment, it is necessary to develop useful building materials from them. With this objective, investigations were undertaken to produce cementitious binders by blending the fly ash with calcined phosphogypsum, fluorogypsum, lime sludges, Portland cement with and without chemical activators. The physical properties of these binders and the data obtained on their performance in water and the durability studies conducted by wetting and drying cycles at different temperatures are reported in the paper. The hydration of the binders as monitored by differential thermal analysis and scanning electron microscopy are also discussed. The suitability of newly synthesised cementitious binders for making masonry mortars and cement concrete has been examined and the findings are reported.

2 Methodology

The industrial wastes such as fly ash, phosphogypsum, fluorogypsum, lime sludges and the Portland cement conforming to relevant Indian Standards were collected from the indigenous chemical plants and the cement factory for their use as raw material.

The cementitious binders were prepared by blending the raw materials i.e. fly ash (as such - 300 m^2/kg, ground - 400 m^2/kg Blaine), calcined phosphogypsum (β-hemihydrate, 320 m^2/kg Blaine), calcined hydrated lime sludge (320 m^2/kg, Blaine), Uncalcined fluorogypsum (3 10 m^2/kg, Blaine), portland cement (325 m^2/kg, Blaine) and a chemical activator (passing 150 micron IS sieve) in different proportions (Table 1) followed by grinding in a ball mill to a fineness of 330 m^2/kg (Blaine). These binders were tested for their various physical properties as per IS:403 1- 1989 [2]. Hydration studies of experimental binders at normal consistency were undertaken by differential thermal analysis (Stanton Red Croft, London), and scanning electron microscopy (SEM Model 508, Holland).

The durability of cementitious binders was examined by their performance in water and by the alternate wetting and drying cycles at 27 to 50°C by immersing the hardened binder cubes (2.5 cm) in water for evaluating their behaviour. One cycle of wetting and drying was comprised of heating the cubes for 16.0 hours at different temperatures followed by cooling for one hour and immersion in water for 7.0 hours [3]. The compressive strength and change in weight of cubes was measured.

The mortar making properties of the binder was studied using binder and sand (F.M. 1.82) in the proportions 1:1, 1:2, 1:3, 1:4 and 1:5 by weight at 105 + 5% flow as per IS:4031-1989. The concrete cubes were cast as per IS:516-1991 [4] using 10.0 and 25.0 percent replacement of Portland cement by the cementitious binder, Badarpur Sand

(F.M.2.2) and gravel in the proportion 1:2:4 at water cement ratio 0.50. The strength and water- retentivity of mortars and concrete mixes were determined.

3 Results and discussion

3.1 Properties of cementitious binders

The properties of cementitious binders are reported in Table 2. It can be seen that the consistency and setting time reduced while the compressive strength increased of binders produced from the ground fly ash and other ingredients than the cementitious binders produced from unground fly ash etc. The increase in strength can be attributed to the decrease in the consistency and the increase in the formation of hydraulic products formed during the progressive curing period. The formation of hydration products are graphically illustrated in Figure 1. for the binder (b) and (a2). The endotherms at 5 10°-520°C, 620°C, 790 and 960°- 980°C are due to $Ca(OH)_2$, fly ash, wollastonite and $CaCO_3$ respectively. Whereas intensity of gypsum endotherms at 160°- 170°C decreased and that of ettringite ($C_3A.3CaSO_4.32H_2O$) at 150°C increased. The small endotherm at 130°- 135°C on low temperature flank of ettringite is due to C-S-H. The endotherms obtained for decomposition of $Ca(OH)_2$ and $CaCO_3$ reduced and that of C-S-H compound (790°C) enhanced in the ground fly ash binders than the unground fly ash binders confirming their contribution in the overall increase in the strength. The formation of typical hydraulic products such as subhedral to anhedral needles of ettringite, hydrated plates of C-S-H and wollastonite and the partially hydrated fly ash spheres found in case of binder (a2) are shown in Figure 2.

Table 2

Properties of cementitious binders based on industrial wastes

Mix Designation	Consistency (%)	Physical' Properties

(a) (b)

FIG.2

Microphotographs of hydrated binder a.2 at (a) **7** days and '(b) 28 days (x 1250)

3.2 Durability of cementitious binders

The performance of the cementitious binders was studied by immersion of 2.5 cm cubes of cementitious binder (28 days cured) in water. Data showed that the porosity and water absorption increased with increase in the immersion period without leaching etc. The absence of leaching of the binders confirm their increased level of stability towards water, hence water- resistance. On subjecting the cementitious binders to wetting and drying cycles from 5 to 50 cycles at 27°, 40°C and 50°C, variation in strength development was found due to variable hydration of the binders. The residual strength at 50 cycles was detected higher than the pristine strength in case of binders based on the ground fly ash due to better hydration of former than latter. However, loss in strength measured in the binders based on unground fly ash etc. was higher probably due to lower formation of ettringite and C-S-H compounds.

3.3 Use of cementitious binders in masonry mortars and concrete

The properties of masonry mortars prepared from cementitious binders (b), (al), (a2) and (b3) showed that. a mix proportion 1:4 (binder-sand) attained maximum compressive strength in the range 2.90 to 5.40 MPa at 7 days and 5.50 to 9.0 MPa at 28 days and the water retentivity of the order of 60.0 to 65.0 percent as against the minimum specified values of 2.5 and 5.0 MPa and 60.0 percent respectively laid down in IS:3466-1981[5]. These values were far better than the traditional cement-sand (1:6) mortars.

The studies conducted on the part replacement of the binder in cement concrete showed that the binder (b) can be partly replaced for the cement in the concrete mix 1:2:4:cement:fine aggregate: coarse aggregate. Replacement of cement by the binder (b) upto 10% and 25% by weight did not produce any detrimental effect on the strength of concrete,

4 Conclusions

1. The cementitious binders can be formulated by judicious blending the industrial wastes such as fly ash, phosphogypsum, fluorogypsum, lime sludges and cement together.
2. The attainment of high strength in the binders is due to the formation of ettringite, C-S-H and wollastonite.
3. The binders are quite durable as they do not show leaching of the matrix when subjected to long term immersion in water.
4. The binders are suitable for making masonry mortars and as part replacement of cement in cement concrete. The production and use of cementitious binders fi-om solid industrial wastes is strongly recommended to solve their disposal problem.

Abstract
In the developed countries, the building stock and infrastructure constitute more than 50 per cent of each country's real capital. A large part of the building stock and infrastructure will sooner or later fall into disrepair and make the economic and the cultural costs significant due to deficient maintenance. To make the maintenance more efficient and reduce the costs there is a need to predict the service life of building components and materials. Methods for service life prediction of building components and materials have been and are developed within an International Standard (ISO). The standard is based on formulas where the length of service life can be estimated. Factors based on knowledge of degradation mechanisms and dose-response functions will be the input. One of these factors quantifies outdoor environmental impact. A considerable amount of environmental data are available from meteorological and environmental research communities, but in its present form it is not sufficient for service life prediction; data must, for example, be made applicable to the micro environment of buildings. In instances where this data does not exist, research must be carried out to produce the necessary information. It is also necessary to have a systematic knowledge of the type and form of environmental degradation agents being characterised and mapped. To produce this knowledge, an extensive service life research is required. This paper describes principles for service life prediction and discuss the need for research, mapping and characterisation of the degradation environment.
Keywords: buildings, environmental characterisation and mapping, service life prediction.

1 Introduction

The building structure is one of the most important areas in a society. In the developed countries, the building stock and infrastructure constitute more than 50 per cent of each country's real capital. To pursue sustainable development and make maintenance more efficient and reduce the costs, there is a need to predict *the service life* of building components and materials. Service life is defined as the "period of time after installation during which all conditions of a building or a building part meet or exceed the performance requirements"[1]. The construction of a new building or facility is generally expensive and may require considerable resources. Hence, building constructions play a significant role in the strive for a sustainable society. In that respect the design life must, for each component, be optimised in relation to the estimated service life of the building.

Principles for service life prediction of materials and buildings have being and are established within national and international standards organisations. For example, in certain countries, within their national standards, codes or practices, the focus is being placed on providing guides to help predict service life (e.g. Durability of buildings and building elements, products and components, British Standard 7543: 1992; Guide for service life planning of buildings, Architectural Institute of Japan, and; Guideline on durability in buildings, Canadian Standards Association CSA-5478). An international standardised methodology for prediction of service life of building materials, components and buildings is presently being elaborated in ISO/TC59/SC14 [1, 2]. The standardised methodology encompasses prediction models which rely on knowledge of degradation mechanisms and dose-response functions. Dose-response functions describe the relationship between doses of environmental degradation agents and the observed effects of degradation. In order to estimate doses, a considerable amount of environmental data on the macro/meso scale is available from meteorological and environmental research communities, however, correlation between this kind of data and the micro environment at the building surface must still be completed.

2 Principles for service life prediction and international standardisation

A methodological way to predict the service life of building materials and components, is object of standardisation in the IS0 draft "Service Life Planning – Part 2: Service Life Prediction Principles" [2], which is partially based on the RILEM Technical Recommendation "Systematic Methodology for Service Life Prediction of Building Materials and Components"[3]. A prediction according to the standard relies on establishing performance-over-time functions that describe how measured values of some chosen performance characteristic of a material are expected to vary over time. With performance-over-time functions established for the range of in-use conditions considered and agreed performance criteria, all essentials elements are known to complete a service life prediction. The methodology includes identification of required information, the selection or development of exposure programmes and evaluation methods, exposure and evaluation, interpretation of data, and reporting of results. It employs an iterative approach that permits improved predictions to be made as the base of knowledge grows. These principles are elaborated in a generic format, i.e. applicable to all types of building components, and may be used in the planning of service life prediction studies, or be the guiding document in the assessment of investigations that have already been performed. The essential steps in a prediction process are shown in Fig 1.

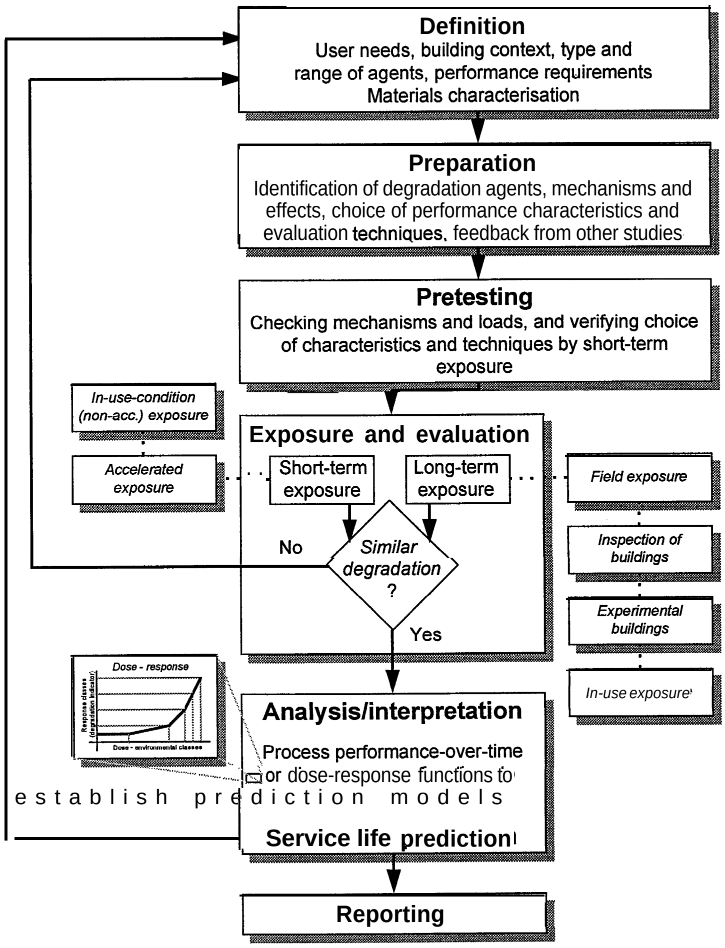

Fig 1 Systematic methodology for service life prediction of building materials and components.

A predicted service *life* of a component may be utilised as a reference service *life (RSL)*. However, the RSL is valid at the conditions employed in the study, and must be adjusted to reflect the specific conditions for a given building, thus resulting in an estimated service *life (ESL)*. This method that takes prediction data and other useful knowledge into consideration when designing a specific object - *the factor method for estimating service life* - is described in the IS0 draft standard “Service Life Planing - Part 1: General principles” [1]. The method estimates the service life using the relation:

$$ESL = RSL \times A \times B \times C \times D \times E \times F \qquad (1)$$

Thus, the reference service life for the component is multiplied by a number of *modifying factors* (A, *B, C, D*,....), each relating to a certain aspect, cf. Table 1. The environmental factor, *D,* can be divided in two parts; indoor and outdoor environmental condition. To estimate the outdoor environmental condition, the environment around a building must be characterised before the factor can be determined, since the factor is site specific.

Table 1 Modifying factors of "the factor method".

Factors related to inherent quality characteristics	A_1	Performance of Materials	Material type or grade. Manufacture, storage, transport
	A_2		Durability features: Protection system
	B	Design level	Details of construction: Joints fixing, incorporation, sheltering by rest of the structure
	C	Work execution level	Site work: Quality to standard or manufactures specifications. Level of workmanship, climatic conditions during execution work
Environment	D_1	Indoor environment conditions	Condensation,aggressiveness of environment, ventilation
	D_2	Outdoor environment conditions	Macro, meso, micro environment conditions
Operation conditions	E	In use conditions	Mechanical impact, category of users, wear and tear, vandalism
	F	Maintenance	Quality and frequency of maintenance, accessibility for maintenance

3 Environmental characterisation and mapping

The service life of a building component is, among other things, dependent on the degradation rate of the materials it is composed of. All materials will sooner or later break down. When the components are placed outdoors, the degradation rate is determined by the magnitude of environmental agents. Environmental characterisation can be provided at a general level, depending on its criticality and the data available. The classification of agents and examples of outdoor environment exposure are given in Table 2.

In principle the list follows the IS0 6241-1984 (E) standard [4] and CIB W80/RILEM140-PSL recommendation [5], describing agents relevant to building performance and their requirements. The degradation agents are classified according to their nature as *Mechanical, Electromagnetic, Thermal, Chemical* and *Biological.* This characterisation implies that the agents are listed according to their own nature and not to the nature of their action at the buildings or components; for instance, a chemical agent, such as water, may have a physical action (for example swelling) or a chemical action (for example hydration dissolution). Moreover, agents in combination may have additional physical, chemical and/or biological actions.

Table 2 Degradation agents affecting the service life of building materials and components.

Nature	Class	Example of outdoor exposure
Mechanical agents	*Gravitation* *Forces and imposed or restrained deformations* *Kinetic energy* *Vibrations and noises*	*Snow, rain and water loads, ice, formation pressure, thermal and moisture expansion, daily temperature, difference, freeze/thaw, driving rain, differential wetting or drying wind*
Electromagnetic agents	*Radiation* *Electricity* *Magnetism*	*Solar and thermal radiation*
Thermal agents	*Extreme levels or fast alterations of temperature*	*Heat and frost*
Chemical agents	*Water and solvents* *Oxidising agents* *Reducing agents* *Acids* *Bases* *Salts* *Chemically neutral*	*Water, oxidising agents (oxygen, ozone, carbon dioxide, sulphur dioxide, nitric oxide), synergistic effect of oxidising agents, acids, salts, sea spray, soot, particles, chemical incompatibility (leaching and leaches, solvents and contaminated land)*
Biological agents	*Vegetable and microbial* *Animal*	*Fungi, bacteria and insects*

As discussed above, models for service life prediction and estimation rely on dose-response functions. Some input values to these functions are doses of degradation agents surrounding the building component. At present, data on doses measured directly at a building are for the most part lacking. However, substantial amounts of environmental data are available from meteorological and environmental research communities, but this in itself is not sufficient for predicting service life; data must be transformed such that it relates to the micro environment at the surface of the building. Data have been collected at different geographical scales for other purposes. One frequently used basis of environmental classification on a geographical scale, is the division of climate into macro, meso, local and micro, as shown Fig 2 [6].

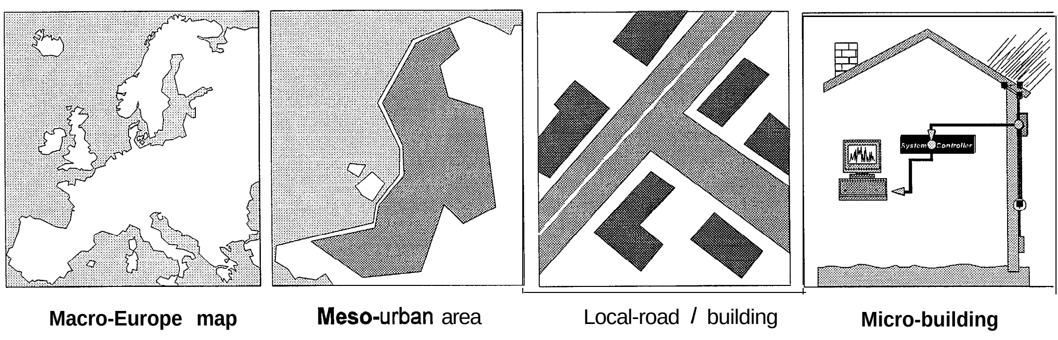

Fig 2 Exposure environment on different geographical scales.

Although at the present time there exists no common or exact definitions of the different scales, the following is now proposed: *Macro climate* represents the gross meteorological conditions described in terms such as polar climate, subtropical climate and tropical climate. When describing *meso climate*, the effects of the terrain and the built environment are taken into account in an area not exceeding 150 km^2. *Local climate* represents the local conditions in proximity to the building, for instance, in the streets around the building. The *micro climate* describes the meteorological variables in absolute proximity of a material surface. Materials' degradation takes place in the micro environment which thus makes the characterisation there of crucial to the determination of dose-response functions and ultimately - the prediction or estimation of service-life.

4 Example of environmental mapping

As previously mentioned, at the macro and meso level there are considerable amounts of data available for environmental characterisation, for example, mean values of: precipitation, temperatures, wind directions, emissions. These kinds of data can, after appropriate correction, be used for characterisation of the micro environment around a building. An example of correction factors that must be considered when transforming meteorological data from the meso level to the local and micro levels is shown in Fig 3. Methods to transform meteorological data from the meso level to local and micro level exist, for example, in standards for wind-driven rain. The driving rain index, which is a product of annual average rainfall (horizontal) and average wind speed, refer to the meso level. With a given correction factor, a value can be computed for the local and micro levels. This provides doses of water loads on vertical surfaces. Using similar methodologies, it will be possible to calculate other degradation agent doses.

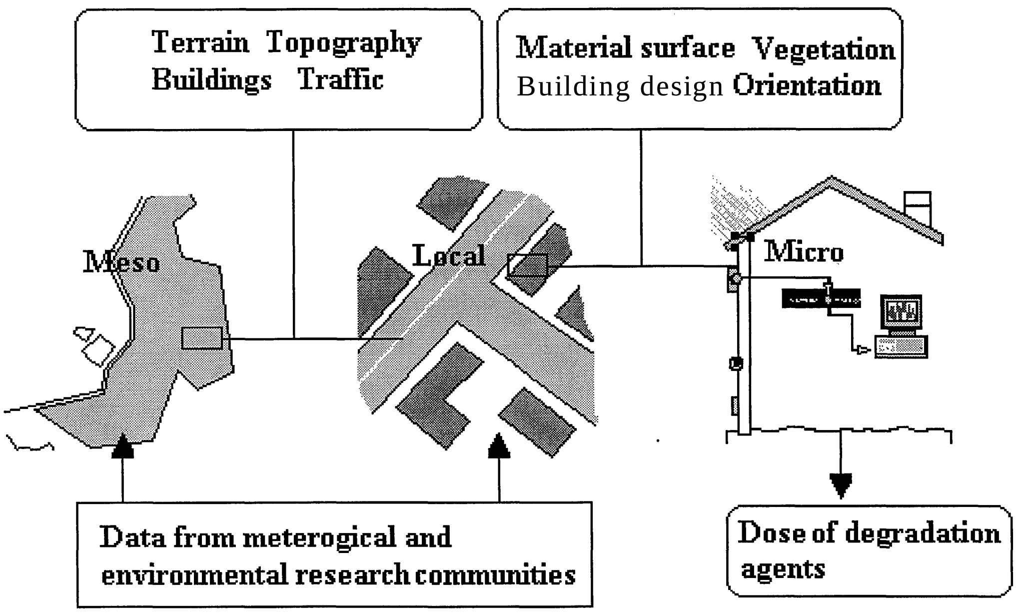

Fig 3 Correction factors to take into consideration when transforming meteorological data from the meso level to local and micro level.

In the EU-project Wood-Assess (ENV-CT950110) one of the objectives is mapping of environmental risks at the meso and micro scale. Building degradation is caused by a large variety of degradation agents. The most serious damage for wooden buildings is the rotting process. At a specific value of moisture ratio and temperature, the critical condition for the rotting process to start is reached. A well-known formula that estimates the potential of a climate to promote rotting is Scheffer's Climate Risk Index **(CRI)** [7]. The formula is based on precipitation and temperature, data that are mostly available on the meso scale. The index can be delineated in maps as geographical contours (isoploths). A problem with using the CRI in estimating the likely micro climate is the local variation in meteorological parameters for a specific building. In the Wood-Assess project one task is to compare the CRI measurements on local scale with the CRI based on data from the nearest weather station (meso scale) and the time of wetness measured in the micro environment of a specific building.

5 Conclusions

By determining the service life of building components, it is possible to reduce resource consumption, as well as reduce costs at production and maintenance of a building. An international project is focused on developing a consistent set of standardised principles for service life estimation [1]. These principles are based on a reference service life that manufactures must themselves establish, for which standardised principles also will be developed [2]. This reference service life is in a general form and has to be adjusted to the specific conditions of a construction. The adjustment can be done with factors by which the reference service life are multiplied. One of these factors is related to degradation agents in the outdoor environment. As the environment is specific for each building, a characterisation must be completed in which the degradation agents are quantified. Standardised methods for the process of characterisation still have to be created.

After that the degradation agents are characterised, a value of the factor has to be determined that relates to the environment in question. The procedure to estimate the value of this factor can, for example, be: index of each agent is taken from maps at a meso or local scale; the index is transformed with coefficients into a micro scale (i.e. the components surface); the transformed index is used as input in performance-over-time or dose-response functions, and the results from these functions are used to determine the value of the factor.

Research needs to be carried out to develop maps of indices and to estimate the coefficients for index-transformation of macro or meso to micro scale. Doses of agents causing degradation should be the basis for this index whereas the relation between data on difference scales should be the basis for determining the coefficients. Today, many of the environmental agents are measured and these data can be used to create the maps of indices. Unfortunately, data are measured only at one geographical scale (macro, meso or local). To estimate the difference between the scales, measurements must simultaneously be conducted at the micro scale. The process of developing methods for environmental dose-scale-transformation coefficients can, for example, be performed as follows: data of degradation agents are collected at the meso/local scale and the micro scale simultaneously; the relation between data (on different scales) is determined, and transferred into a general condition as coefficients, while considering transformation models.

Stratified Layer Building systems

M. Imperadori
Politecnico di Milano, Dipartimento di Ingegneria dei Sistemi Edilizi e Territoriali, Italy.

Abstract

Building in quality and respecting the environment are two big challenges of the construction world for the coming millenium. The use of *dry assembled systems* is a way to meet specific requirements for a building and, at the same time, it gives a guaranty of flexibility, as well as a possibility of disassembling and reuse or recycle of components. To optimize quality request and procedure of recycling, these systems use products of the industry assembled on site.

This paper deals with *lightweight buildings* composed by structures and addition of independent layers, choosen to give focused performances, preengineered and built on site with dry and mechanical connectors.

Keywords: Lightweight Buildings, Stratified Layer Systems, Dry Assemblies, Building Quality, Life Cycle Planning.

1 Introduction

The "now society" is characterized by very fast changes and that could be seen in many different fields of the industry: from telecomunications to informatics, from biotechnology to micromechanics. The world of constructions is for its own nature more lethargic and needs more time to get in direction of new ways of conceiving, realizing and managing its product: the building.

This concerns even more if we talk of building for housing and living in comparison with special structures where the approach is very innovative and very often a special technology, which is newly designed and requested by the big scale of these projects.

Anyway housing is the real challenge because the budgets are more restricted and that means to achieve results, in terms of quality of living and of reducing the environmental impact, in a restricted economic frame.

Very suitable 'for this appears the orientation on *dry assembled lightweight systems,* and the use of industrial products available on the market.

Conceiving *lightweight buildings* is a very new subject especially for central and southern Europe, where the construction is mainly based on monolithic systems with masonry or concrete structure. In northern Europe, Canada and USA Lightweight Buildings belong to tradition, both in wood or steel gauge frame structure, but still there are open fields also to improve these systems.

In this way the contemporary technology can be diffused for common use and gives results of quality if the products are applied following proper "new rules of the constructing art".

2 The Quality Frame

In the field of Industry the Total Quality Management has become a successful1 procedure to obtain products which will offer the consumers the expressed requirements and at the same time controlled production methods with always more attention on reducing toxic emissions.

Translating this to the building industry the subject has to deal with different steps which complicate the problem. Very often we speak about "the chain of quality" in building constructions, which could be divided in:

- Quality of Product
- Quality of Process
- Quality of Project

The *quality of product* is well defined by the standards serie IS0 9000 and the European Community Directive 89/106 about Construction Products. With these tools the producers can guaranty quality controlled products, and this means certified and with CE label [1].

The very big question is to keep the label valid in the following and complicated phases: the interaction with other materials and at least the behaviour of the product in a major entity which is the finished building. The weak points of the "quality chain" are in fact the *quality of building process* and the *quality of project and design.*

To reinforce this weakness it is possible to open a discussion about new systems to conceive and realize the building: this means quality control in all the steps of construction and new design methodologies.

Tools to obtain this could be, in the design phase, the application of the standards now under development about Service Life Planning in the Drafts of IS0 TC59/SC14 [2][3]. This could help especially if the standard is used in an interactive way with the design, giving feed-backs and guideline to realize better solutions in terms of economics, environment and quality of living.

To guaranty this and to guaranty that the *quality of product* will not be lost, during its application in following phases, an active *quality control* should be always adopted to avoid misusing and to keep a correct *life cycle planning* valid.

At least one should introduce new ways of managing the project and its realization which are possible with *stratified layer systems* [4].

3 Stratified Layer Systems

The constuction field is characterized by a lot of “actors”:

- Producers Industry
- Universities and Research Groups
- Contractors
- Workers
- Engineers and Architects

Making the technology has to be seen as an active cooperation between designers and producers [5]. This cooperation brings cultural developement for both of them, respecting the rules of codes and standards.

A real example of this cooperation is the French research circle “Architecture e Industrie” lead by Eric Dubosc, architect in Paris professor at the University of Lille, and Marc Landowski, architect in Paris and member of CSTB Consulting Committee. Their aim is to develop, together with producers, building technologies, mainly related with housing [6][7], based on *dry and lightweight buildings,* able to guaranty:

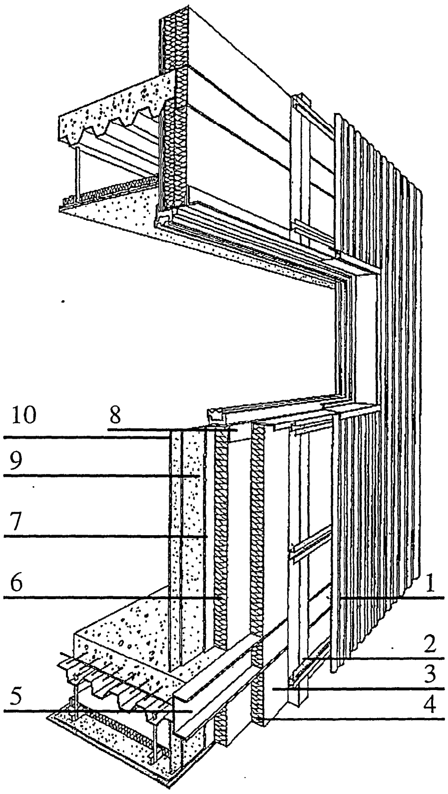
- Quality Performance at affordable price
- Use of Industrial Products
- Low Environmental Impact
- New Building Management
- Perfect Logistic and Ergotechnic

The *stratified layer systems* are conceived as separated and independent units:

1. OUTSIDE ENVELOPE
2. STRUCTURE
3. INSIDE ENVELOPE

Between these units the installations run easily accessible for cheking and eventual maintainence [8].

The primary structure, normally in steel, is a frame of beams and pillar supporting horizontal steel welded plates. The secondary structure, like a steel gauge frame [9], sustain the *stratified Layers* which are dry connected in a *sort* of *panelized system.*



Figl. Example of an outside stratified facade. La Venerie, Housing project in Montargis Le Franc, 1994 by Dubosc and Landowski.

In figure 1 we can identify, from outside towards inside, ten different layers in this composite wall :

- <u>Outside Envelope</u>
1. Coil coated corrugated steel sheet
2. Secondary structure supports
3. Air layer
4. Mineral wool for sound and thermal insulation

- <u>Structure</u>
5. Primary loadbearing structure of steel

- <u>Inside Envelope</u>
6. Mineral wool for sound and thermal insulation
7. Damp barrier
8. Secondary structure supports
9. First gypsum board layer
lO.Second gypsum board layer with finishing

Every layer is choosen and engineered to give a specific performance to the requirements expressed by the utilizer or to react to physical and chemical loads.

This means that every layer works under specific loads without interactions and gives a focused response, once we know the characteristics of inside and outside environments.

In a way the *stratified layer system* itself plays an important role for the reliability of *durability tests and prediction.* In fact the co-action of loads, like in monolithic traditional buildings, complicates the reliability of prediction based on accelerated tests or simulations.

The disconnection of the layers in *lightweight buildings* gives the opportunity to set up "Dose-Response" functions and evaluate the behaviour of a product [10], and so also the durability and the maintainance plan, with less uncertainity.

In this case the appliance of Service Life and Life Cycle Planning, Drafts of IS0 TC59/SC14, could be used as design tool based on reliable data, collected by research centers and producers, to give an active impact on the choices of appropriate material and to set up a proper maintainance plan.

4 Design for the Environment: Elasticity versus the Mass

The environmental impact of a building has to be seen in all its life cycle:

- Production
- Construction
- Operating Conditions
- Maintainance
- Reuse or Recycle, once the lifetime of a component or the purpose of the building itself is reached

Lightweight buildings are conceived as *"high environmental tech"*, because they create cycles of use. Every part of them could be substituted, reused or recycled with low consumption of energy.

Traditional monolithics buildings add more embodied energy using everlasting connections, which means use and waste of water. As a parallel the dry connections in *stratified layer systems* always allow a reversibility and demountability of the components [11]. This is a big advantage also in terms of flexibility which is a very actual request. If we notice the very fast changes coming in our life, we can also see an added value to those buildings which can adapt themselfs easier to new issues of use or maintainence.

A traditional monolithic building has a weight of 7-10 times more than a *lightweight building* to give the same performances. This means waste of energy because of transports, waste of water, materials and time which also means waste of money. The behaviour of *stratified Layer buildings* is based on elasticity properties, reacting to the physical loads by elastic deformation. Every layer is preengineered to give right performances to requirements of:

- Acoustic comfort
- Fire proofing
- Thermal and humidity comfort
- Seismic safety

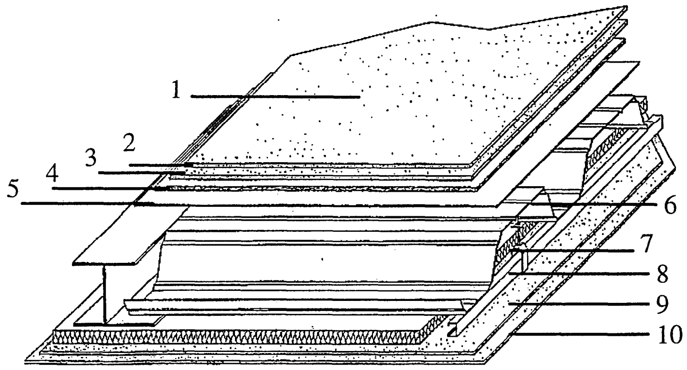


Fig2. PCIS, Plancher Composite Interactif Sec(dry composed interactive slab). Parc de Tailles, Saint Martin d'Heres, 1996 by Dubosc e Landowski.

In figure 2 is a dry lightweight floor for housing stratified, from top towards bottom:

1. Finishing carpet
2. 13 mm anhydrite panel
3. 13 mm gypsum panel
4. 12 mm glued wood panel
5. 3 mm mineral wool to cut the sound bridge
6. 2 - 420 - 200 loadbearing corrugated coil coated steel plate
7. 70 mm mineral wool for sound insulation
8. Secondary structure to hang the ceiling
9. 13 mm gypsum panel
10. 13 mm gypsum panel with finishing

The performances tested by CSTB are:

- Loadbearing surcharge: 2,50 kN per square meter; max. free span 5,8 m
- Total height. 0,32 m
- Total weight: 97 kg per square meter
- Fire: REI 30 with 13 mm gypsum boards on ceiling, REI 60 with 15 mm gypsum boards.
- Acoustic: Airborne sound insulation > 66 dB(A). Impact sound insulation < 54 dB(A); with only plastic covering: deltaL = 13 dB(A).

The system has won the "Decibel d'Or" in 1997 for its special acoustic performances, superior to the level for the label "Qualitet Comfort Acoustique".

5 Conclusions

The use of materials available on the market and industrially produced gives the opportunity to have quality products. The use of them in *dry* systems allows to reduce the uncertainity of behaviour due to uncontrollable on site elaboration which is always affected by the weather and by human errors.

With *layers systems* workers become more "high-tech artisans" and they can operate carrying light loads and working on a dry on-site.

The Architectural possibility is always left free and this plays also a role on the visual impact on the Environment without constructing buildings with the same aspect for different people and geographic frames.

Forward steps of applied research are opened in direction of integration between layers and installations. For example, to create irradiating heating and cooling systems which use low temperature aggregates and leave the possibility to use renewable energy sources like sun and geothermic energy, or creating photovoltaic cells panels to transform the house to an active energy catcher [12]. Lightweight technologies could be seen as a way to improve and develop new solutions in construction field without overloading the Environment. The application of *stratified layer systems* to methodologies proposed by IS0 TC59/SC14 (see paper in this section Hed, G., *Service Life Planning in Building Design)* could be active tools to obtain *quality buildings*, with reliable *service life predictions [* 13].

6 Aknowledgements

Göran Hed, Centre for Built Environment Gävle, Royal Institute of Technology, Sweden, has contributed to this paper with many valuable and constructive discussions. Thanks to Prof.Arch.Eric Dubosc, from Dubosc e Landowski - Paris, for very precious material, viewpoints and explanations, both for architectural and technical point of view about total dry systems.

Scientific tools for assessment of the degradation of historic brick masonry.

K. Van Balen
R.Lemaire Center for Conservation, K.U.Leuven, Leuven (Heverlee), Belgium.

Abstract

The aim of the research on brick masonry degradation supported by the D.G. XII is presented.

A systematized questionnaire has been conducted that allows the collection of expertise from different sources in relation to damage on historic brick masonry structures. The main initial sources are literature, data from in situ investigation carried out on historic brick masonry buildings and laboratory simulation tests. This information is collected in an **"Atlas of damage to historic brick structures"**. containing uniform terminology and a uniform description of damage types and damage origins. This information is schematized into relations between damage types, causes and the physical phenomena related to a set of deterioration processes. Particular attention is paid to the interaction between the different materials of which ancient brick masonry is composed and the effect of environmental factors.

The deterioration causes can only be understood with a knowledge of the different historic brick masonry construction types and the historic, climatical and geographic context in which those masonries have been built; used and eventually restored.

A **Masonry Damage Diagnostic System** is developed that - through systematization of this knowledge and relations - will guide the person using this expertise toward the assessment of damage type and damage cause. It also provides information on the type of investigation that has to be carried out on the masonry to be diagnosed, in order to improve the quality of the information about the damage type and damage origin. Therefore, appropriate (monument-friendly non-destructive) testing techniques are evaluated on their likelihood of increasing the precision of the diagnosis. For the creation of the expert system an expert's system shell is used based on decision tables.

The scientific methodology used for the development of both tools is given.

Key words: Masonry damage diagnostic system, expert system, historic brick structures, masonry, damage atlas.

1 Introduction.

Conservation and restoration of historic structures depend on various factors and include aspects related to different disciplines. For architectural historians involved in decision taking processes for the conservation of historic buildings the decay problem is often evaluated in a different way as by engineers or material scientists. From the other hand historical information (e.g., severe damage which occurred in the past by an accident) is a very valuable source of information if existing damage is to be evaluated.

Multi-disciplinary approach and possibility of exchange of information between different partners are hence crucial when choices between options have to be made. Diagnostic tools to evaluate the condition of brick monuments will have to take this into account.

A research group coordinated by the author developed instruments like the Masonry Damage Diagnostic System (MDDS) and a Atlas of Damages of historic brick structures which aimed at improving the diagnosis before intervention but which also can be used to evaluate previous interventions

2 Masonry Damage Diagnostic System and Atlas of damage to historic brick structures.

2.1 Objective

The objective of the project is to improve our knowledge of the effects of environmental factors on damage to Europe's cultural heritage and to guarantee better treatment and protection of our heritage, by providing the professionals who work on the analysis of ancient buildings with an expert system including a damage atlas.

2.2 Scientific approach

The aim of the project was to create an instrument bases on scientific information which could increase the number of persons to execute general monitoring of historic buildings. By increasing their number there should be a shift toward maintenance type interventions on historic buildings instead of more "heavy" restoration interventions [1]. Therefore groups of technicians, architects, engineers should be helped in executing correct analysis of the major part of (more simple) damage cases, leaving the more difficult and special cases to the smaller group of leading professionals. The latter will be thus only involved in those cases where high specialism is required. It has also been noticed that even for specialists those instruments could be a helping guide when they have to deal with fields in which they do not have very specialized knowledge. To define the group of less specialized professional (nevertheless having a broad background) the profile of the "Monumentenwachters" (Monument Watchers) of the Netherlands or in Flanders has been taken as a reference. The specificity of the scientific approach can be summarized by the following headings.

2.2.1 Multidisciplinary approach:
The approach takes into account different dimensions of the problem from material sciences, environmental sciences, biological sciences, historic sciences, architecture and urban development;

2.2.2 Complexity:
The durability of the masonry does not only depend on the behaviour of one material but on a complex interaction of different materials and different boundary conditions (e.g., traffic, pollution, precipitation, orientation, etc.);

2.2.3 Scope:
The evaluation and interpretation of damage do not so far include a proposal for treatments, but is limited to the diagnosis. It gives precise descriptions of damage types and the process responsible for this damage in the given circumstances.

2.2.4 Damage approach:
The relation between damage definition (type) and damage cause (mechanism) is based on a thermodynamical approach: resistance against stress defines the damage (function). In that respect approaching from visible damage, the process of decay is the right way to make tools that can be used for monitoring.

2.2.5 Usefulness:
The definition and terminology are based on maximum use of visual analyzing techniques and maximum collection of relevant data at the site. Additional guidance is given through testing techniques from non-destructive to destructive techniques if necessary.

2 3 **Methodology**

The methodology used is based on the scientific principles of research. In the problem stated, damage to historic brick structures, and the development of the Masonry Damage Diagnostic System defined the scientific description and deductions of the physical mechanisms causing the damage. Inherent choices have been made in relation to the order of input taken into account for the deduction: it started with the most easy way of identification which is visual analysis (this also explains the usefulness of the damage atlas) and then included in order the in situ and laboratory tests. A thermodynamical model of decay of materials as developed in the project [2] defines damage as a result of stresses and resistance allowed damage types and damage causes to be linked. This was then developed in terms of processes within the Masonry Damage Diagnostic System. The development of the Masonry Damage Diagnostic System allowed us in many cases to limit the problem only to those parameters which are described really necessary (goal oriented), thus omitting irrelevant elements while the link with the practice remains guaranteed.

This approach is unique in this field and the experience of the project demonstrated the scientific interest of this engineering approach for the evaluation of deterioration of ancient brick structures. It is an applied scientific approach producing practical results for the conservation of historic brick monuments.

2.4 Research results.

2.4.1 Terminology.

In the first stage of the work common definitions had to be set up which should be useful within the different instruments of the project. A first set of damage types has therefore been defined which is useful for the questionnaire but could be developed within the Masonry Damage Diagnostic System. The hierarchic concept allows the user to narrow his definitions gradually. This approach was based on the assumption in the project that defining goes hand in hand with increasing knowledge. Vague knowledge needs broader terms while added information has to narrow the set of terms. In the questionnaire the group of damage types is given with the subset of more precise terms. The logic in the definition was based on the visual discrimination. It has been defined so that in the order of the analysis the visual appreciation was the first "instrument" used. As the questionnaire and the related damage atlas are related to this first analysis, it was logical that the definition of damage types should use visual criteria. Within the Masonry Damage Diagnostic System the same terminology has been used while the “instrument” itself allows the user to check his interpretation of the terminology by answering questions defined by the conditions contained in the definition of the term. The structure of the terms of the damage types and definitions given in terms of conditions will be illustrated later.

2.4.2 Questionnaire.

The original questionnaire with which the project was started and which stemmed from the collaboration of the experts of the NATO-CCMS pilot study on Conservation of Historic Brick Structures has been modified considerably as described in one of the project reports [3]. The main reasons for this development are found in the interaction with the setup of the terminology which was developed in relation to the Masonry Damage Diagnostic System. Another argument was the subdivision of the questionnaire according to the order of investigation of the damage type into its possible cause. The first type of analysis is based on visual analysis and in site measurements while the second part has been made for the integration of laboratory results leading in the third part to a synthesis and an interpretation.

It was experienced that even experts contacted by purpose are hesitant to formalize the collection of information in a questionnaire if they see no direct interest or reply leading them to the diagnosis. As an instrument to monitor the questionnaire seems to have the disadvantage to be to lengthy, not precise and synthetic enough. This seemed very discouraging but it was realized that in fact this event proved the advantages of the Masonry Damage Diagnostic System. It has therefore been concluded that the questionnaire should be developed electronically. So that the user, after giving some basic information on the building and according to the previous answers he has given, is requested to answer only those questions which are relevant to the problem, which is what the Masonry Damage

Diagnostic System does. The latest version of the questionnaire itself became simpler and has been developed with a view to the rapid collection of the necessary data related to pictures for the damage atlas.

It was also seen that in practice very few professionals and owners are willing to deepen the diagnosis with laboratory tests and even with tests in situ. It is the experience of most of the partners in the project however that in many cases only those types of analyses can provide the necessary information for a full diagnosis. There are many evidences as the example described in on the case of a neo-gothic church in Pamel, near Brussels [4] that the analyses of the pore structure of the mortars and bricks, and the chemical composition of the different mortars used, are necessary to define whether the damage to the brick was due to the mortar or to the composition of the bricks. In this matter the project has the task of proving the interest of different types of analysis for the diagnosis of damage and to stimulate proper diagnostic methods in that respect.

Within the project the questionnaire is also used as a structured way of collecting documentation on different cases from all the partners. Examples from Belgium, Germany, Italy and the Netherlands have also been documented in this way. The full-scale masonry models of the Politecnico di Milano set up for monitoring damage processes are also included to check the possibility of evaluating the effectiveness of the questionnaire from a dynamic viewpoint, i.e., can the questionnaire inform us about the speed of the degradation process [5]?

2.4.3 Damage atlas.

A classification of damage patterns found in brick masonry has been set up [6]. The terminology used follows the same structure and setup as the questionnaire and the Masonry Damage Diagnostic System. The definitions are more extensive than the definitions presented in decision table form in the Masonry Damage Diagnostic System and possible damage causes are also given. A complete set of illustrations of the different damage types is provided in the atlas with an explanation about the possible causes of the damage. Consistency with the Masonry Damage Diagnostic System was guaranteed as they were developed to be used together. An example of a page of the damage atlas as it will be published is given in Fig. I.

2.4.4 Masonry damage diagnostic system.

The Masonry Damage diagnostic System (MDDS) [7] is a Knowledge-based System (KBS). It is a database with information and additional knowledge to create relations according to given answers and questions. It is the translation of expertise into a system computers can handle. The knowledge is structured and can be consulted using a **Decision Table** System Shell (DTSS) developed by TNO-Bouw. It is actually a programme running on Macintosh computers but a Windows version is on its way. The Masonry Damage Diagnostic System is a prototype and is not for sale. It is the aim of the partners of the project to create links with organisations that would like to develop the existing system for their use and co-finance in this way the updating and extension of the system.

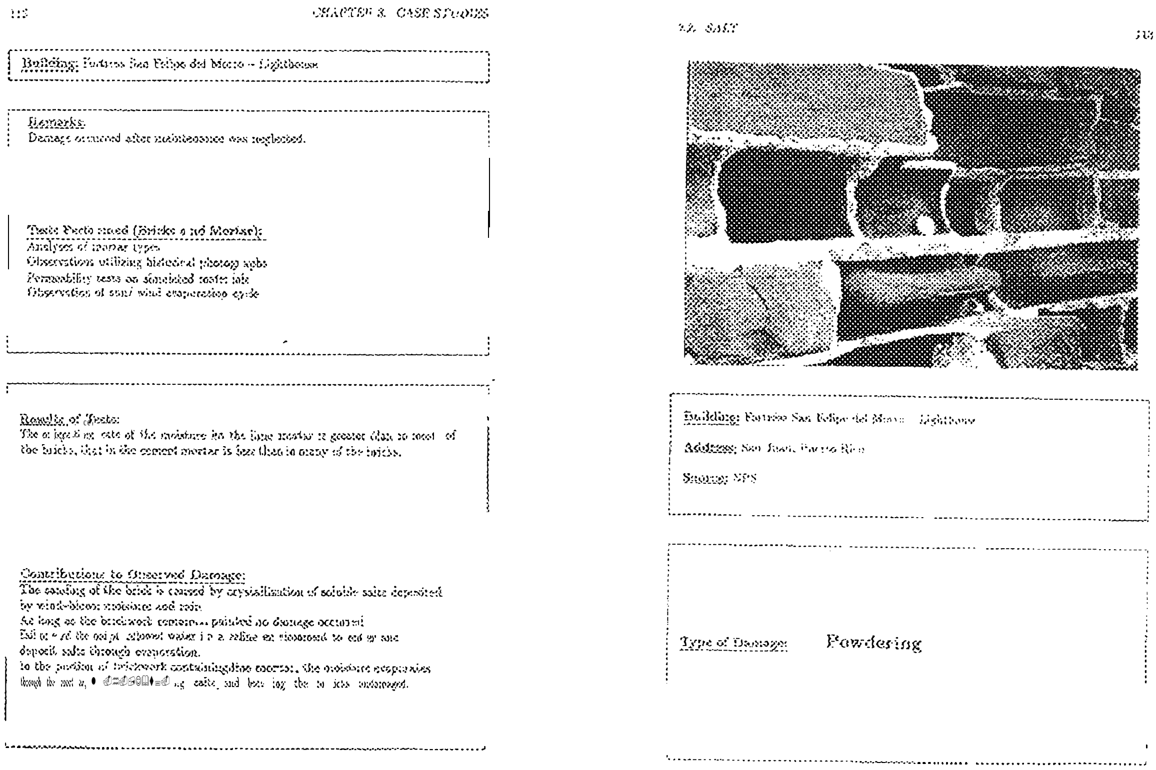

Fig. 1: : Example of a page of the damage atlas.

The knowledge is translated into a large set of decision tables themselves containing sets of conditions and actions. The set of condition tables is structured in a hierarchic way and can be presented as a decision table tree [8].

Fig.2 presents the starting branches of the tree with the sub-tree of processes checked by the system. Fig.3 shows the tree of the damage types.

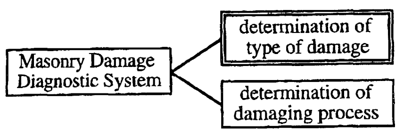

Fig. 2: : Tree structure of the main branches of the Masonry Damage Diagnostic System: determination of the type of damage (detail in next figure) and checking of damaging process responsible for the damage.

The computer programme aims to make the consultation of the Masonry Damage Diagnostic System user-friendly. In contrast to the questionnaire the Masonry Damage Diagnostic System will adapt its questioning according to previous answers given. Comparative data as pictures and comparative results of test trends are also given so that if there is uncertainty or when the answer to be given is not clear, additional information can be consulted. A typical screen picture is given in Figure 4.

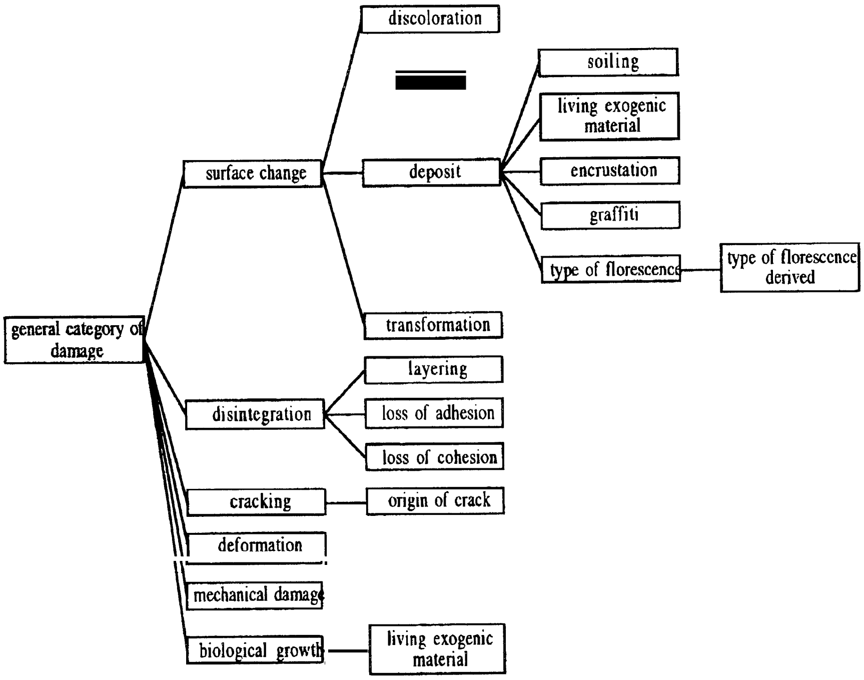

Fig. **3:** : Structure of the decision tables containing the knowledge about the determination of damage types; the hierarchic approach corresponds with the structure of the damage atlas.

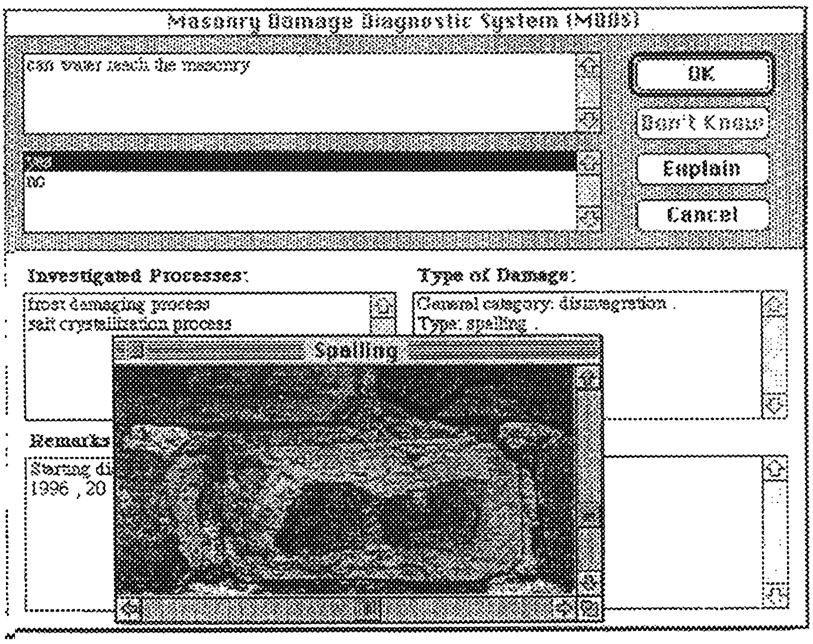

Fig. 4: : Example of a consultation screen using the Masonry Damage Diagnostic System.

The output of the Masonry Damage Diagnostic System is given immediately on the screen, but a printed report of the consultation is also generated. This document can be used as a report by the user. The results of a consultation can be stored in a file which allows progressive and step-by-step consultation in different stages. During the progress of the project it has been shown that it is very useful to create, using the Masonry Damage Diagnostic System, an interesting collection of examples of damage. The structure of the KBS within the Masonry Damage Diagnostic System obliged the users to work in a very systematic way while developing the system and using it afterwards.

3 Conclusions

The description of the damage types on historic brick structures has been improved. The link between terminology, questionnaire, damage atlas and Masonry Damage Diagnostic System is guaranteed by accurate definitions and the hierarchic concept of the damage types descriptions. In the same way the description of possible damage causes and the processes leading toward the above-mentioned damage types have been improved. The increase in systematization which was sought by the project is a necessary and interesting by-product of the creation of Knowledge Base systems (KBS).

The Decision Table System Shell (DTSS) has proved to be a very interesting tool for the development of the KBS.

The collection of different types of information using the questionnaire and other related summary sheets allowed the research team to make an interesting collection of degradations of different types. Those examples are useful for the elaboration of the damage atlas.

Reactions on the complexity of the questionnaire and uncertainty on the part of the user about which information should be mentioned in this document prove the advantage of the Masonry Damage Diagnostic System. It is certain that in the dialogue between the expert system and the user the latter will feel more comfortable as he will think that the questions which are asked are relevant to the problem, though on the other hand the expert system will limit his questioning only to that information it can consider in its reasoning. Further development of the Masonry Damage Diagnostic System could be guaranteed by the integration of research results from other projects and by the inclusion of data available on the degree and effect of pollution. Let us not forget however that no expert system will ever be as competent in each of the domains of expertise as real experts. Nevertheless the Masonry Damage Diagnostic System will be of great interest for many routine operations where leading professionals are now wasting their time and could be replaced by low-profile professionals if they are helped with a system such as the Masonry Damage Diagnostic System, provided that one issue of the system remains: “for this (difficult and complex) case I have no answer. Please call an expert”.

The performance of surface treatments for the conservation of historic brick masonry

R.P.J. van Hees
Department of Building Technology, TNO Building and Construction Research, Delft, the Netherlands

Abstract
An evaluation was made of the performance and the effectiveness of surface treatments, mainly water repellents, applied in the past on historic brick masonry. In the three European countries involved in the project over 60 case studies were carried out. Besides, laboratory research was carried out, so that the two research lines could be combined. The main aim of the project was the assessment of the performance of surface treatments for the conservation of masonry monuments, and, further, to evaluate the risks of failure and damage and to develop methods for the prediction of the performance.

Essential for the assessment of the performance of water repellents in the field and in the laboratory is the water repellent behaviour, checked on the brick / mortar system, and the evaluation of any damage observed, in relation with the presence of the treatment. This approach to the evaluation of the effects of treatments, using materials in combination, forming thus a system, proved to be very important: a different behaviour of brick and mortar after treatment could be observed, as well as interactions and mutual influences.

The *effectiveness* (water repellency) of a treatment can last for a long time, even more than 30 years. To this conclusion the following should be added: i) there is no clear relation between the age of the treatment and its effectiveness, ii) the effectiveness of the treatment within one building, even within one wall is quite variable, iii) the mortar joint is, from the point of view of water penetration, the weakest part of the (treated) system. The main reason for an insufficient performance of treatments lies in most cases in the lack of preliminary investigations, meant to outline the state of conservation of a building and to furnish the basis for: i) deciding on the necessity of a treatment, ii) selecting the most suitable treatment product.

This paper is an elaboration of the Summary Report, by R.P.J. van Hees and S. Naldini, which forms part of the final report on the project 'Evaluation of the performance of surface treatments for the conservation of historic brick masonry'. The project was carried out within the EU Environment Programme, under contract nr. EV5V-CT94-05 15.
Keywords: historic brick masonry, water repellents.

1. Introduction

Surface treatments, as part of the conservation, are carried out aiming to preserve from further decay and to prolong the life in service of monuments.
The application of surface treatments (of the type studied) on historic buildings started in the 1960's, but still the knowledge on treatment products and their effects on the materials should be improved. The situation in the three participating countries, Belgium, Italy and the Netherlands forms the base for this research project. The situation in the three countries is considered reasonably representative for the countries within the European Union.
In Italy treatments have been always used, whereas in Belgium they were not met with favour in the beginning; in the Netherlands only water repellents have been applied: after a period of favour, the attitude has become more cautious.
Main aim of the project was, to improve the knowledge on the effects of surface treatments on the service life of walls in historic buildings; most important aspects are: i) the performance in the course of time, ii) the risks of failure and damage, iii) the prediction of the performance.
In this paper an overview is given of the main research lines and results of the project, without however being extensive and complete.

2. Methodology

2.1 Research lines

The evaluation of the performance and durability of surface treatments resulted the following (interrelated) research lines:

- assessment of the state of preservation of treated walls of historic buildings;
- assessment of the performance of treatments in laboratory, making use of: i) single materials, ii) little test walls (combination of materials, that is brick and mortar), iii) real scale test buildings located in the open air.

In Italy and Belgium, water repellents (protectives) are often used in combination with consolidants, whereas, in the Netherlands, only water repellents are used. The study of water repellents was therefore essential to evaluate the state of treated monuments.
Treated monuments to be investigated were chosen with the help of the authorities in charge of their care, restoration architects and producers of treatments. Prior to the investigation on treated walls in monuments, a research was carried out aiming at collecting information on the reasons for treating, the treatment performed and the methodology followed. The results of the research where quite alarming:

- in most cases no report existed on the work performed;
- information was difficult to be obtained;
- motivations for treating, when traceable, were hardly scientifically based.

Therefore it is advised that authorities should dispose of reports on treatments performed (incl. motivations and monitoring), which should be available for consultation.

A study was carried out on the attitude of governmental Bodies responsible for the monuments towards treatments. The restoration ethics of each country influences the philosophy of the conservation interventions. Although in several countries guidelines on treatments exist, there may be a gap between theory and practice.

2.2 The choice of materials and of treatment products for testing

Old, traditional and (to a certain extent) inhomogeneous bricks were used for testing, as they possess similar characteristics to those of the bricks found in monuments. Further, the choice was based on the fact that they also have a life in service and a history. Mortars were chosen that are used for restoration in the participating countries.

Water repellents and consolidants were chosen, which were and still are available on the market; the selection was completed with a water repellent which had been used in the past, but was no longer available. The products were obtained from the producers. 4 Types of water repellents (8 on single materials) and 2 types of consolidants have been used in the laboratory research.

3. Results and discussion

3.1 General

In the study on the attitude of authorities towards treatments it was found that:

- Documents concerning philosophical and ethical aspects of restoration are often found too theoretical and far from the practical problems met by those involved in conservation.
- Guidelines on treatments are sometimes so extensive and therefore so complicated that they are not used. End users need above all realistic guidelines and documents.

Important conclusions on the performance of treatments could be derived from the combination of results obtained in laboratory with results obtained in case studies.
The water repellent effect of a treatment can not be considered the only criterion to assess its *performance.* The performance of a treatment should be evaluated, taking into account its various functions, which are or are claimed to be:

- to make the treated surface water repellent and to avoid water penetration;
- to protect the surface from damaging mechanisms in which moisture is essential;
- to avoid chemical transformation of calcitic materials, due to wet and dry deposition and moisture;
- to prevent biological growth (especially thriving of algae).

Essential for the assessment of the performance of water repellents in the field and in the laboratory is the water repellent behaviour, checked on treated brick, mortar and the *brick / mortar system,* and the evaluation of any damage observed, in relation with the presence of the treatment. This approach to the evaluation of the effects of treatments, using materials in combination, forming thus a *system,* proved to be very important: a different behaviour of brick and mortar after treatment could be observed, as well as interactions and mutual influences.

3.2 Laboratory research on single materials, little walls and test buildings

3.2.1 Single materials

Research on single materials has confirmed [4] that for one type of substrate, differences in effectiveness are obtained after ageing, even within one class of chemically similar water repellents. Moreover, for one type of water repellent, the effectiveness depends on the substrate.

3.2.2 Little walls

The research showed that both water repellents and consolidants do improve the durability of mortar joints under the attack of acid rain. Water repellents, though, provide the better protection. Treatments (both water repellents and consolidants) may give a (short term) protection against the growth of algae.

A big difference was found in laboratory comparing the consumption of treatment products applied by capillary absorption (as is usual in case of small specimens of single materials) with that of products applied by spraying until they flow over the surface (as done in case of wallettes). Also a big difference in penetration depth was found, especially concerning mortar joints. These findings are important as they underline the difference that might exist between results of tests in laboratory and the performance in practice.

3.2.3 Test buildings

The research on the walls of test buildings meant for studying the effects of treatments confirmed the above mentioned results showing that:

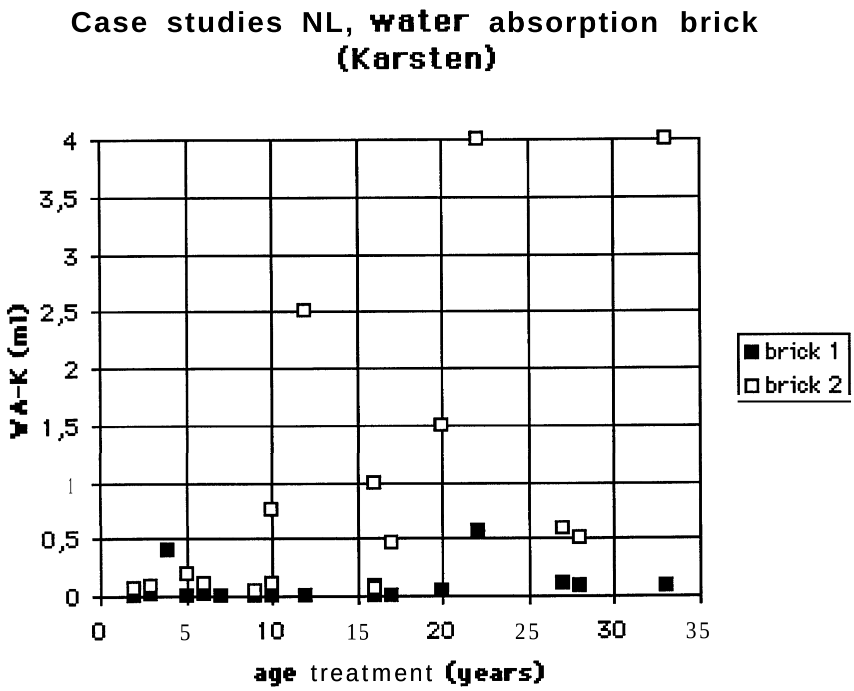
- the way of application of treatment products can affect their penetration depth;
- decay related to rain penetration can take place when pointing is not treated:
- in the case of repointing, the new material should also be treated;
- the damaged (pointing) mortar should be maintained (repaired, substituted) before treatment, in order to avoid the occurrence of damage.

3.4 Performance and failure. Combination of field and laboratory research

The *effectiveness* (water repellency) of a treatment can last for a long time, even more than 30 years (see fig. 1). To this conclusion the following should be added:

- there is no clear relation between the age of the treatment and its effectiveness;
- the effectiveness of the treatment within one building, even within one wall is quite variable;
- the mortar joint is, from the point of view of water penetration, the weakest part of the (treated) system.

Although treatments have in general only a limited influence on vapour diffusion, their influence on the drying behaviour of masonry is considerable. The drying behaviour of treated masonry was investigated in this research project as one of the aspects of the performance of the treatment. The impact of treatments on drying proves to be quite high. The importance is mainly shown in cases of water penetration (incl. rising damp, leakages..) where the slower drying behaviour may support the development of damage.



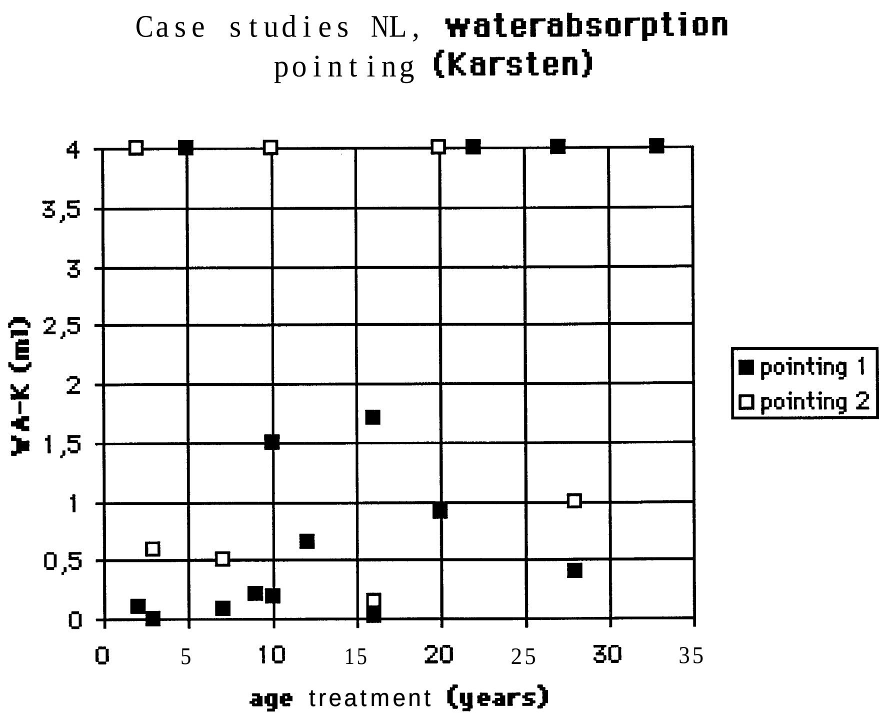


Fig. 1 Effectiveness of water repellents. Water absorption (Karsten pipe) on brick and pointing; best and poorest values for case-studies in the Netherlands, WA-K (ml)= abs. after 15 min. -/- abs. after 5 min., see [l].

Re-treatment of substrates (treated with a water repellent in the past) is possible. The first treatment has the highest influence on the drying behaviour. Only in case of the first treatment being a water based product, the next treatment was found to have a significant influence on the drying behaviour.

Failures and causes of failure were evaluated. Combining the results of the research in the field with those of the research in laboratory, the main causes of damage could be understood and the role of the treatment evaluated, see [2], [6]. Important results are:

- treatments play an important role in damaging processes such as salt crystallization and frost action: they may increase the damage to the materials or contribute to develop circumstances suitable for damaging processes to occur;
- treatments can not (always) offer protection against dry deposition attack: (black) crusts (gypsum) were found both in treated monuments and obtained in ageing tests on treated materials;
- the application method has an important influence on the effectiveness of the treatment: a different effectiveness was observed comparing brick and mortar joints; a low effectiveness of a treatment on mortar may explain water penetration through mortar joints of a treated wall;
- lack of scientifically based planning and lack of knowledge on the behaviour of treatments have serious consequences on the effects of treatments: in the case of repointing of a treated building, for example, if new pointing is not treated, the possibility of water penetration is almost equal to masonry not treated at all, which increases the risk of damage;
- the lack of knowledge on products available on the market is quite alarming. Products, of which the actual composition is not indicated, are put on the market as *reversible, natural, offering protection* to the materials, without affecting them, which responds to marketing strategies more then to the needs of the conservation of monuments. A method was developed to determine the type and origin of a product, applied in the past. This method allows to make a ‘fingerprint’ of the applied product which can be compared to that of known products.

4. Conclusions and recommendations

The knowledge on historical building materials and on conservation treatments possessed by the people involved in conservation, at all levels, needs improvement: local authorities and restoration architects and technicians (the responsible people in restoration campaigns) should be provided with thorough, but essential and clear guidelines on treatments (when, how to perform treatments). An important task for scientists is to make the results of their research available and applicable in practical situations for different groups of end users.

The main reason for an insufficient performance of treatments lies in most cases in the lack of preliminary investigations, meant to outline the state of conservation of a building and to furnish the basis for:

- deciding on the necessity of a treatment;
- selecting the most suitable treatment product.

'Golden rules' are proposed including the methodology to carry out an effective preliminary research, as well as guidelines to evaluate the obtained results in view of a treatment, and the clue to select the correct treatment product (when necessary).
The main points for correctly proceeding in treating monuments are summarised as follows:

- Pre-investigations should be carried out for evaluating the state of preservation of the monument, before deciding to use a treatment. The research should be centered on the definition of the type/s of decay present and on the diagnosis of the decay mechanisms leading to it/them (in particular: presence/sources of moisture, salts; ref. [3], [6]).
- In order to avoid confusion clear terminology and definitions to indicate damage should be used. Definitions should be preferably based upon existing sources like MDDS or Damage Atlas, that were developed in the EC project Expert system for the evaluation of the deterioration of ancient brick masonry structures (EV5V-CT92-0108), see [5], [7].
- A well balanced choice should be made on treating or not treating and eventually on the type of treatment. The decision should be based upon the results of the pre-investigation.
- Before treating, repair and substitution work (e.g. detailing, pointing, cracks; incl. leakages and rising damp) should be done, for a good performance of the treatment.
- The quality of products to be used should be guaranteed (for example through certification).
- The applicator should take into account the difference between brick and mortar and the possible consequences of the inhomogeneity of the materials.
- Restoration archives should be kept and maintained by the authorities. Archives should be accessible for all people dealing with the conservation of monuments.' Treatment should be considered an important intervention and therefore be documented in the restoration archive.
- Control (monitoring) and maintenance of treated masonry are necessary. In case of interventions like repointing, re-treatment needs to be done.

Future research
Several items were met that could not be studied in depth during the current project. The most important findings that need further investigation and meet a real need in building practice are given here:

- Algae growth, a problem that occurs even after treating masonry with a water repellent.
- Problems concerning mortar joints (loss of bond, pushing out, disintegration) are considered to be among the most budget consuming maintenance questions. Maintenance, repair and choice of material are a very important research item.
- Limits (quantity and quality) of salt content in relation to treatments.

Acknowledgements
This research was made possible by the financial support of the EU, DG XII (contract

nr. EV5V-CT94-0515) and was further sponsored by the Netherlands Governmental Service for the Preservation of Monuments and Historic Buildings (RDMZ) and Government Building Agency (RGD). Partners in this research project were: TNO Building and Construction Research (TNO Bouw) - Netherlands, co-ordinator; Royal Institute for Cultural Heritage (IRPA - KIK) - Belgium, contractor; Polytechnic University of Milan (PDM - DIS) - Italy, contractor; ICITE - Italy, subcontractor.

Non-destructive tests and computer methods applied to the conservation of historical buildings

A. Nappi
Department of Civil Engineering, University of Trieste, Trieste, Italy

Abstract
The problem of maintenance and recovery of historical buildings is addressed, by focusing on diagnostic methods and final check of restoring techniques. Basic issues and results are discussed, which are concerned with a research project supported by the *European Commission - Environment and Climate Programme* (Contract EV5V-CT92-0106). The project was centred upon the application of non destructive test methods, numerical models for structural analysis and parameter estimation techniques to be applied before and after the use of reinforcement techniques. A major objective of the work program was the definition of criteria and guidelines for an optimal choice of the most convenient experimental methods. To this aim, applications to real, practical cases (before and after treatment) were considered. Some emphasis was given to the Ground Probing Radar (GPR), to sonic measurements and to a new approach based on electromagnetic monofrequency waves (a technique that allows one to measure water content and to obtain tomographies suitable for checking grouting processes).

The problem of structural assessment was also discussed by considering system identification approaches, which are suitable for estimating material constants and for detecting damage processes. Further efforts in the context of computer methods were made to study and develop convenient numerical models for masonry.

Next, pseudodynamic tests on shear brick masonry walls were considered with the aim of studying the behaviour of injected materials and/or reinforcement techniques in the presence of time-dependent loads. Thus, a simple pseudodynamic testing procedure was developed and evaluated as a possible experimental method suitable for obtaining useful information on materials and on techniques aimed at monument rehabilitation, without any destructive or intrusive action upon the building.

Eventually, the following goals of the research programme were achieved:

- calibration of sonic techniques and GPR for monuments made of brick and stone masonry, with particular emphasis given to the evaluation of grouting processes
- use of monofrequency electromagnetic waves to detect moisture content and/or perform 2D- and 3D-tomography for the evaluation of grouting processes
- better knowledge of classical techniques and enhanced capability of combining different experimental methods in order to optimise their use
- development of a pseudo-dynamic testing procedure to evaluate injections and, in general, reinforcement techniques in the presence of time-dependent loads

Keywords: Cultural heritage, diagnostics, monitoring, non-destructive tests, numerical models, pseudodynamic tests, system identification.

1 Introduction

Non-destructive investigation techniques [1-5] are largely used because of the outstanding advantages they provide in many different fields, from quality check of industrial processes to medical applications, from monitoring of structures to the control of environmental actions. In recent years a constant effort was made in order to exploit non-destructive tests for the conservation of monuments. In this area, they offer enormous benefits, since the structural behaviour can be continually monitored, the effects of environmental factors can be checked, the basic features of hidden parts can be explored and, to some extent, the mechanical properties of materials can be determined. Test data also represent an important support for numerical approaches applied to historical buildings, since they give information on the accuracy of numerical results (in terms of displacements, strains, vibration frequencies and so on). Experimental methods may also be combined with system identification procedures [6-12] and provide optimal values of unknown parameters.

The consciousness of the above issues and the wide-spread interest in non-destructive testing techniques are also reflected by an impressive effort made by the European Commission in order to encourage research projects largely focused on the use of non-destructive experimental methods [13]. One of these projects, coordinated by the author, was explicitly devoted to non-destructive tests, numerical models for structural analysis and parameter estimation algorithms to be applied before and after the use of reinforcement techniques. A comparative study of non-destructive investigations was performed with the aim of establishing criteria and guidelines for an optimal choice of experimental methods applicable to the conservation of our architectural heritage. The work program was largely based on practical cases and several *in situ* tests were performed in France and in Italy, by utilising electromagnetic methods, sonic measurements and flat jacks (devices that give useful information on elastic constants and local stresses in masonry structures). New experimental techniques that make use of electromagnetic monofrequency waves were also studied and developed, with the aim of measuring water content and obtaining two- or three-dimensional tomographies, which allow for a critical evaluation of grouting processes [5,14].

The project was also centred on numerical models for brick masonry (accounting for damage and plastic strains), on system identification approaches and on a simple pseudodynamic testing procedure, applicable to masonry shear walls and suitable for checking injections and/or reinforcement methods subject to time-dependent loads [15].

2 Seismic methods

Most of the experimental activity was concerned with sonic measurements and electromagnetic techniques. These methods are derived from geophysics and, in general, provide information about the space distribution of a physical quantity (sonic velocity, dielectric permittivitty and so on). Unfortunately, a direct relation with mechanical properties can hardly be found, in spite of some successful applications of sonic tests that provide some correlation between sonic velocities and stiffness parameters. In any case, geophysical observations clearly describe the general features of the observed objects at a cheap price and without any damage, suggesting optimal locations for further, partially intrusive investigations (such as endoscopy and mechanical tests on cores). As obvious, the performance of each method highly depends upon the specific application and is controlled by several parameters. Thus, a major goal of the research project discussed here was to compare different techniques when applied to different practical situations encountered with historical buildings.

In the case of sonic tests travel times of seismic waves across a medium are measured. Measurements of this kind straightforwardly provide average velocities of the seismic waves, because the distances between transmitting and receiving devices are known. In this way a sort of average information is obtained, that depends upon physical properties of the media encountered by the wave along its path. Therefore, when average seismic velocities are mapped, inclusions or areas characterised by damaged materials can be detected. It is possible to enhance the method by means of two- or three-dimension tomography [16-18]. In this case, the information given by several measures of travel times provides a detailed map of velocities inside the wall. Essentially, hundreds of rays (paths followed by the seismic waves) are determined by using several receivers for each source. Next, velocity distributions are estimated by means of convenient algorithms. Typical output maps are obtained by using different colours (or different shades of grey) and by relating colours to velocities. A significant application is shown in Figure 1, where sonic velocities (as measured before and after injections) are reported with different colours. Measurements were taken at a pillar of the bell-tower of Chioggia Cathedral (near Venice, Italy). Data reported in Figure 1 refer to a cross section of the pillar. The effect of injections can be clearly noted as white areas correspond to higher velocities, which denote a decrease of voids.

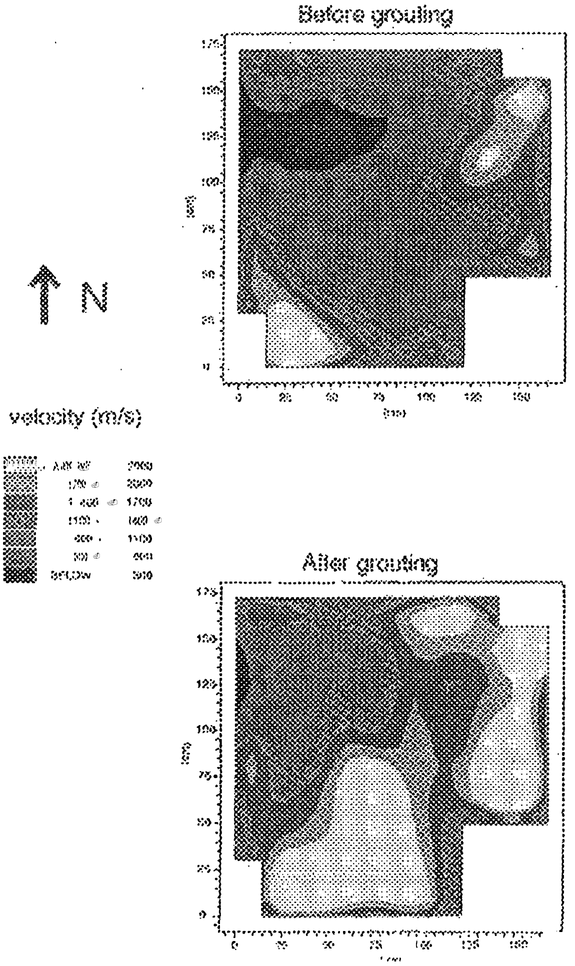

Fig. 1 - Sonic tests performed by LCPC, Centre de Nantes, before and after grouting [5]

3 Electromagnetic methods

Electromagnetic waves can also be considered for investigating hidden areas, since their propagation inside a medium also depends upon physical properties. Experimental tests on monuments are usually performed by using frequencies in the range between some hundreds MHz to 1 GHz. Waves are generated by means of specific antennas. When the so called reflection mode is used, the same device acts both as transmitter and as receiver, while the so called transmission mode requires a second antenna (receiver).

Probably, the most popular device that makes use of elecromagnetic waves is the Ground Probing Radar (GPR), originally developed for geophysical applications. It can be used in the transmission mode. The measured quantities are the velocities of short electromagnetic pulses, whose travel times depend upon electromagnetic properties of the medium (such as permittivity or conductivity). It can be applied to homogeneous structures and provides information about the presence of inclusions and/or different materials. Since large areas can be explored in relatively short times, it is an excellent non-destructive technique suitable for detecting potentially critical locations, where further investigations (e.g., sonic measurements) or samples for mechanical tests may be needed. Depth penetration is about 1 m with brick masonry and a few metres with stone structures. The GPR method can also be used in the reflection mode. In this case, pulse echoes reflected on heterogeneities are detected. The technique is useful to find fractures and inclusions. It is usually effective if the depth is less than 1 m with brick masonry, while a few metres are possible in the case of stone structures. Results are mostly presented by using profiles in pseudocolours (with different colours corresponding to different electromagnetic velocities). An application is shown in Figure 2, concerned with a stone wall at the Castle of Vincennes (Paris). The length of each thin (essentially vertical) line is proportional to the travel time needed to cross the medium and come back. The straight, thick line at the top corresponds to the surface along which the antenna is moved, while the thick lines underneath correspond to the end of the wall. Travel times are similar and show a homogeneous zone.

One further, possible application of electromagnetic waves in the so called transmission mode consists of using monochromatic (monofrequency) waves rather than pulses In this case, the measured quantity is their attenuation. The technique is applicable to homogeneous structures and allows one to detect moisture [5], to evaluate the global homogeneity of a medium and to define convenient locations for drilling cores. During the development of the project, monofrequency waves were used in Venice (Scuola Grande di S. Rocco) in the presence of high levels of moisture, since a wall facing a canal was tested. Measurements showed an excellent correlation between higher attenuation and higher levels of humidity at locations close to the canal. Another set of tests was carried out in the framework of the project at Padua (bell-tower of Santa Giustina's Church), where monofrequency waves were used before and after injections. Next, tomographies were obtained (cross sections fully analogous to the ones shown in Figure 1). Also in this case the performance of the method appeared quite good, since a lower attenuation (and, hence, a reduced presence of voids) was found after grouting.

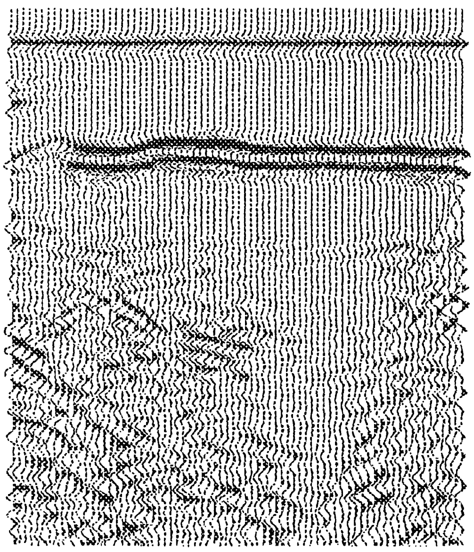

Fig. 2 - GPR tests performed by LCPC, Centre de Nantes [5]

4 System identification

System identification plays a major role in the conservation of historical monuments, since it provides optimal values of unknown parameters that characterise a system. Such parameters may be concerned with the global response of a structure (such as elastic constants and/or damping factors), with local effects (such as damage phenomena) or with the nonlinear behaviour of materials (such as yield limits and/or hardening moduli). Optimal values of unknown parameters are found by minimising the difference between the response of a structure to a given input and the response (to the same input) computed on the basis of a discrete model. Thus, the solution of the problem requires a close interaction between numerical modelling and non destructive tests. Both deterministic and statistical approaches can be followed. The second approach takes into account error measurements, uncertainty concerned with initial parameter estimates (as suggested by previous experience) and uncertainty concerned with final parameter estimates (after applying the parameter estimation procedure).

Two problems were considered during the development of the project and were solved by using a Bayesian approach, so that error measurements and *a priori* knowledge were accounted for. The first problem was concerned with material characterisation and Young's moduli were estimated. An iterative procedure [19] was needed, since the problem is nonlinear. The approach was explored by testing a brick masonry shear wall. First, some severe damage was induced by means of cyclic loads. Next, the wall was reinforced by injections. Parameters were estimated before and after injections. Numerical results were supported by the outcome of sonic measurements, that showed a satisfactory agreement between higher stiffness parameters and higher sonic velocities. The second problem concerned with system identification was centred once again on the estimate of stiffness parameters, but vibration frequencies were assumed as measured data. Also in this case a Bayesian approach was followed [20] and parameters were estimated for the bell-tower of Chioggia Cathedral.

5 Pseudo-dynamic tests on masonry shear panels

The project presented in the paper was also concerned with pseudodynamic tests on masonry shear walls. Thus, a test procedure was investigated, which is suitable for inducing damage by using a standard load history (a sort of pseudo-random sequence of external actions). In this way different structural components may be subjected to repeatable time-dependent loads and their behaviour can be studied in an objective way before and after injections or reinforcements. In our case loads were applied by using the El Centro record (1940) and by imposing different values to the peak ground acceleration, say a_{max}. Both unreinforced and reinforced walls were tested by using a simple steel frame suitable for applying compression and shear loads to mason& walls by means of two vertical screw jacks and one horizontal screw jack (*cf.* Figure 3).

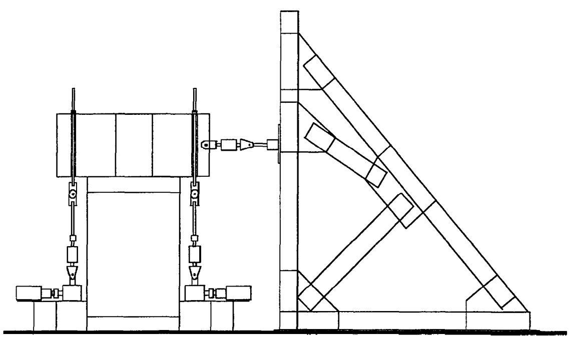

Fig. 3 - Test rig (University of Trieste)

As typical with this kind of tests, experimental and numerical methods were combined. Indeed, by considering a certain ground acceleration record and by assuming one mass located along the upper edge of the wall, the classical equation of motion for one-degree-of-freedom systems was solved: $m\,a + c\,v + r = f$. Here, m is the mass, c the damping parameter (to be properly selected), a the acceleration, v the velocity andf the applied horizontal force. The parameter r represents the force that would occur if a given displacement were imposed in a quasistatic way. Note that r depends upon the current stiffness of the system and is often unknown in many practical cases concerned with damage processes. For the numerical solution of the governing equation, the time history was divided into a convenient number of steps and, at each step, displacement increments were found by using an explicit algorithm (that is, on the basis of the values attained by acceleration, velocity and displacement at the beginning of the current step). Of course, at the beginning of the first time interval both the displacement and the velocity are zero, while the acceleration a is equal to the ground acceleration. In any case, when the displacement at the end of a given time step has been computed, it is imposed to the specimen under test and the reaction r is measured by using a load cell. Next, by introducing the input force f=$m\,a_G$ (where a_G is the ground acceleration at the end of the current step), the velocity and the acceleration at the end of the time interval can be found.

Here, some results are reported that clearly show some damage induced by the testing procedure and the effectiveness of injections utilised for the deteriorated specimen. Figure 4 gives displacement vs. time plots related to five pseudodynamic tests (a_{max}=0.8 g). The plots show a significant decrease of stiffness at the end of the test sequence. Figure 5 gives similar plots for the same wall after injections. It is quite clear that no significant damage is caused by the sequence of tests and that the reinforced wall features a much better behaviour.

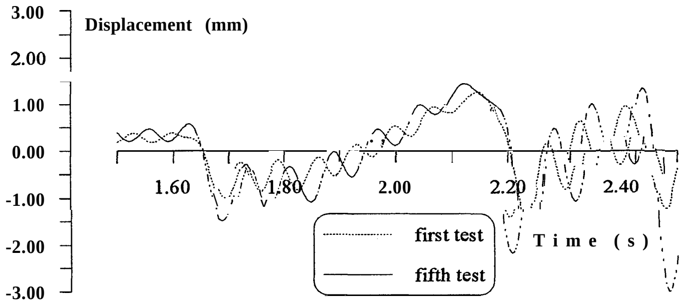

Fig. 4 -Displacement vs. time plot concerned with pseudodynamic tests

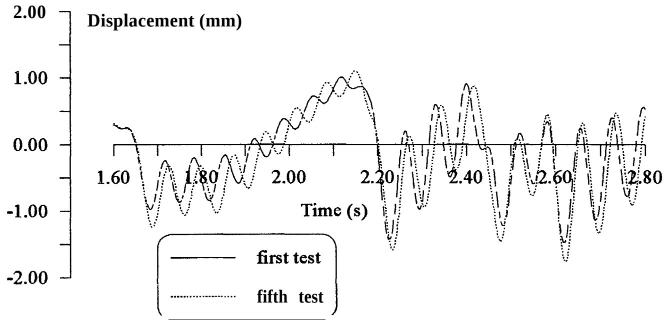

Fig. 5 -Displacement vs. time plot concerned with pseudodynamic tests (reinforced wall)

6 Closing remarks

The project presented in the paper (and supported by the *European Commission - Environment and Climate Programme)* gave the opportunity of investigating several non-destructi.ve techniques suitable for historical monuments. Classical and innovative applications could be explored, with particular emphasis given to the potential advantages provided by the combined use of different test methods. Significant applications were considered including monitoring procedures, evaluation of reinforcement techniques and diagnostics. A key feature of the project (and a major issue of the guidelines suggested by the project itself) is the interaction among different experts, such as geophysicists, architects and structural engineers.

Some emphasis was given to the application of seismic and electromagnetic methods to masonry, which is a complex material (owing to anisotropy) and is often present in historical buildings. Further interest is given by a case study concerned with a monument located in Venice, where unique environmental conditions provide a significant benchmark both for traditional techniques and for innovative methods (such as the one based on monochromatic electromagnetic waves).

Non destructive inspections based on electromagnetic waves and sonic measurements had a major role during the development of the project because of the high current interest and because of the need of investigating new potential applications. It is clear, however, that further, well established techniques (such as endoscopy, thermography and so on) may also be used when they appear to be useful and/or when their application is suggested by seismic or electromagnetic methods. Indeed, these non-destructive methods may also call for partially intrusive investigations (such as mechanical tests on cores) and/or system identification procedures (aimed at material characterisation and/or damage detection and/on monitoring).

A major problem raised by monuments is concerned with the implementation and enhancement of numerical models for structural analysis. For the sake of brevity this issue is not discussed here, but some emphasis was given throughout the project. In addition, the importance of strong interactions with non-destructive inspections was stressed, since efficient discretisations require accurate information on materials and properly selected experimental data for a reliable check of numerical results.

Finally, a simple pseudodynamic testing procedure was developed, since it may be convenient for some special purposes, such as a careful check of injections and reinforcement techniques in the presence of time-dependent loads.

Durability of cracked fibre reinforced concrete exposed to freeze-thaw and deicing salt

E.J. de Place Hansen
Dep. of Structural Engineering and ‘Materials, Technical University of Denmark, Lyngby, Denmark

Abstract
The research project “Design Methods for Fibre Reinforced Concrete” is currently carried out in Denmark. The project involves studies of properties of fibre reinforced concrete (FRC) in fresh state and during hardening, calculations of FRC-structures, test methods and design tools for FRC-structures and finally durability of FRC-structures.

Durability studies are carried out by subjecting FRC-beams to combined mechanical and environmental load (chloride penetration, water uptake). Mechanical load is obtained by subjecting beams to 4-point bending until a predefined crack width is reached. A test arrangement is developed. The surface crack pattern is characterized using video-scanning and digital image analysis. Additional durability tests (freeze-thaw, water vapour diffusion, chloride permeability) and studies of pore structure are made on specimens drilled or sawed from FRC-beams after being mechanically loaded. It is the aim to identify important mechanisms for the effect of the fibres on the durability and the pore structure based on these studies.

The test programme involves three different concrete qualities, water-powder ratios of 0.5, 0.44 and 0.38 including both fly ash and silica fume. Both steel fibres (ZP, 0.4 vol%) and polypropylene fibres (PP, 1 vol%) are used as well as main reinforcement. Uncracked FRC-beams and beams without fibres are used as reference.

This paper presents results from exposure to combined freeze-thaw and deicing salt attack on concrete with water-powder ratio 0.38. The test emphasizes the need for a critical evaluation of the mix design and mixing methods when designing FRC-structures. The scaling is increased by a factor 5 to 10 when adding fibres to the concrete while the air content is below 4% by volume. The variation of the scaling increases when adding fibres. The larger the crack width of a mechanically induced crack the less scaling at freezing.

Capillary water uptake in uncracked specimens of FRC was 20-30% higher at 1°C than at 20°C for both ZP- and PP-fibres, while the temperature had no effect on the water uptake in plain concrete. Studies of the pore structure must be made to clarify the relation between scaling at freezing, water uptake and fibres.
Keywords: Air entrainment, capillary water uptake, cracks, deicing salt, degradation mechanisms, durability, fibre reinforced concrete, frost resistance.

1 Introduction

The ability of fibres to arrest cracks and to minimize the extent of cracking and the crack width is the main item for the research project "Design Methods for Fibre Reinforced Concrete". The change of crack pattern is expected to improve the durability of FRC-structures compared with plain concrete. The background for this part of the project studying the durability of FRC-structures is described in [1].

In the laboratory the different degradation mechanisms are normally treated separately and in most cases no mechanical load is involved when materials are tested for durability. However, natural exposure of concrete structures consists of a combination of mechanical and environmental load (frost, chloride etc.). Therefore, in this project specimens are subjected to combined load.

The main goal of the durability studies is to indicate whether fibre reinforced concrete exposed to a combination of mechanical and environmental load is less or more durable than concrete without fibres. Secondly, it is the aim to identify important mechanisms for the effect of the fibres on the durability. An overview of the research programme is given in [2].

This paper describes freeze-thaw and capillary water uptake tests, both intended for laboratory use, cf. Section 3. Investigations are made on cracked specimens after unloading (freeze-thaw) and on uncracked specimens (both methods), in order to investigate the effect of fibres and cracks. The capillary water uptake was applied after the freeze-thaw test to further analyse the effect of fibre reinforcement on the frost resistance. The concretes are compared with regard to frost resistance and water uptake.

2 Materials

The concrete referred to in this paper is named SA relating to the environmental class (more severe than aggressive). It has a water-powder ratio of 0.38 including both low-alkali sulphate-resisting cement (285 kg/m' concrete), fly ash (60 kg/m^3) and silica fume (on slurry basis) (24 kg/m^3). Fine aggregates (O-4 mm): 758 kg/m^3. Coarse aggregates: 535 kg/m^3 + 565 kg/m^3 (8-16 and 16-25 mm). Coarse aggregates are crushed rock. Air entrainment as well as plastizicers are included. Three different concretes were investigated: SA-0, SA-PP and SA-ZP, cf. Table 1. SA-0 is referring to a concrete without fibres.

Fibre	PP	ZP
Material	Polypropylene	Steel, hooked ends
Length	12mm	3omm
Cross-section	35 x 250-600 μm	d = 500 μm
Amount	1 .o vol%	0.4 vol%

Table 1 Fibres. Material, size, mount.

When adding fibres to the concrete mix a corresponding amount of coarse aggregates is removed. When adding PP-fibres also the amount of superplastizicer is adjusted and the amount of cement paste is increased 10% at the expense of coarse aggregates.

3 Test methods and test arrangements

Reinforced beams with dimensions 100x200x1150 mm are used as specimens. In the following the test setup for subjecting the beams to mechanical load as well as the methods for measuring the frost resistance and the water uptake are presented.

3.1 Mechanical load

A test setup has been developed to permit beams to be subjected to combined mechanical and environmental loads as described in [1]. Mechanical load is obtained by exposing the beams to 4-point bending, resulting in transverse cracks on the center part of the beam cf. [1]. The surface crack pattern is characterized using video-scanning and digital image analysis.

The beams were 5 months old at the time of testing. They were kept under water until they were loaded and crack widths were measured. The loading of the beams was carried out within 15 minutes. After unloading the crack widths were measured again and specimens for the freeze-thaw test were sawn fi-om the tensile side of the beams.

3.2 Freeze-thaw test

Every test consisted of four specimens from two different beams cast in separate batches. Three of the specimens were tested with one crack in the longitudinal direction of the specimen. One specimen was tested without cracks as a reference. The dimensions of the test specimens were 50x125x200 mm.

Testing was performed according to Swedish Standard SS 13 27 44 [3] at the Technological Institute in Taastrup. Before testing the specimens are covered according to Figure 1 and exposed to a 3 mm thick layer of 3% NaCl-solution, protected from evaporation with a plastic foil. The specimens are then exposed to freeze-thaw according to a specified temperature cycle [3]. After 7, 14, 28, 42 and 56 cycles the amount of scaled material [kg/m^2] is determined.

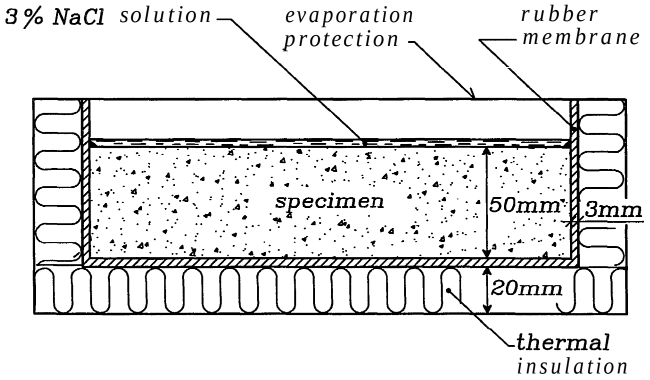

Figure I Test setup for freeze-thaw according to [3].

3.3 Water uptake

Capillary water uptake was applied on separate specimens after the freeze-thaw test to further analyse the effect of fibre reinforcement on the frost resistance.

Specimens were exposed to water using a RILEM method as described in [4]. The water uptake can be characterized by the amount of water, Q [kg/m^2], sucked up at the end of the test when the water uptake has almost ceased.

The water uptake tests are designed to study the effect of the temperature and the concentration of the salt solution. Tests are made at 20°C and 1°C with water or 3% NaCl-solution. Only the tests with water are treated in this paper.

Two 50x125x100 mm specimens from each concrete were prepared for each of the four exposure conditions. The specimens were sawn from the compression side of the beam, where no cracks are visible. Before the water uptake the specimens are stored at 50°C for 2 days and the vertical surfaces are sealed with paraffin wax to avoid evaporation.

4 Results

4.1 Freeze-thaw test

In Table 2 test results from the freeze-thaw test are shown as amount of scaled material [kg/m^2] after 56 cycles for all the specimens. Also the average crack widths [mm] measured in loaded state are given. After unloading the crack widths are reduced about 66%. In Table 2 the results are grouped according to the fact that specimens originates from two different batches.

SA-0		SA-PP		SA-ZP	
scaling [kg/m^2]	crack width [mm]	scaling [kg/m^2]	crack width [mm]	scaling [kg/m^2]	crack width [mm]
0.05 1	0.19	0.53	0.27	0.30	0.16
0.11	0.12	1.09	0.07	0.29	0.20
0.087	0.23	0.97	0.15	0.91	0.08
0.10	0	1.41	0	1.29	0

Table 2 Scaling after 56 freeze-thaw cycles and crack width in loaded state.

The development of scaling in [kg/m^2] during the freeze-thaw test is shown in Figure 2 (uncracked specimens) and Figure 3-5 (cracked specimens).

4.2 Capillary water uptake

Figures 6-8 show the average water uptake during two exposure conditions, cf. two different temperatures (20°C and 1°C) and pure water. Figure 9 shows results from an earlier study on water uptake at 20°C, [1].

5 Discussion

5.1 Freeze-thaw

According to Figure 2 and 3 SA-0 has a very good frost resistance since no specimen has more than 0. I kg/m² material scaled after 56 cycles. SA-PP shows a frost resistance on the border between acceptable and unacceptable and SA-ZP is characterized as acceptable (average value less than 1.0 kg/m² after 56 cycles). However, the results indicate that the scaling decreases when the crack width increases, especially for SA-ZP, cf. Table 2 and Figure 4. SA-ZP would be characterized as having a good frost resistance according to [3] if the upper two values in Table 2 originating from the same beam and with the largest crack widths are treated separately.

The fact that the specimens originates from different batches do not seem to explain the results. Neither the properties of the concrete in the fresh state nor the compressive strength after 28 days water curing indicates any differences between the batches.

While the concrete without fibres (SA-0) was designed for an air content of 5.5 vol%, the actual air contents measured in the fresh state by the pressure method were much lower: SA-0 4.2 vol%, SA-ZP 3 vol% and SA-PP 2.5 vol%. The results therefore emphasizes the need for a critical evaluation of the mix design and the mixing methods when designing FRC-structures. To be effective in relation to frost resistance not only the amount of air entrainment but also the stability of the air pore system is decisive.

Even when a satisfying air content is achieved (about 6 vol% for a concrete with water-cement-ratio 0.4-0.5) the PP-FRC normally behaves worse than plain concrete when tested according to [3] although it is having an acceptable frost resistance according to the test method, [5]. On the other hand, in more than one case it seems that the laboratory test has been to tough compared with experiences from natural weathering, [6].

In order to further analyse the freeze-thaw results it was attempted to investigate the effect of fibres on the durability of concrete by performing water uptake tests.

5.2 Water uptake

Comparing the results of the water uptake it seems that the water uptake in SA-PP and SA-ZP is dependent of the temperature and lower than in SA-0. The water uptake in SA-PP and SA-ZP is lowest at 20°C, about 30% lower than in plain concrete, based on the water uptake at the end of the test (145 h). At 1°C the water uptake is only 10-15 % lower than in plain concrete. This indicates that the addition of fibre reinforcement and a reduction of the temperature uptake has opposite effects on the water uptake. Normally entrained air will absorb water very slowly because of the size of the air pores Therefore differences in air content between the concretes can only explain differences in water uptake as measured within four days, cf. Figures 6-8, if the existence of fibres have a (negative) effect on the air pore system .

Only very few specimens are involved and the variation of some of the test series is quite large. Therefore the results has to be taken more as an indication of the effect of fibres and temperature on the water uptake. Actually earlier tests showed no effect of PP-fibres on the water uptake at 20°C as shown in Figure 9. 'The concretes had the same air content as in the current tests. Therefore it is necessary to study the pore structure of the concretes to encircle the mechanisms involved when FRC are exposed to freeze-thaw or water uptake.

5.3 Mechanisms

In an earlier study of the long term performance of FRC it was shown that the PP-FRC had a larger length deformation and a higher degree of micro cracking after freeze-thaw exposure than concretes with other fibres (steel, glass etc.). Analysis of surfaces of fracture showed unsatisfactory bond between fibres and matrix [7].

Compared to steel fibres PP-fibres have a lower bond strength to the cement matrix, [8] which could explain the higher scaling. During the freezing phase the pressure from the water could eventually loosen the PP-fibres from the matrix thereby open the material for more water and thereby accelerating the degradation.

If a PP-fiber has the possibility to loosen from the cement paste then a small canal can theoretically be created between the fiber and the paste. This is due to the fact that the thermal expansion coefficient of PP-fibres is ten times higher than for concrete ($100 \cdot 10^{-6}\,C^{-1}$ vs. $10 \cdot 10^{-6}\,C^{-1}$). However, a temperature change from 20°C to 1°C will only reduce the diameter of the PP-fiber with 0.2%. This reduction is much to small to explain the higher water uptake at 1°C compared with 20°C. On the other hand, canals could open the pore system and thereby increase the connectivity. The real problems in this argumentation are 1) why is the water uptake in SA-0 then even larger than in SA-PP no matter what temperature, 2) the hypothesis can not be applied to ZP-FRC since steel has a thermal expansion coefficient comparable to concrete.

6 Concluding remarks

According to the freeze-thaw tests the FRCs are less durable than plain concrete, primarily because the FRCs have a lower amount of air entrainment Addition of fibres reduces the crack width since the FRC-beams were subjected to 20-30% higher load than plain concrete before the freeze-thaw tests in order to achieve corresponding crack widths. PP-fibres results in higher scaling than ZP-fibres which can be related to lower bond strength between fibres and matrix.

The water uptake of FRC depends on thetemperature. At 1°C the water uptake is 20-30% higher than at 20°C. Only in concrete with PP-fibres this can be related to different thermal expansion coefficients between fibres and matrix. Therefore studies of the pore structure must be made to identify mechanisms for the effect of the fibres on the durability.

Further investigations should also include new freeze-thaw tests on concretes with comparable amounts of air entrainment to separate the effect of the amount of air entrainment from the effect of fibre reinforcement on the frost resistance. Finally, the repeatability of the water uptake results should be verified.

Hydraulic conductivity of combiliners in solid-waste landfills

R. Willocx, D. Van Gemert and J. Maertens
Civil Engineering Dept., Katholieke Universiteit Leuven, Heverlee, Belgium

Abstract

A combiliner is a combination of a geomembrane with a geosynthetic clayliner or a geomembrane with a layer of compacted clay or with sand-bentonite. The paper deals with the hydraulic conductivity or resistance of geomembrane/clayliner combinations. These thin liners are easier to apply, save space and are more economical. However, they are sensitive to local damages like fissures and pinholes, which might have drastic influence on the sealing properties, so that protection of the environment is no longer guaranteed. Since perfect contact between the clayliner and the overlying geomembrane is impossible, a small space exists between them. This space is called interface and its properties affect the water flow through a damaged combiliner.

A mathematical model for the flow through a damaged combiliner is based on the second order differential equation describing the flow. The flow depends on two important properties of the components: the hydraulic resistance of the geosynthetic clayliner and the transmissivity of the interface. They depend on several parameters: the effective compressive stress on the combiliner, the kind of leachate that is flowing, the hydraulic head,. . . Also the size and the shape of the flaw in the geomembrane influence the flow. This paper examines the influence of the compressive stress in more detail.

It presents a manner to derive the relationship between the compressive stress and the transmissivity of the interface. Therefore the differential equation is solved, using results of laboratory experiments. These experiments are carried out in large-size permeameters, at variable compressive stress levels on the combiliner. As a result of the calculations it will be possible to predict the transmissivity of the interface when the compressive stress is known.

This research is a preliminary phase in the construction of a complete mathematical model for the flow through damaged combiliners.

Keywords: clayliner, geomembrane, geosynthetic composite, hydraulic conductivity, pollution

1. Introduction

The hydraulic resistance levels of the bottom and top leakage protection systems of waste disposal sites in Flanders are prescribed in the Flemish Regulation for Environmental Protection VLAREM II [1]. Several systems are proposed to meet this requirement. This paper deals with combiliners (a combination of a geomembrane and a geosynthetic clay liner (GCL)). This cover system has several advantages in comparison to other cover systems. A thick layer of compacted clay (CCL), for example, does not serve its purpose in case of differential settlements or desiccation that cause cracks and loss of water tightness. The use of only a geomembrane as a cover system is limited because it is vulnerable to punctures. A geomembrane overlying a CCL protects the clay liner from desiccation from above, but differential settlements, punctures and the installation of the layer still cause big problems.

The major advantages of the use of combiliners (geomembrane + GCL) are [2], [3], [4]: an easy and rapid installation; a guaranteed quality, since the components are prefabricated; the clay in the GCL is bentonite, which has self-healing capacities in case of puncture; since the GCLs are thin (10 mm), more volume is available for waste [5]; the cover is rather easy to repair; both components can be anchored at the top of the site's slopes if necessary.

Disadvantages are [2] : potential slippage between both components; vulnerability to punctures; low shear strength of the hydrated clay.

The low shear strength of the GCL is improved by the 'needle-punching' system [4], [6]: the bentonite is sandwiched between woven and nonwoven geotextiles connected by fibre piles. This prestressing effect gives a higher shear strength and a capacity of self healing in case of puncture. Since the fibre piles prevent the vertical swelling of the bentonite, it can swell laterally in case of puncture which results in a self healing effect.

The major problem with combiliners is the fact that they are often damaged [7]. The causes of damage can be distinguished in three categories: mechanical causes (differential settlements, vehicular traffic during installation, punctures from underlying waste, creep,...); biological (by burrowing animals) and chemical damage (reactions with leachate, ultraviolet light, aging,...); damage due to improper seaming during construction [7], [8], [9].

Because of potential damage composite action between the geomembrane and the GCL is required to guarantee a cover with a sufficiently high hydraulic resistance. However, this resistance no longer goes to infinity, because the absorption capacity of the composite is limited. The question to be answered is: what is the remaining hydraulic resistance in the short and long run of a damaged combiliner and by what is it affected?

The development of a mathematical model for the flow through a damaged combiliner requires results of permeability tests. These tests are carried out in large-size permeameters.

2. Mathematical model for the flow through a damaged combiliner

A damaged combiliner can be modelled by three layers (Figure 1): the overlying geomembrane (with a flaw), the GCL and the interface between them. This layer is present because perfect contact between the geomembrane and the GCL is impossible (wrinkles in the geomembrane, irregularities between the geomembrane and the GCL,...[8]).

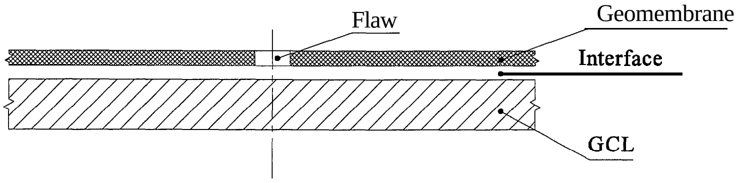

Fig. 1: Model of a damaged combiliner

When water flows through the flaw in the geomembrane, lateral flow occurs in the interface, with simultaneous infiltration into the GCL. This leads to the model shown in Figure 2. The amount of water that flows through the combiliner depends on the

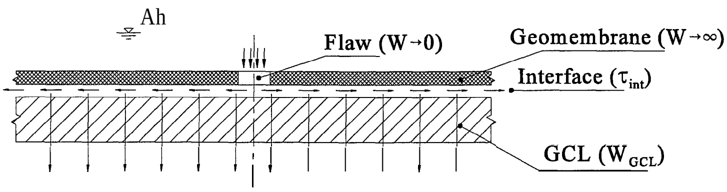

Fig. 2: Model of the flow through a damaged combiliner

hydraulic properties of the components. These properties are not constant, but depend on the conditions in situ. It is necessary to investigate the influence of these conditions on the effectiveness of the cover system. The components of the model will be described hereafter. The factors affecting their properties are pointed out.

The upper layer is the geomembrane. Ideally its hydraulic conductivity is zero, but because of damages and improper seaming flow is possible. The flaws are considered to be perfectly permeable. This means that there is no loss of hydraulic head due to flow through the flaw [7], [8], [9]. The geomembrane itself is assumed to have a hydraulic conductivity equal to zero, which means that diffusive fluxes are not considered. However, permeation can be an important factor in some cases [S]. The type of geomembrane, the size and the shape of the flaw are parameters to be observed.

The GCL can be described by its hydraulic resistance W_{GCL}. W_{GCL} is defined by the ratio of the thickness d_{GCL} to the hydraulic conductivity k_{GCL}:

$$W_{GCL} = \frac{d_{GCL}}{k_{GCL}} \tag{1}$$

W_{GCL} depends on the compressive stress on the combiliner, the kind of leachate (dissolved ions, affecting the behaviour of the bentonite) and the hydraulic head on top of the GCE. Research in the Reyntjens Laboratory [10] resulted in a formula describing the relation between the mean effective compressive stress on the GCL σ_{GCL} (in kPa) and W_{GCL} (in days):

$$W_{GCL} = 1\,960 \times (\sigma_{GCL})^{0.491} \qquad (2)$$

This formula has been derived on the basis of a small number of experiments on Bentomat® GCLs. The leachate was tap water from the city of Leuven. The results of formula (2) are compared with results of other researchers. For σ_{GCL} = 9 kPa, [6] obtains k_{GCL} = 4.10^{-12} m/s for a Bentomat® GCL (thickness 9.4 mm). This means a hydraulic resistance of 27200 days. With formula (2) this would be 5765 days. Formula (2) seems to underestimate the hydraulic resistance. Comparison with [11] seems to confirm formula (2): for σ_{GCL} = 3 5 kPa, k_{GCL} = 1.1 0^{-11} m/s (W_{GCL} = 11574 days with d_{GCL} = 10 mm). Formula (2) gives for σ_{GCL} = 35 kPa: W_{GCL} = 11230 days.

The interface is modelled by its transmissivity τ_{int}. τ_{int} is defined as the product of the thickness d_{int} and the hydraulic conductivity k_{int} of the interface:

$$\tau_{int} = d_{int} \times k_{int} \qquad (3)$$

[12] shows that the transmissivity has an important effect on the flow rate through the combiliner, much more than the size of the flaw or k_{GCL}. It is clear that τ_{int} depends on the compressive stress on the combiliner, since this influences the thickness of the interface. Particularly this relationship is examined in the experiments presented in this paper. Other parameters are the amount and the type of bentonite in the interface, the type of geomembrane, the type of GCL (determines the type of geotextile), the water pressure, the presence of waves or wrinkles in the geomembrane and possibly the kind of leachate that is flowing.

The flow shown in Figure 2 can be described by a differential equation of the second order as a function of the water pressure in the interface (h_{int}) [8] (see also Figure 3):

$$r\frac{d}{dr}\left(\tau_{int}\frac{dh_{int}}{dr}\right) + \tau_{int}\frac{dh_{int}}{dr} - rh_{int}\frac{1}{W_{GCL}} = 0 \qquad (4)$$

τ_{int} and W_{GCL} are dependent on h_{int}. h_{int} itself is not constant for the whole interface: under the flaw h_{int} is equal to the hydraulic head above the combiliner (Ah), but further away from the defect h_{int} becomes smaller, until it reaches zero. This means that there is no difference in water pressure above and under the GCL. Figure 3 shows the variation of h_{int} with the distance from the center of the pinhole: $h_{int}(r)$. The distance at which h_{int} is zero is called the radius of the wetted area (R). Flow occurs only in the wetted area because only there hydraulic gradients are present: laterally in the interface and vertically on the GCL.

3. Required data

The differential equation (4) is given as a function of τ_{int}, W_{GCL} and $h_{int}(r)$. τ_{int} and W_{GCL} can be written as a function of the effective compressive stress on the components.

For W_{GCL} formula (2) is used. A similar expression is assumed for τ_{int} (with τ_{int} in m^2/s and σ_{int} in kPa) [13]:

$$\tau_{int} = a \times (\sigma_{int})^b \qquad (5)$$

In equations (2) and (5), σ_{GCL} and σ_{int} are no constants: they depend on the distance from the flaw, because $h_{int}(r)$ is not constant.

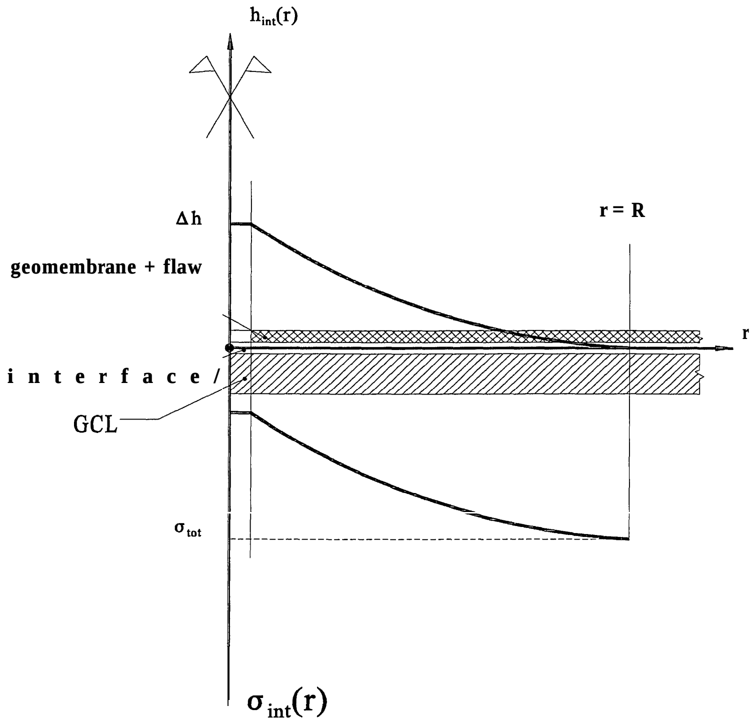

Fig. 3: The variation of h_{int} and σ_{int} in the interface

The unknowns in the differential equation of second order become a, b and $h_{int}(r)$. Since τ_{int} decreases when σ_{int} increases, b is assumed to be equal to -1 as a first approximation. To solve the-equation the real flow through the flaw should be determined experimentally.

4. Experimental program

The aim of the experiments is to measure the amount of water that flows through a damaged combiliner. Therefore, six permeameters with a diameter of 300 mm are installed in the Reyntjens Laboratory. These permeameters are equipped with hydraulic jacks to obtain the desired value of σ_{tot}. In this stadium of the research only the influence of σ_{tot} is being investigated, but further research will observe the other parameters (the size and shape of the flaw, the kind of leachate, the water head,. . ..).

The permeameter is shown in Figure 4. In this configuration water cannot flow along the edges of the geomembrane: the flow is forced to pass through the flaw. The GCL is smaller than the geomembrane, so that water can flow freely out of the interface. The measured amount of water is composed of the amount that has flowed through the GCL and the amount coming from the interface. The sum is equal to the flow through the flaw.

Since the GCE is hydrated before the measurements start, only the steady flow conditions are considered. This is a worst-case scenario: when the GCL is not saturated, flow in the GCL will lead to saturation and swelling of the GCL instead of flowing

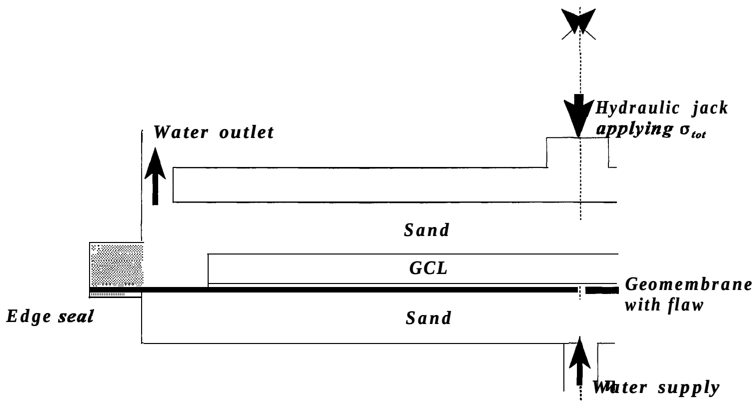

Fig. 4: Permeameter used in the laboratory

through it [14]. However, attention must be paid to situations where the GCL is hydrated with other liquids than water: the hydraulic resistance can be much lower in these cases [15].

5. Interface transmissivity

After installing the combiliner in the permeameter, loading and hydrating it, the measurements can be started. Measurements are continued until the measured water flow remains constant, indicating that the state of equilibrium for the given σ_{tot} is reached. σ_{tot} is then increased and measurements are continued until a new equilibrium is achieved, etc.

For each value of σ_{tot} the differential equation (4) can be solved, obtaining $h_{int}(r)$ and the coefficient a in

$$\tau_{int} = a \times (\sigma_{int})^{-1} \qquad (6)$$

Since σ_{int} is a function of r, τ_{int} also depends on r. A general value of τ_{int} is obtained by taking the area-mean value of $\tau_{int}(r)$: $\tau_{int\ m}$.

When $h_{int}(r)$ is known, $\sigma_{int}(r)$ can be calculated and an area-mean value $\sigma_{int,m}$ is obtained. By putting the values of $\tau_{int,m}$ in a graph with the representative values of $\sigma_{int.m}$, one can evaluate the dependence of $\tau_{int,m}$ on $\sigma_{int,m}$ (Figure 5). The data are fitted with a function of the form

$$\tau_{int,m} = c \times (\sigma_{int,m})^{d} \qquad (7)$$

The following values are obtained:

c = 2.30 10^{-10}

d = -0.71

These results are for a combiliner composed of a HDPE geomembrane with a thickness of 2.5 mm and a GCE with a thickness of 10 mm (Bentomat®). The flaw was a circular hole with a diameter of 10 mm, Ah was 1 m and the leachate was tap water.

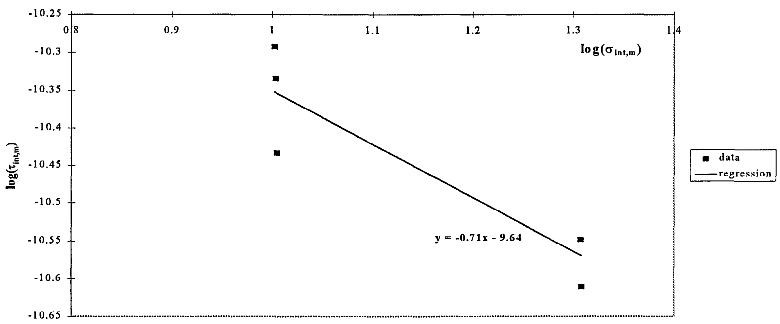

Fig. 5: $\tau_{int,m}$ as a function of $\sigma_{int,m}$

With this results, it is possible to predict the value of $\tau_{int.m}$ for a given value of the compressive stress on the combiliner. The flow through the combiliner can be calculated using the obtained value of $\tau_{int.m}$ in the differential equation (the reverse procedure). This leads to a mathematical model for the flow through a damaged combiliner.

This model is a model for a combiliner in a permeameter: the wetted area is as large as the GCL. In reality the wetted area is larger: [9] obtains values of R varying between 30 and 90 cm, depending on the diameter of the pinhole, k_{GCL} and Ah. If the aim is to make a model for a damaged combiliner under field conditions, it is necessary to take into account this important difference.

The value of d in formula (7) (d=-0.71) is in contrast with the value of b in formula (3) (b=-1). The latter one was just an assumption. The solution of the differential equation should be redone with b=-0.71 as a better assumption. An other remark is that this procedure is based on a limited number of preliminary tests. More test results are required to verify the values in formula (7). The application of it must be done with care, because a number of questions still have to be answered.

6. Conclusions

Solving the second order differential equation makes it possible to evaluate the transmissivity of the interface between the geomembrane and the GCL. The solution of the equation requires results of laboratory tests in large-size permeameters. A reliable prediction of the transmissivity in terms of the compressive stress can be made if enough results are available. The influence of other parameters will be investigated in coming research, leading to a model for the flow through combiliners. The results of this model can be compared with results coming from field measurements on combiliners. Such project is still in progress. The behaviour of a cover system for a waste disposal site with steep slopes (45 °) in Antwerp (Belgium) is investigated. The major problem with such steep slopes is the stability of the top layers. There is a relation between the stability of the cover and its water content [13]: a saturated layer is less stable than an unsaturated one. The failing of a drainage layer can endanger the stability of the slopes. A model for the flow through the cover system is useful in dimensioning the drainage layers and thus ensuring the stability.

Durability of Building Materials and Components in Agricultural Environment

B. Svennerstedt
Department of Agricultural Biosystems and Technology, Swedish University of Agricultural Sciences, Alnarp, Sweden.

Abstract

The agricultural environment has its main influence on floor surfaces in buildings and structures. The floor surfaces are exposed to a chemical and physical environment, which is very aggressive, because of different factors originating from manure, drinking water and feed stuff.

Floors and other building components of farm buildings show different degrees of degradation. Concrete material, which is often used in floors and walls need a high material quality to resist against the chemical and physical attacks.

This paper will present a brief review of recently performed research about durability of building materials and components in agricultural environment.
Keywords: Farm buildings, agricultural environment, durability, concrete material, wood material, steel material.

1 Introduction

In agricultural production one can roughly distinguish between the following types of farm buildings: 1) animal houses for cattle, pigs and poultry 2) slurry pits and silos for manure and 3) storage structures for agricultural products.

Farm buildings are built of different materials and components, such as concrete material (floor and foundation structures); concrete, steel or wood materials (wall structures) and steel or wood materials (roof structures).

The agricultural environment, both inside and otside farm buildings, is very aggressive. The biological activity in organic matter produces aggressive substances towards building materials as well as towards animals and persons. It is especially the chemical environment, which influences the building materials. Inorganic and organic acids, natural manure and different salts of artifical manure products have a great impact on the durability of building materials and components in farm buildings.

Research about durability of building materials and components in agricultural environment has been focused on concrete for agricultural purposes. Most of this research has been carried out at different institutes and universities in Belgium, Ireland, the Netherlands and Sweden. Within the organisation European Agricultural Engineers (EurAgEng) a working group (SG15/TG1) was formed in 1996 with the aim to put together performed research and plan for new research activities within this area of durability research.

This paper will present a review of recently performed research about durability of building materials and components in agricultural environment.

2 Agricultural environment

2.1 Animal houses

The chemical and physical environment of animal houses can be divided into two distinct parts: 1) the air environment and 2) the wet environment on floors, walls and equipment.

The *air environment* depends on a wide variety of influences, such as the characteristics of the housing system (layout and volume of the building, type of roof, thermal insulation, ventilation, handling of manure), the types of animals housed and the physical environment (sun radiation, temperature, air speed, relative humidity). There are a large number of gases in the air environment but most of them occur in low concentrations. The presence of manure also considerably influences the air environment.

Table 1 presents the recommended maximum concentrations of the gases in stables, which occur in the highest concentrations. Measurements of concentrations of ammonia and carbondioxide at floor level up to 0.3 m above floor level demonstrated the following [1]:

- NH_3 concentrations range from 2 – 50 ppm (yearly mean: 4 – 13 ppm);
- NH_3 and CO_2 concentrations are considerably lower during summer periods than in winter periods;
- the use of natural or mechanical ventilation has no significant influence on NH_3 and CO_2 concentrations. Too low ventilation rates cause an increase of especially the CO_2 concentration;

The content of dust from animal houses originates primarily from the animals, the fodder, the straw material and the manure.

Table 1. Recommended maximum concentrations of gases and dust in stables [1].

Gas /dust	Concentration
CO_2	3000 ppm
CH_4	500 ppm
H_2S	0.5 ppm
NH_3	20 ppm
dust	1.5 mg/m^3

The acceptable range of air temperature strongly depends on the type of animal housed Table 2 contains acceptable temperature ranges for housing systems. These temperatures are valid for a zone ranging from floor level to 0.3 m above floor level. The floor is assumed to be dry, not heated and made of concrete.

Table 2. Acceptable extreme temperatures in housing systems for animals [1, 2, 3].

Animals	Temperature [^0C]
dairy cattle, fattening bull	5 - 20
young cattle< 1 yr	10 – 24
pigs < 20 kg	23 – 33
fattening pigs	17-25
sows	12-25
broilers < 2 months	17 – 33
broilers	15-22
laying hens	15-22

The highest concentrations of aggressive substances are found in the wet *environment*t on the floors in animal houses. The wet environment consists of minerals and salts of different species. It has been concluded at analysing the chemical composition of manure and silage that the highest concentrations of chloride has been found in poultry manure, 0,34 % and the lowest has been found in cattle manure, 0,05 % [4] .

The wet environment on the floors in animal houses also consists of high concentrations of organic acids. It has been concluded at analysing the chemical composition of samples of organic matter from different places in houses for pigs, cattle and poultry, that there are concentrations of acetic acids up to 8 %. The acid concentrations seem to increase when the time for the fermentation process in the organic matter increases [4] .

2.2 Manure and silage storage systems

Three types of *manure* can be distinguished:

1. Liquid manure, which contains urine with a maximum dry matter content of 3%.
2. Slurry, which is a mixture of urine, faeces, feed residues and water. The slurry has to be regularly mixed to facilitate pumping from the storage. The dry matter content is 2-20%. Table 3 contains information on the chemical composition of slurry from three animal categories.
3. Solid manure, in which about 90-95% of the nitrogen is organically bound. This is only 30-50% and about 5% for slurry and liquid manure respectively [2].

Table 3. Chemical composition of slurry, in g/l [5].

Chemical component	Cattle	Fattening pigs	Laying hens
Nitrogen (N-Kj)	3.8 - 7.6	4.3 - 11.5	5.9 - 15.7
Ammonium (NH,-N)	0.2 - 4.4	1.3 - 5.5	2.6 - 9.2
Phosphate (P_2O_5)	1.3 - 3.1	3.6 - 6.6	0.3 - 12.0
K_2O	3.3 – 11.0	2.0 - 6.1	0.3 - 11.5
CaO	1.6 - 3.3	2.4 - 4.4	0.9 - 19.6
MgO	0.8 - 1.6	0.6 - 2.0	0.1 - 2.4
Cl^-	1.8 - 4.2	0.6 - 3.3	0.1 - 3.2
SO_4^{2-}	2.0 - 3.0	1.0 - 2.0	2.0 - 4.0
Acetic acid	5.5 - 7.0	3.2 - 11.0	11.0 - 22.0
Propionic acid	1.6 - 2.0	0.7 - 3.0	4.0 - 7.5
PH	7.0 - 8.8	7.3 - 8.6	6.7 - 8.3
Dry matter (% m/m)	7 - 9	4 - 11	11- 18

Most *silage* is stored on concrete, either in bunker silos (base slab plus walls) or on a base slab only. The dry matter content of fresh, compacted silage is about 18-24% . The quantities of silage effluent coming out of the fresh silage can be up to 200 1 per ton of silage (pressed pulp: 10-50 l/ton; maize: 50-100 l/ton; brewer’s grains: 100-150 l/ton; wet grass: 100-200 l/ton). The effluent produced during storage of e.g. grass and maize is drained towards the front of the base slab, collected and pumped into a slurry pit [6, 7, 8]. The pH value of the effluent can be 3.5 - 4, the main acids being lactic and acetic acid.

Fertilizer can also be stored on slabs. It may contain considerable amounts of nitrogen (up to 25%), phosphate (P_2O_5; up to 45%), potassium (K_2O; up to 60%), calcium (CaO; up to 55%), manganese (MgO; up to 25%) and sodium (NaO; up to 5%). In horticulture, liquid fertilizers containing e.g. Ca^{2+}, Mg^{2+}, K^+, PO_4^{3-}, SO_4^{2-}, CO_3^{2-} or NO_3^- are increasingly being used [9].

Potatoes are stored at temperatures of about 5 ^{0}C and treated with fungicides containing acids or chlorides. Germination retardents contain chloride. Resistance against mechanic loading, for instance by loading by lift trucks, should be taken into account.

3 Durability of Building Materials and Components

3.1 Floor Structures

In animal houses there are three main types of floors; solid floors, unperforated floors that are laid directly on the ground and slatted floors, which permit drainage of urine and faeces from the animals [10] . The major advantages of slatted floors are the complete omission of straw and an appreciable reduction in labour time requirment for cleaning of the floor. The animals are cleaner because of the fast removal of the manure and areas of possible reduction in the immediate vicinity of the animals are eliminated [1 1] .

These floor types are all made of concrete material. The solid and unperforated types are mostly made of ready mix concrete but the slatted types (slatted beams and cassettes) are mainly made of precast concrete. In 1991 work was started to establish an European standard [12] for slats, such as single beams, twin slats, multiple slats and perforated panels. The standard classifies the slats according to cattle on one hand and pigs, sheep and goats on the other hand. Requirments are given for concrete compounds, concrete strength, concrete quality, position of the reinforcement, floor slats geometry and surface characteristics.

According to the european standard the demands of the concrete quality for floor slats are that the water/cement ratio should not exceed 0,45 and the cement content should not be less than 350 kg/m^3 at a concrete cover ≥ 40 mm.

Degradation

Several field investigations have shown severe degradation on concrete slats [13, 14] .The degradation of the concrete material is due to the aggressive environment on the floors in the animal houses. It has been concluded that there are three main degradation mechanisms; the influence of the organic acids as lactic and acetic acid, the reinforcement corrosion and the mechanical wear.

Most of *the organic acids,* especially acetic acid come from the manure. The lactic acid originate from acidified meal/water mixtures and is therefore the main source of severe concrete degradation near or in between the feed and water supply.

Lactic and acetic acid are very aggressive, because their reaction with free lime of the concrete produces very soluble calcium salts [15] . When those salts are leached, the concrete porosity will increase and the pH in the pores will decrease. Following factors, besides water/cement ratio and cement content, influence on the degradation of concrete by lactic and acetic acid; 1) cement type, 2) aggregate type, 3) addition of fly ash or silica fume, 4) addition of polymers, 5) application of cement-bound surface layer and 6) impregnation.

Reinforcement corrosion is an important degradation mechanism for floor slats of concrete material. High concentrations of carbondioxide in dairy farms may give rise to carbonation of concrete slats. In general the risk of chloride initiated corrosion in floors is higher than the risk of carbonation initiated corrossion because of the high cloride content found in floors of farm buildings [13] . The high chloride content may arise from manure and feed residues and sometimes from accelerators used in the concrete.

Mechanical wear occurs on floors in animal houses. Because of the mechanical wear the floors of animal houses may become too slippery, which may result in paw disorders. It has been suggested a concrete floor with a regular hexagonal pattern in order to improve the slippery safety [16] .

3.2 Wall Structures

Farm buildings are mostly designed as industrial buildings with structural systems of stone, brick, timber or steel material. Structural systems of stone or brick in old farm buildings are covered on the inside and outside by painted plaster systems. The structural systems of timber and steel are usually covered by wood fibre and hardened gypsum boards or steel sheets, when new buildings are designed.

The equipment inside animal houses often consists of steel, zinc and aluminium structures combined with wood fibre and cement based boards. The equipment is often made of bad quality because it will rather often be changed depending on the animal production.

Wall structures of manure and silage storages are mostly made of concrete material. Especially wall structures for silage storage structures are often painted on the inside as environmental protection.

Degradation

Field studies of corrosion in houses for fattening pigs have shown severe attacks on the lower parts of the equipment (Figure 1). The massloss has been measured to 200 and 50 µm/year for steel and zinc structures respectively. Corrosion attack on aluminium structures are very severe in pig houses on those points where manure and feed have gathered.The attacks are not spread evenly over the material surface but are concentrated on special points [17].

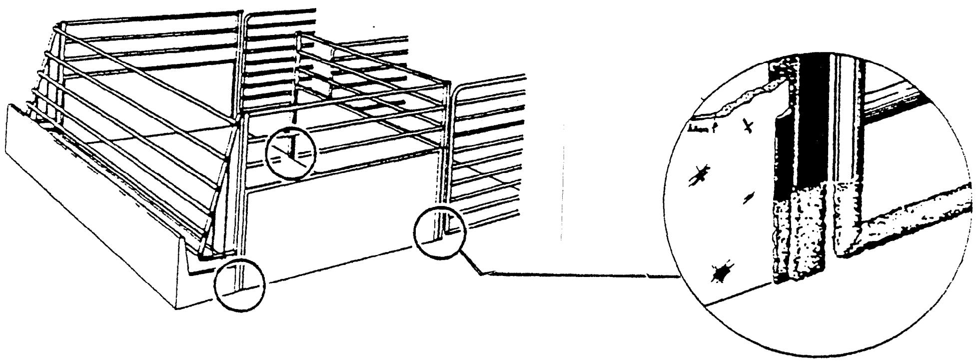

Figure 1. Example of building components in pens for fattening pigs with high risk of corrosion [17].

Micro biological corrosion may occur in agricultural environment. Such corrosion occur under anaerobic circumstances and neutral pH-values. The cause is mainly sulphate reducing microbes. Steel structures for covering manure tanks have been exposed to this type of corrosion [18].

Timber walls in farm buildings are protected against biological degradation by constructive design and by applying chemical preservatives. The recommendation is to design against degradation before using wood treated with chemicals.

Fungi are the biological degradation that cause most damages in farm buildings. It is the decay producing fungi that are worst because they reduce the strength by removing lignin and cellulose [19].

3.3 Roof Structures

Today steel compete hard with timber as a structural material for roof structures of farm buildings. Principally the roof construction consists of either beams supported by hinged or fixed posts or rafters supported by posts in combination with girders. In farm buildings post and beam timber structures range up to 25-30 m span and they can be very cost effective for spans between 7 and 20 m [19] .

The ceiling constructions can be an insulated ceiling with wood-based panels or spaced boardings as cladding material. A breathing ceiling with air inlet through the insulation is comfortable when spreading the air into the pens. Insulated parallel roofs of self-supporting elements are effektive to create good air volumes for the animals. Uninsulated roofs are usually made of steel sheets or glas fibre board sheets.

Degradation

Degradation of roof structures in animal houses mostly concerns the inner surface of insulated ceilings. Because of high air humidity the unpainted steel sheets corrode very fast. Unpainted steel sheets also-corrode very fast on the surface faced to the outside climate.Wood-based panels often show mould on the inner surface of the ceiling.

4 Discussion

The environment in buildings and structures used in agriculture consist of many different factors. There are handled large amounts of organic material such as different feed stuff and manure, which leads to high biological activites especially inside animal houses. The micro biological activities cause creation of organic acids. Inside animal houses high humidities and varying temperatures often occurs.

Because of the aggressive physical and chemical agricultural environment building materials and components deteriorate very fast and this is very costfull for the agricultural sector. This is a major problem concerning the durability of building materials and components in farm buildings.

In the future it is important to investigate the chemical and physical environment more intensively in the most exposed places of farm buildings. This knowledge can be used as a tool at choosing material and components with prolonged durability.

5 Conclusions

The agricultural environment has its main influence on floor surfaces inside farm buildings. The floor surfaces are exposed to a chemical and physical environment, which is very aggressive, because of different elements originating from manure, drinking water and feed stuff.

Floors and other building components of farm buildings show different degrees of degradation. Concrete material, which is often used in floors and walls need a high material quality to resist against the chemical and physical attacks.

Upgrading the use of recycled aggregates

R J Collins
Building Research Establishment, Watford, UK

Abstract
Use of crushed concrete and masonry in the UK is mainly for lower grade applications and its resource potential (as measured by its position in the marketplace) is frequently undervalued. In recent years there have been moves to demonstrate its wider potential eg in ready-mixed concrete for the new Environmental Building at BRE. This paper describes progress in collaborative programmes with UK industry to improve guarantees of quality for use in concrete blocks, precast concrete, and by the introduction of a pilot scheme for quality control. This paper also introduces new work to improve the availability of information and in particular the establishment of an internet-based materials information exchange. This is designed to be attractive by being simple, quick and self-maintaining.

Concrete blocks were made with up to 75% recycled aggregate on a full-scale industrial plant and tested in beam-and-block test floors. All performance indicators were exceeded by a very wide margin. With regard to precast concrete, no effective difference was found in initial tests with the replacement of up to 20% of coarse aggregate or 10% of fine aggregate with reclaimed product. Quality control of recycled aggregates for these construction products should not need to be very onerous - with floor infill blocks because of the massive safety margin, and with reclaimed product in precast because this is already a much better controlled source than demolition waste. The prospect for some utilisation of fine recycled aggregates in higher-grade applications is considered possible both in the precast application and for cement manufacture.
Keywords: cement, concrete blocks, demolition, flooring, internet, precast, quality control, readymix, recycled aggregates

1 Introduction

Worldwide demand for aggregates is on an increasing trend and long-term projections indicate that the UK is no exception. As in the UK, there is an increasing commitment to the principles of sustainable development, with an emphasis on the need to make greater use of waste and recycled materials and use primary aggregates more efficiently. Although waste and recycled materials already account for about 10% of the aggregates used in the UK, there is a considerable potential to increase this level of usage and it is UK Government policy to promote this where this furthers aims of materials conservation and environmental protection.

Many countries, including the UK, already have a substantial use of recycled aggregates in road construction, where fairly large quantities of low-specification aggregates have traditionally been required. While attempts are being made to increase this usage in the UK, it must also be borne in mind that the construction of new roads on virgin land is not a sustainable activity and that already this is losing its importance with respect to road maintenance and the construction of high-speed rail networks and urban transit systems. All of these activities generally require a greater proportion of materials produced to higher specifications. It is against this background, and the decreasing availability/increasing cost of landfill, that efforts have been made towards putting in place higher-grade outlets for recycled aggregates.

2 Specifications for recycled aggregates

European standards for all types of construction aggregates are currently being prepared and are intended to include the use of recycled aggregates, provided, of course, that they meet performance requirements for the intended end-use. An ad hoc group of the relevant Technical Committee (TC 154) has prepared a technical report on the specification of recycled aggregates from which specification clauses will be drafted for inclusion in the product standards. Unfortunately this will not be ready in time for the projected implementation date (the year 2000) for the first package of aggregates standards. Thus implementation of European (CEN) specification requirements for recycled aggregates may have to wait for the first revision of these standards, or at least until amendments are issued.

Specifications for recycled aggregates in concrete prepared in the Technical Report of the ad hoc group for recycled aggregates are based on the RILEM Recommendation [1]. Additional recommendations made by the ad hoc group include additional quality control procedures - rates of testing, and very importantly, the input control of materials entering recycling plants.

3 Recycled aggregates in ready-mixed concrete

The RILEM Recommendation was used as a basis for the specification of recycled aggregates in ready-mixed concrete in BRE's new Environmental Building [2] and in the construction of a strong floor facility at BRE's Cardington Laboratory [3]. The use of this specification in conjunction with the British Standard for concrete (BS5328) had already been explored as a permissible within the UK Building Regulations as part of a study carried out by BRE for UK Government Minerals Planning [4]. Quality control procedures relating mainly to input control and frequency of testing were put in place for each of these projects.

A new project to assist a more general application of recycled aggregate in ready-mixed concrete has been started at BRE. This involves partnerships of demolition firms, recycling plants, readymix companies and clients. The clients in the first instance will be Local Authorities in which there are various pressures to promote recycling - these are applied by Central Government and relate to permissions for mineral extraction and the provision of landfill space. Naturally, Authorities in urban areas, particularly in SE England are under the greatest pressure. The aim of the project is to put in place quality control procedures to allow a more general use of recycled aggregates in higher grade applications. This may not just be for structural concrete, but could also be used, for example, for cement-bound sub-base materials in roads - a use which was introduced in the Highways Specification in 1991 [5], but not, as far as it is known, taken up.

It is intended that the quality control procedures will be backed up by a BRE Digest to be published in 1998. This Digest will bridge the gap between specifications as drafted for CEN and current UK practice.

4 Recycled aggregates in manufactured products

In the BRE study on specifications [4] another route for the application of recycled aggregates was identified and this is potentially simpler to implement. Manufactured products should be guaranteed by the manufacturer as fit for purpose. Thus, in principle, the quality control of any input of recycled material needs to be verified only by the manufacturer of the product. In practice, however, not all products are specified purely on performance and standards often contain both recipes and performance requirements. In these circumstances, proof may be required to the satisfaction of the user that a recipe can be varied without detriment to the product.

4.1 Concrete blocks

Another partnership project led by BRE has concentrated on the use of demolition waste in precast concrete blocks. The intended use for these blocks was for beam-and-block flooring systems. This was considered to be a fairly non-onerous end-use since there are no weathering requirements and the general experience with loading tests on floor is that the margins of safety are very large (at least a factor of 10).

Initial studies in this project were concerned with the requirements for recycled aggregates to be used in conventional blockrnaking plant. These plants rely on the free fall of materials in hoppers etc and thus a sufficient proportion of fines must be removed from the recycled aggregate to ensure that clogging of the plant does not occur. The grading of the recycled aggregates thus needs to be coarser than that needed to produce dense, well-compacted blocks. Some natural sand needed to be added to the recycled aggregate at the mixer ie it was not possible to produce good blocks containing 100% recycled aggregate with conventional plant. Blocks with up to 75% recycled aggregate could be made with no difficulty. (ARC Conbloc using materials supplied from Pinden

Plant & Processing). Floor loading tests were carried out by Kingsway Technology on blocks from 3 trial runs containing between 50% and 75% recycled aggregates. Beam-and block floors 2.9 x 3 metres were constructed for each trial run and finished with a 50mm thick 3:1 sand:cement screed which was left to cure for 28 days. Each floor required the use of 6 beams and 70 blocks. Floors were loaded centrally via a 100mm square plate. Results for ultimate load gave safety factors of between 33.7 and 39.0, and deflection was well within limits given in BS8 110 for the structural use of concrete.

4.2 Precast structural concrete

A further partnership project led by BRE in association with members of the Precast Flooring Federation, Leeds, Nottingham Trent and Sheffield Universities is concerned with the recycling of rejected precast elements within precast works. Wastage of concrete within precast works due to a number of factors such as breakage, poor compaction, malformation and off-cuts can sometimes approach 10%. Although some materials have been crushed and used as hardcore rather than landfilled, there would be further advantages if the material could be fed back into the production line. Use of reclaimed product in precast is already practised in some countries where this is allowed in the specifications. The challenge in the UK where current specifications preclude its use is to produce an industry code of practice/industrial standard that will be acceptable within the construction industry as a whole.

Trials are being carried out at 4 precast works, and initial tests on various levels of replacement should be complete early in 1998. Initial results indicate that there is little if any effect from the replacement of 20% of the coarse aggregate and 10% of the fine aggregate by reclaimed product. Reclaimed product is a purer and more consistent material than recycled aggregates from demolition waste and thus requirements for quality control are very much reduced. The incorporation of a small percentage of fine material without detriment also illustrates the purer nature of reclaimed product - most research workers have found the fine material from demolition waste to be too contaminated for very successful use in concrete.

When the use of reclaimed product in precast works is well established as routine within the construction industry, it may be possible to consider an extension to this practice. If buildings were "deconstructed" rather than "demolished" then precast elements could be retrieved and returned to the manufacturer for recycling.

4.3 Cement manufacture

Demolition materials can form a source of raw materials for the preparation of raw feed to cement kilns producing Portland cement. This forms part of a Brite-Euram project "Construction recycling technologies for high quality cement and concrete" led by the Spanish cement company Lemona of Bilbao with Labein also of Bilbao. BRE is part of the consortium which also includes work on concrete technology by Holzmann, Prüftechnik and BAM of Germany and Taywood Engineering (UK). It is hoped that cement manufacture will be able to cope with the higher level of pollutant found in the fines derived from crushed demolition material, and thus, together with the use of recycled aggregate in concrete, offer the potential of high grade applications for all size fractions.

5 Materials Information Exchange

One of the key restraining factors which prevents the more effective use of demolition materials and surplus construction materials is lack of timely information on arisings and information regarding potential construction projects or production processes where such waste could be utilised. A potential user of waste needs to know what waste is becoming available and when (or for how long), in what quantity, where, and what cost. Conversely, a producer of waste, whether construction, demolition or at a materials production site will ask similar questions in relation to potential disposal routes. Timely notification of material availability and future sources will facilitate advance planning and greater take-up of material.

In response to these requirements BRE, with support from the UK Department of the Environment, Transport and the Regions have developed an intemet-based Materials Information Exchange. This consists of four parts:

- A 'board' showing materials for free collection or sale, with text and menu boxes for nature of arising, quantity, location, cost and timing
- A category of unutilised materials, for example, over-ordered stock available
- A 'Materials Wanted' board with text and menu options similar to above
- An 'up and coming' demolition board to notify potential users of future sources.

The system is available to any operator who has an internet connection. In operation the exchange is not complex and relies on a series of predesignated 'click' boxes giving options relating to most of the details required. The operator generally only needs to input contact point of the supplier or user. The system will automatically search all input data to match the search commands. The time for both inputting and extraction of information is measured in seconds rather than minutes. Furnished with the contact information, the operator is then free to negotiate for the use of the material.

The Materials Information Exchange is designed to be self-maintaining and users are free to enter or extract information directly from the system without the need to contact a third party. The self-maintaining nature of this system means that there are no subscriptions or user fees. It is considered that the simplicity, speed and cost-free nature of the system will provide an attractive package to the industry and ensure take-up and use of the system. The address of the system on the internet is:

http://helios.bre.co.uk/waste

BRE are about to commence an integrated awareness, consultation and review exercise with potential users, industry trade associations, Local Authorities etc., targeted initially on London and SE England. This aims to encourage take-up of the scheme and, in the light of consultation, to identify improvements that will increase the effectiveness of the exchange.

6 Future developments

BRE, Construction Directorate of the UK Department of the Environment, Transport and the Regions, the UK Environment Agency and Hertfordshire County Council intend to establish a Sustainable Building Network aimed primarily at Local Government which has a crucial role to play in developing and implementing ways of promoting sustainable practice in industry on a local and regional basis. They act as clients in specifying construction projects, as influencers through environmental fora such as Local Agenda 21 and as enforcers in planning and building control.

As well as providing information on current best practice, and facilitating the building of partnerships to achieve these aims, it is intended that the Network will provide a positive feedback of new ideas and experience eg Hertfordshire County Council anticipate undertaking a study of reuse and recycling of materials in the construction of schools and are willing to share their information through the forum.

Changeable Internal Surfaces for Seasonal Flexibility

P. J. Martin
Faculty of Design, The Robert Gordon University, Aberdeen, Scotland

Abstract
Even in the North of Scotland, there are times of the year when heat reflection or retention are no longer the principal properties required from interior building surfaces to achieve thermal comfort for its occupants with minimum energy consumption . As a structure passes through its thermal balance point after the winter months it would be better served by internal surfaces which admit rather than resist heat . This paper considers the practical implications of employing materials or systems that change with the seasons to reflect the external climate .

The widespread use of plaster and plasterboard satisfies the need for a material which provides a rapid response to heating systems used intermittently to match the demands of a fragmented pattern of occupation . If cooling systems are employed in the summer , the ability to respond quickly may also be an asset . As passive and or night-time cooling becomes more widespread ; these conventional lining materials become less appropriate outside the heating season .

Aside from the energy gains to be anticipated from such surfaces , there is the added value to be derived from greater flexibility in future interior arrangements and enhanced sensory stimulus as surfaces change with the seasons . If the right surface finish is chosen , passive humidity control is also possible . The performance of these surfaces is modelled with standard thermal analysis software .

The particular material considered is the traditional Tapestry , which is a well established art form and still well perceived in contemporary society . Experiments with suitable fabric have shown that in transient conditions the thermal properties are a match for foil backed plaster. The use of wall hangings as functional art with a long life expectancy is explored and the benefits of the reintroduction of this portable surface are explained .

For ease of interpretation this article will concentrate on offices which are probably the category of building most likely to benefit from the ideas being promoted. Quantitative analysis in the form of energy consumption and life cycle analysis is presented to gauge the magnitude of the benefit to be anticipated from these variable surfaces .
Keywords: Thermal Admittance, tapestries, sustainable surface finishes.

1 Introduction

A number of recent buildings have used enhanced thermal mass of internal partitions to enable passive cooling to be achieved . A good example of this is the new Scottish Office building in Leith Docks, Edinburgh. Here an inner leaf of precast concrete has paint applied directly to the concrete . This gives a much higher thermal admittance value than would a more conventional finish . For an office where cooling represents a significant part of the annual energy budget this is a reasonable strategy. The ability of the structure to come up to temperature on a cold Monday morning, however, will be compromised by this choice of material. The Scottish Office building was heralded as a testing ground for green principles when it was the subject of a review in the Architects' Journal [1] yet on a cold dark day the prospect of contemplating slabs of painted concrete may not provide much inspiration or warmth for the occupants. The belief that the addition of mass to a building will reduce its energy requirement is now widespread ; according to another recent article which cites the example of a typical naturally ventilated office with 100% double glazing and internal gains of 35 W/m^2, thermal balance at zero energy is anticipated to occur at an external temperature of 0°C [2]. This level of information is not, however, new and has been available in a BRE Report for some time [3]. This report felt able to predict the effects of mass in promoting natural ventilation in what seems to be a very palatable form but few people seem to have been using it .

The ability of a surface to absorb heat is essentially a skin effect and so only a relatively small volume of material is required to influence interiors . Very often the actual interior surface used changes on an all too regular basis as owners and occupants follow trends in interior design or as the occupants themselves change . It is not always fully appreciated that even a fairly thin coat of new material to an internal surface can influence the behaviour of the room it encloses. If this is recognised and interiors are designed to allow flexibility with season and type of use then tangible benefits should ensue. People exchange heat with their surroundings predominantly through convection and radiation from the clothing that they chose to wear. The experience of thermal comfort is usually described by the Dry Resultant Temperature of the room which is a combination of air and surface temperatures . People are much more likely to appreciate the conditions in a space if they are exchanging heat as radiation rather than convection from systems which move air . In domestic construction attempts to use hot air systems have not been well received in the UK and a straw poll of owners of such systems would probably show that a significant number of these systems have been abandoned , yet in offices they are the norm. Creating environments which allow surface temperatures to become much lower than the air which they enclose is not likely to be well received. As people spend more time in environments with forced air movement (car , plane and office) are they experiencing the best conditions that can be achieved? If heating or cooling is to come from surfaces rather than air then those surfaces must be kept at the correct relative temperature so that in winter too much mass is not readily available to require there to be warm air supplied at too high a temperature for optimum comfort .

2 History

Before the widespread use of plaster as a surface finish it was common to use textile hangings as a decorative feature . As well as providing decoration , these hangings would provide insulation and more importantly allow the rooms to heat up much more rapidly than would be the case with exposed stone or brickwork . The use of a thin covering which is disinclined to absorb heat over a massive material which is able to dissipate heat enables the heating or cooling phases of interiors to take place as quickly as possible . This reduces the period of use and creates a more reactive system . Timber lining could also be used to provide an enhanced warm up mechanism but is not demountable to the same degree . Cost was of course a major factor and so for those who could not afford to commission a tapestry , less elegant and more unsavoury linings were often chosen using material readily available from the fields or recycled materials such as newspapers in the place of wall paper; today such practice would be questionable yet the thermal properties of these surfaces may well have made them a good choice . There is now evidence of some excellent Scottish tapestries which no doubt enriched the lives of those who were able to see them as well as providing the low admittance to be welcomed on a cold Scottish morning. Although these tapestries were expensive and perhaps a status symbol they were ‘long lasting and portable . Tapestries such as those uncovered at Traquair House, Scotland were widely used in the great houses of the 16th and 17th Century . These would have supported local textile artists at this time . Wall hangings are still relatively widely available today although many feature reproductions of scenes from this golden age .Less frequently contemporary artists have been commissioned to create corporate images to hang in company offices or meeting rooms . Examples of works commissioned for a particular position in a particular building are quite rare in the last few decades , one such example is the Aberdeen Art Gallery Tapestry [4] which was designed to reflect light according to time and season .

3 Internal Surfaces

3.1 Thermal Properties

The ability to be able to lower surface temperatures in the summer and raise them in the winter allows a building to reduce the convective heating and cooling requirements and so reduce energy consumption for internal climate control . Such a system combines the benefits to be experienced in a timber structure when in heating mode with those of a massive stone church during the cooling season . Even a temperature rise of a half or one degree which is to be expected from a wall hanging in a lightweight structure is worth the effort of attaching it to the walls . For heavyweight surfaces the gains are greater and if a low emissivity material is attached to the rear face of the hanging then another degree or even two is possible .

The use of wall hangings in winter allows for them to be removed in summer and if the wall behind is of heavyweight structure it is possible to provide cooling during this period with thermal mass . For this to work it is important to be able to demonstrate that the wall hanging is able to match the thermal properties of plasterboard which it could replace where seasonal flexibility is required .

A simple experiment was devised to measure the relative performance of internal surfaces when subjected to gentle winter heating . The results of warming four surfaces against a cold medium grade concrete block wall are shown as Figure 1.

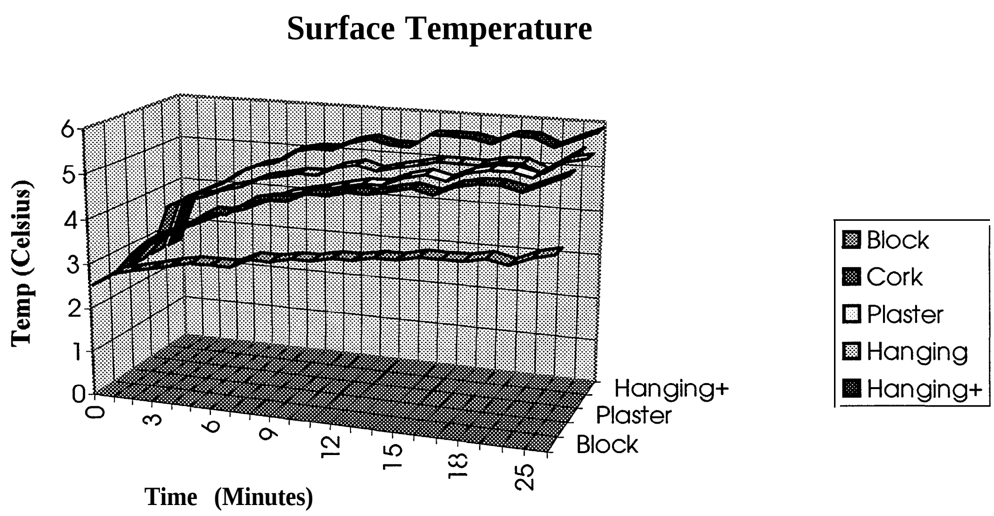

Figure 1

It can be seen from these results that lining the blockwork with cork , plaster , hanging and hanging with a foil backing gives increasing ability to raise the surface temperature of a room and so increase the radiant element of thermal comfort for occupants of that room under heating mode These properties are similar to those found for plasterboard and polyurethane in pioneering work on admittance in the 1970s [5].

3.2 Energy Saving

The admittance of a concrete block wall can be seen to fall from 6.0 to 3.0 W/m^2 °C when covered with a tapestry of modest thickness which is similar to the effect found when stone walls are timber lined . It is easy to demonstrate the gains of such a strategy with the computer simulation software widely available these days , rather than make extravagant claims by choosing an office with very high casual gains such as the 35 W/m’ it is better to claim 10 to 20% using an example which has had many of the casual gains removed from it by adroit design .The potential of variable admittance can be demonstrated to achieve a 20% reduction in the annual energy requirements for a two storey office of 360 m^2 [6] by reducing heating loads without increasing cooling , humidification or dehumidification requirements but further work is in hand by the Author to provide data on the thermal and moisture properties of surfaces which might be used in this way . The building used in the simulation was a cellular office with concrete block partitions and the hangings were applied to these partitions only to reduce cost and condensation risks .

Thermal energy loads are shown for the exemplar building , Figure 2 , to demonstrate the improved performance when the wall hanging is used compared to the exposed concrete block. In this simulation the hanging was removed for the months of June to October.

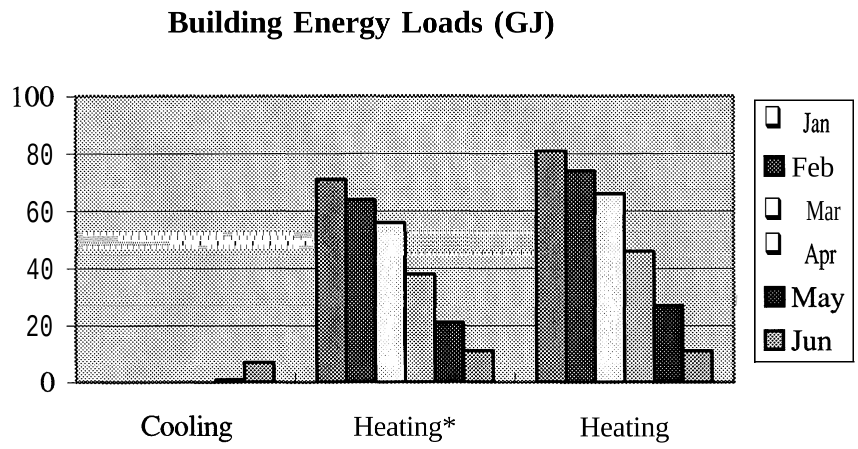

Figure 2

The experiments of Figure 1 , modelled in Figure 2 used a Cotton Hanging but similar performance might be expected from Wool or Jute fibres .

3.3 Humidity Health and Fire Issues

The question of where to put the variable admittance surface should be mentioned . Whilst it is reasonable to use the floor for this purpose there are health issues associated with floor coverings regarding dander shed by people and other nutrient sources which might encourage colonies of dust mite to take up residence . Walls are a much safer option and depending on the internal arrangements may provide a greater surface area . The other improvement that natural fibre hangings in particular can achieve is humidity control . When rejecting air conditioning a project team will also reject the opportunity to control humidity . Fortunately in the higher latitudes this is less of a problem but the dangers of high or low humidities are still being discovered so it is as well to keep within the range 40 - 60% . Whether this is achievable depends on the activities within the building and the ability of the surfaces to act as a buffer for transient conditions . Once more the painted concrete wall is not ideal for this purpose. Wool fibres for example which can hold 16% of their weight within the fibre structure (that is bound up in the structure and not available to other organisms), they have the potential to dry air from 0.02 kg/kg to 0.002 kg/kg moisture content and under the right temperature regime this could achieve a change from 80% to 20 % Relative Humidity [7].Any material attached to walls must not provide a substantial fire load , Wool for example is able to suppress ignition ; further tests of performance in fire are being conducted by the Author’s host institution.

4 costs

The use of a basic solid wall with only a simple paint finish can bring the costs of a project down , yet the use of a tapestry which may be a bespoke item will more than remove this saving . The additional cost for new construction may be taken as simply the difference between that of plasterboard (1.5 ECU / m^2) and a mass produced jute wall hanging (34 ECU / m^2). Taking into account future refurbishment , total cost may not be all that much higher than for a conventional set of materials . If the energy saving per year (80 GJ) is set against the cost of the extra materials (240 m^2) using a price for energy of 20 ECU/GJ the simple payback period is 4.9 years . There are now a number of lower cost mass produced rugs which are available at reasonable prices if a short term fiscal view is to be taken . It would appear that the changes proposed might be at no additional cost or at worst fiscally neutral . It is for clients and users to decide on the advantages in terms of sustainability and embodied energy .

5 The Contemporary Paradigm

Not everyone wishes to employ traditional solutions to modern problems . There are opportunities to develop technical solutions more clearly identified with the twenty-first century . It would be possible to create surfaces which were of low admittance but consisted of an open porous structure which could be closed when the weather became cooler. If this were to be fixed to the surface of a massive substrate then the flexibility already demonstrated with hangings which require to be removed or rolled up , could be reproduced at the flick of a switch .

In recent years there have been few significant developments in interior finishes and the trend towards massive construction for cooling may provide the necessary stimulus to the Building Products Industry to enrich the range of materials on offer. The development of textile materials with aluminium foil backing might also have wider commercial potential.

6 Value added

The provision of a basic structure which is finished by occupants allows greater ownership of the interior space thus created. For companies wishing to promote corporate identity this may be attractive so long as this identity has some reasonable life in the marketplace . The desire to promote and commission cultural art which is also functional should add weight to this concept , be attractive and add value to the building .As an organisation grows and moves on to new premises there is then the opportunity to take familiar elements of the old workplace to the new building . The building itself may be the creation of an international style of office but local culture can be reflected in wall hangings as it has for centuries and in doing so satisfy the principles of Agenda 21 and Agenda 2000 [8].

7 Conclusions

The use of natural ventilation assisted by massive elements within the construction of offices is to be commended . As with any new ideas there will be successes and lessons to be learned . By paying due regard to all seasons in the design of low energy offices further performance gains can be achieved .The use of higher specification interiors which might be expected to have a longer life and thereby a lower total cost risks should be reduced and flexibility retained . The latest breed of low energy offices may have their problems but the shift towards greater occupant control should be able to enable the users themselves to overcome these .

The Problems of Phosphogypsum Utilization in Lithuania

E. Blazevicius, R Kaminskas, A.V. Raginis
Institute of Architecture and Construction, Kaunas, Lithuania

Abstract

There are no mines in Lithuania but there are fertilizer waste dumps. For many years phosphor fertilizer has been made in Kedainiai chemical plant in the central part of Lithuania using apatite as a raw material which is brought from Kola peninsula. During the production of **1** t of phosphoric acid 4,5 t of phosphogypsum is produced. For many yers phosphogypsum has been transported into the dump in which more than 8 mln tones of phosphogypsum have been accumulated. Phosphogypsum includes volatile fluor and phosphoric acid. Ecological polution of the waste materials is obvious, however, according to Lithuaniain laws the plant does not pay any fee for the damage.

Institute of Architecture and Construction has prepared several technologies concerning the utilisation and remaking of the phosphogypsum wastes into building materials and products. The report is based on the problems of their characteristics and realization.

Keywords: Lithuania, phosphogypsum, utilization, waste.

Introduction

Lithuania lacks sources of natural gypsum. That's why Latvian natural gypsum from Seurieše pit was used in the production of gypsum products. This pit has been exploited for a very long period of time in spite of comparatively low quality of gypsum.

However, in Lithuania we have large amounts of fertilizer production waste. For many years phosphorus fertilizers have been produced by Kedainiai chemical plant (today joint stock comp. "Lifosa") which is in the central part of Lithuania. The main raw material used is apatite brought from Russia, Kola Peninsula.

With the production of one ton of phosphorus acid there form 4.5 ton waste material, i.e. phosphogypsum. For many years phosphogypsum has been transported into the so-called waste-hills in which more than 8 mln. tons have been accumulated.

Phosphogypsum includes volatile fluor, the remainders of phosphorus acid and other harmful materials. The pollution of the environment is obvious enough, but still, according to the present laws of Lithuanian Republic, the enterprise does not pay any fees. The Institute of Architecture and Construction has prepared some technologies concerning the utilization of these waste materials and the processing of phosphogypsum into building materials and products.

Technology of the utilization

Already in 1987 in Kedainiai near the chemical enterprise a plant for phosphogypsum processing into P-modification building gypsum was built according to the project made by the institute. The wasteless technology was based on the neutralization of phosphogypsum but not its washing with water.

The essence of the technology is as follows:

- phosphogypsum dehydrate in which there is no more than 1.3% of general P_2O_5 and 0.9% P_2O_5 which is water soluble is neutralized with lime cream and the pulp is filtered;
- filtrate is once again used for lime cream preparation;
- filtered phosphogypsum is dried;
- dried phosphogypsum is dehydrated;
- the product is cooled down;
- the product is ground;
- the product is stored and stabilized.

This technology of β-semihydrate gypsum production is distinguished itself by many advantages: there were no technological flowing waters, the process was continuous, and the product produced distinguished itself by stable properties: the beginning of binding – 13-15 min., the end – 20-24 min., strength under pressure after 2 h is 5-6 MPa, strength under pressure of dried products 12-13 MPa. Gypsum slabs, blocks, mixtures for finishing works have started to be produced of this building gypsum in Lithuania.

In 1990 with the restoration of Independence in Lithuania the economical situation changed. The amount of production diminished and the size of building material industry decreased about 80%. The phosphogypsum processing plant did not manage to adjust to new conditions and in 1993-94 β-phosphogypsum plant was finally closed. At present this product is no longer produced in Lithuania.

From 1997 the joint stock company "Lifosa" changed the technology of fertilizer production, and the waste material is no longer dehydrate phosphogypsum but semihydrate acid phosphogypsum. A very small amount of it the plant processes into a high-quality a-modification building gypsum. The main properties of this gypsum are:

- the beginning of binding – 16 min., the end – 32 min., strength under pressure after 2 h – 14.4 MPa;
- P_2O_5 general – 0.33%, P_2O_5 water soluble – 0%;
- fluor general – 0.25%, fluor water soluble – 0%.

However, today the amount of the production does not meet even the minimal demand of producers and consumers.

In 1997 the firm "Palemono keramika" using the technology invented by the Institute of Architecture and Construction produced the first experimental batch of a new building material – anhydrite cement. The raw material for this binding material – i.e. dehydrate acid phosphogypsum – has been taken from that part of phosphogypsum waste-hills where new waste materials were not transported in last years. The upper and the middle parts of the hills (2/3 of the height) have been thoroughly examined. The chemical tests showed that during many years rain and other natural factors considerably diminished the amount of harmful admixtures in the phosphogypsum – dehydrate waste. The average chemical compositions was as follows: R_2O_3 – 2.03%; CaO – 31.63%; SO_3 – 44.82%; F general – 0.2%; F water soluble – 0.04%; pH – 2.6-4.8%;

The essence of anhydrite cement production technology is the following: acid phosphogypsum – dehydrate is neutralized by lime cream in clay mixer, then clay and glass slime (the waste got during TV screen grinding) additives are introduced and the produced mixed material is burned in gyrator furnace. The approximate composition of materials is: 79.0-79.3% phosphogypsum; 16% clay; 4% glass slime; 0.5-1% lime. The production was carried out in a claydite shop of a plant "Liapor". Anhydrite cement was burned at 850-900°C and the product produced in granulated shape. The chemical composition of the granulate is: SO_3 – 36.45-41.05%; CaO – 32,0-33,27%, R_2O_3 9,35-15,6%, P_2O_5 water-soluble – 0.03%; F general – 0.03-0.06%; F water soluble – 0%. The mechanical strength of the granules 1.5-2.0 MPa; volume mass 967-985 kg/m^3.

In the next stage the granulate is ground and then we get anhydrite cement. The main physical-mechanical properties are these: the beginning of binding 1 h 20 min., the end – 2 h 15 min., the strength after 28 days under pressure is 20-30 MPa, under bending – 3-4.5 MPa.

This binding material can successfully replace the ordinary portlandcement in many building spheres. It should be also profitable from the economical point of view as anhydrite cement is burned at much lower temperature than portlandcement. Yet, its production size is still small.

Conclusions

In Lithuania, as well as in the former SU, gypsum materials and products took an insignificant place in the nomenclature of building materials. Because of extremely low prices of energetic resource cement was used nearly in all spheres.

With the change of both political and economic situation building materials made of gypsum have been widely used, especially for interior trim. In fact all these materials are being imported.

However, the amount of local phosphogypsum waste with the realization of technologies suggested by the Institute of Architecture and Construction, could ensure a long-term production of gypsum materials. At the same time, it would give the possibility of the gradual diminishing of accumulated phosphogypsum waste dumps.

Repair of environmental constructions with the high-performance concrete SIFCON

R. Breitenbücher
Philipp Holzmann AG Frankfurt/Main, Germany

Abstract
SIFCON (Slurry Infiltrated Fibre Concrete) is a High-Performance Concrete, which provides a high ductility due to a steel-fibre content of about 10 % by vol. In addition, an extremely dense microstructure is characteristic of SIFCON. With this material, existing structures handling with water contaminating fluids can be repaired so that they can fulfill the adequate environmental requirements. The high fibre content of SIFCON requires a special method of production: in a fibre bed, which is first spread onto the existing structure before, a high performance mortar is infiltrated. Due to the high fibre content, SIFCON shows a high resistance to impact and abrasion as well as a favourable control of crack widths. Therefore structures, which suffer abrasion and impact, can be improved by SIFCON.

SIFCON as a ductile layer of high performance fibre concrete with an extremely high amount of fibres can be used also to minimize wear and tear. However, SIFCON does not perform any load bearing function, because it is applied only in relative thin layers.

Further applications could be the improvement of airport runways, concrete pavements, parking floors, sewage plants etc..

Until now the fibres for SIFCON surfaces have been spread by hand. To improve the efficiency mechanical procedures are necessary. Suitable instruments - for small areas as well as for large and long lanes - are being developed at the present time.

1 Introduction

Structures dealing with water-contaminating substances must guarantee the protection of soils and ground- water. The. political framework for such buildings in Germany is constituted in the water protection law (WHG) which states:

"Installations for storing, filling, producing and handling of water-contaminating substances . . . have to be built in such a way that the contamination of the environment, especially ground water, is prevented".

Considering this law (WHG) many existing installations, in which water-contaminating substances are stored, filled or handled, have to be repaired and sealed subsequently. Typical examples are gasoline stations, fuel depots and chemical industry plants. If the existing structure is still on able to fulfill the loadbearing function, i.e. it has not to be totally rebuilt, a subsequent application of a sealing layer can satisfy the appropriate regulations. For such sealing layers often polyurethane resins (PUR) or steel are used. However, layers of high-performance steel fibre concrete (SIFCON) have been used in Germany recently and are a significant and efficient alternative for such secondary barriers.

2 SIFCON

SIFCON is the short term for "Slurry Infiltrated Fibre Concrete". This cement-bound fibre material was developed in the USA almost 15 years before and was successfully used in several buildings [1,2]. SIFCON is a fibre concrete with an extremely high steel fibre content of about 10% by vol., corresponding to nearly 800 kg/m^3.

The high steel fibre content improves the ductility of the usually somewhat brittle material like concrete and cement mortar to several orders of magnitude nearly as strong as steel [3]. At the same time an optimal crack distribution is obtained. The typical crack width is limited to ranges of O.Olmm to 0.03mm.

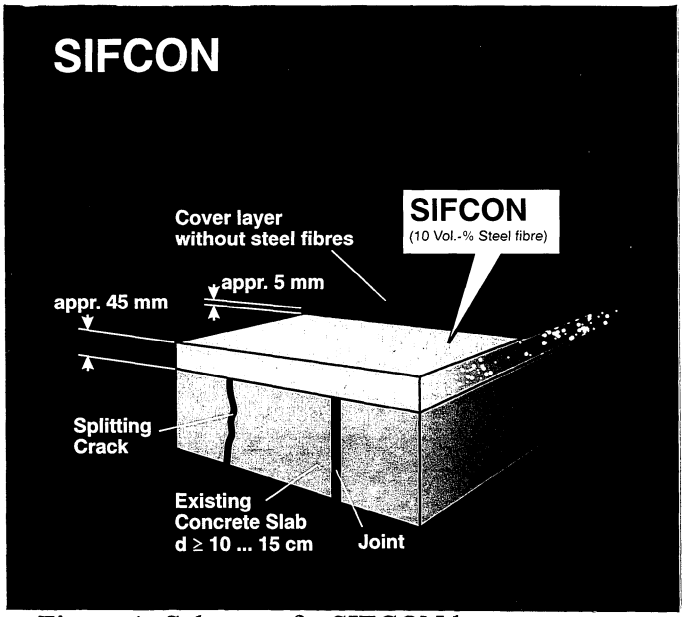

Figure 1: Scheme of a SIFCON layer

The special mixture of the infiltrating mortar ensures a very dense microstructure. Both components, steel fibres and mortar, guarantee a high-quality cement-bound material. Due to the high ductility SIFCON can be applied without any joints over large areas (Figure 1). In addition to alternative sealing layers SIFCON also offers economic advantages, when the long durability and low maintenance are taken into account.

3 Production procedures for SIFCON

Due to the extremely high fibre content in SIFCON the steel fibres cannot be mixed in as usually in a standard concrete mix. So a special method for the SIFCON-production had to be developed [4]. In the first step, the steel fibres are spread direct onto the existing structure, for example a floor slab. This loose filling results automatically in a fibre content of about 10 % by vol..

In the second step the mortar with fluid consistency is infiltrated into the steel fibre bed (Figure 2). For a complete filling the surface is treated with a vibrating screed to improve the infiltration.

Technically no further work would be necessary. However, the steel fibres, which are directly at the surface can corrode and raise rusty spots, which however only are visual blemishes. Nevertheless to prevent such effects an additional cover layer of about 5 to 10 mm of regular mortar is placed fresh in fresh onto the SIFCON layer (figure 3). The final surface can be finished as required individually in each case; e.g. brushing, smoothing etc.. Finally, the SIFCON-area has to be cured carefully.

Fig. 2: Infiltration of the mortar in a fibre bed

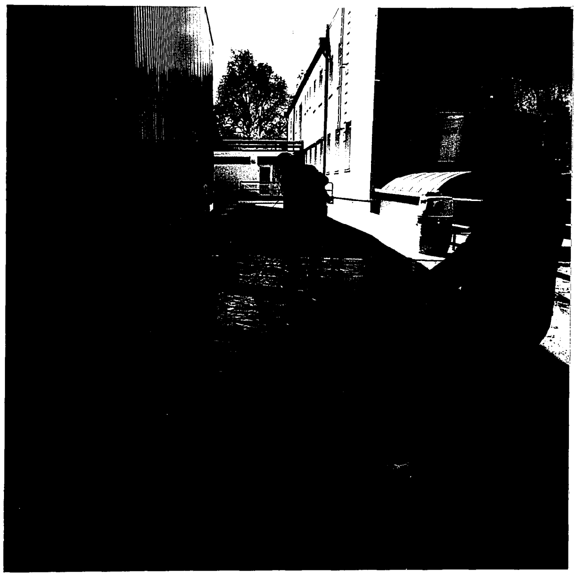

Fig. 3: Addition of the cover layer with regular mortar

4 Constituents and mortar compositions

4.1 Steel fibres

Loose steel fibres must be used to ensure non-compacted filling. Staple-like fibres, 30mm in length and 0.5mm in diameter, have been found very suitable. Short fibres result in a denser structure than long fibres.

4.2 Infiltrating mortar

To enable the complete infiltration of the fibre bed, the mortar must be of fluid consistency and the maximum aggregate size has to be limited to about 0.7mm. For this purpose following mix for the infiltrating mortar has been developed (Table 1):

Table 1: Mixture of infiltrating mortar

Cement	CEM I 52,5 R (high fineness)	kg/m³	1000
Water		kg/m³	330
Aggregate	Silica sand 0/0,7 mm	kg/m³	860
Additive	Superplasticizer (naphtasulfonate)	kg/m³	35
	Stabilizer (artificial silicium dioxide "nanosilica")	kg/m³	10

The very dense microstructure in the hardened mortar especially is obtained by the low w/c-ratio and the addition of silicium dioxide.

It is very important that the mortar has a high homogenity without lumps or segregations. With standard concrete mixers this cannot be guaranteed in all cases. Though special mixers with high speed has to be used.

4.3 Mortar for cover layer

The cover layer, which has to protect the SIFCON-layer from corrosion, doesn't contain any steels fibres. To minimize the tendency of cracking, the mortar has to be optimized with respect to minimal shrinkage. For this purpose in comparison to the infiltrating mortar the maximum aggregate size is enlarged to 5 mm and the cement content is reduced to 600 kg/m^3. A part of the cement (up to 100kg/m³) can be replaced by fly ash. Additionally 6mm long synthetic fibres (polypropylene, polyacylnitrile) are added to contoll the possible crack widths in the surface.

Table 2: Mix of cover layer mortar

Cement	CEM I 52,5 R	kg/m³	600
Water		kg/m³	195
Aggregate	Natural sand 0/2 mm	kg/m³	800
	Crushed basalt 2/5 mm	kg/m³	770
Additives	Superplasticizer	kg/m³	21
	Stabilizer	kg/m³	8
Synth. fibres (l= 6 mm)		kg/m³	6

5 Properties of SIFCON

5.1 Mechanical properties

Due to the high amount of steel fibres SIFCON distinguishes from normal concrete especially in its deformation behaviour and in ductility. With the mortar mentioned in Table 1 SIFCON exceeds a compressive strength after 28 days of about 90 MPa. In other investigations - using infiltrating mortar of normal strength - a significantly increased ductility also in compression tests was prooved (Figure 4) [5].

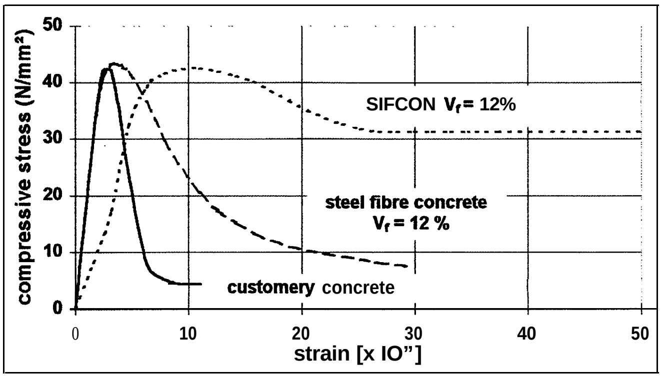

Figure 4: Stress-strain curve of SIFCON under compression (from [5])

In spite of the high compressive strength the modulus of elasticity of SIFCON is distinctly lower than that of ordinary concrete. In extensive studies [3,6] moduli of elasticity between 15000 MPa and 23000 MPa were ascertained, correlating with the flatter stress-strain curve in Figure 4. This mainly results from the small aggregate sizes used in SIFCON. However, a low E-modulus is of advantage for minimization of restraint stresses in the thin layers layers without any joints.

The ductility-increasing effect of the steel fibres can be clearly demonstrated in bending and tension tests [6]. SIFCON samples exceeded flexural strengths between 40 and 45 MPa, which is 6 to 8 times of the values of ordinary concrete. Furthermore, after exceeding the ultimate load the sample does not break. The specimen can be deformed furtheron to a large extend (Figure 5). In this photo also can be seen, that the steel fibre bed is filled completely with the infiltrating mortar.

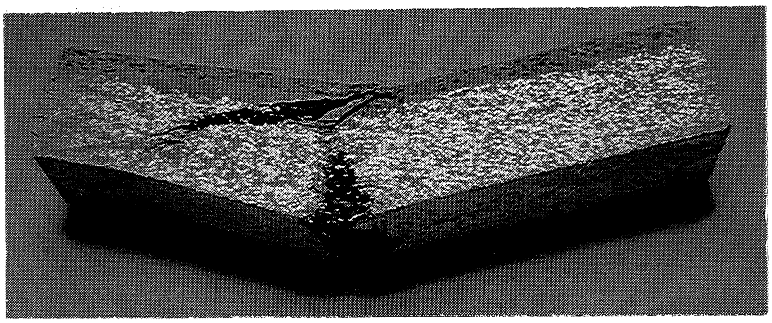

Figure 5: SIFCON sample after bending test

A typical result of a centric tension test is presented in figure 6. A number of strain gauges, displaced in respect to one another, were applied on each sample, to study the deformation behaviour at the main fracture area and at normal zones [7]. While in the real fracture zone (DMS 5) the deformation increases to a very large extend at a high stress level, in the other sections after final break the deformations decrease nearly in a elastic manner.

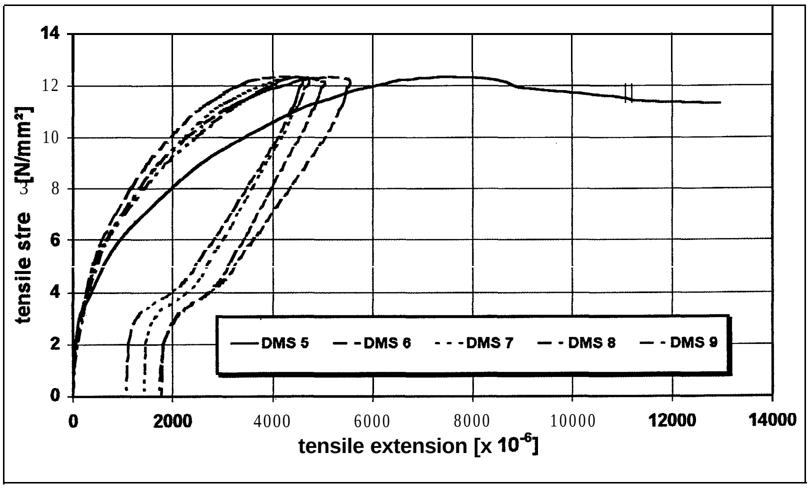

Figure 6: Stress-strain curves of SIFCON under centric tension (from [7])

The special composition of the mortar (w/c-ratio, addition of nanosilica) leads also to a high resistance against abrasion and freeze-thaw. In freeze-salt-tests according to the CDF-method the SIFCON samples after 50 cycles had a loss in mass of about 185 g/m², while in previous experiences values up to 1500 g/m² are accepted. These results show that SIFCON-mortars according table 1 and 2 have a sufficient freeze-salt-resistance also without artificially entrained air pores.

5.2 Tightness

The tightness of SIFCON against the penetration of fluid mediums cannot be proved in the common way. Due to the high amount of steel-fibres the specimens cannot be splitted in normal manner. For this reason penetration tests of SIFCON are carried out on slabs with a thickness of only 5cm. The specific fluid is applied under pressure to the surface. As criterion the time period is determined when the fluid reaches the opposite side. Alternatively the slabs after a fixed test period can be cut, the surfaces are sprayed with sulphuric acid and then heated with a flame to fix the extent of penetration. Details to these tests are shown in [8]. Until now penetration tests have been done with water, acetone, gasoline, diesel and various oils.

Based on these investigations, it could be proved that a SIFCON-layer of 45mm in thickness fulfills the requirements according to the German guideline “Concrete construction and water polluting fluids” (DAfStb) for protection against a single penetration (accidental event). In the case of an intermittent penetration, for example at gasoline stations, the thickness of the SIFCON layer must be at least 8 cm [9].

6 Details for Construction

The high ductility of SIFCON allows constructions of large areas without any joints. All deformations which normally take place within a construction joint are converted into deformations within a very large number of small cracks. Nevertheless;- joints cannot be prevented in all cases (e.g. between various working sections). However, such joints can be connected homogeneously. For this purpose the edges of a sectional layer are fixed by an angled formwork. As soon as the infiltrating mortar has set sufficiently the formwork is removed and the mortar along the edge is washed out at the surface, so that the fibres in the edge are partly set fee and partly fixed in the already constructed SIFCON layer. To continue the layer, new fibres are spread right against this edge and the mortar is poured in the next step. Samples taken from the joints show no structural discontinuity. In bending tests the main fracture even appeared outside the joint. Nevertheless, if a joint should open in an exceptional case, the crack can be grouted easily and permanently with a suspension of cementlime.

As every cement-bound system the infiltrating mortar of SIFCON also shrinks. However, these deformations are restrained to a large extend by the steel fibres so that the shrinkage deformations of the SIFCON system in generell are relative small.

Warping of the layer due to shrinkage gradients or a horizontal flaking at the edges can be prevented by bolts, which are fixed in the existing subbase and are bound completely into the SIFCON layer. Due to these anchors and the high bond between the SIFCON-mortar and the subbase high restraint stresses are raised which are absorbed by the formation of the very small cracks.

For retaining basins additional surrounding walls or edges have to be built around the sealed hoizontal areas. These can be constructed with SIFCON, too. For this purpose the infiltrating mortar is washed out at the base joint as mentioned above or additional steel fibres are spread into the still fresh mortar. Then into a formwork of the basin walls separate layers of steel fibres of about 5 to 10 cm are spread and infiltrated with mortar. The formwork should be vibrated to improve the infiltration. By repeating these steps also high vertikal walls can be constructed with SIFCON.

7 Practical Applications

At the end of the 70's special high-performance components were produced with SIFCON in the USA, for example safes, repairs of highways and bridges, prefabricated beams and silos for ammunition and rockets [1,2].

In Germany SIFCON first time was used by Philipp Holzmann to repair and upgrade a 1200 m^2 large industrial area [10], where chemical products are handled and stored, according to the requirements of the German environmental laws. The existing subbase consisted of reinforced concrete jointed slabs, each 5x5m. Most slabs showed large cracks. The whole existing concrete area was cleaned by high-pressure water jetting before the steel fibres were spread. By this preparation the required bond between SIFCON and the existing concrete was achieved, which could be proved afterwards on cores. The retaining basin was built as described in paragraphs 3 and 6.

In a similar project, various slabs in the basement of an old chemical chlorine production plant, were sealed to comply with the requirements. The basement floors of tiles and concrete and similar surfaces were directly covered with a SIFCON layer. A wall section in a garbage chute, which had to absorb the impact of the grabbers, was covered with SIFCON 1.0 m high and 8 cm in thickness. Single layers of 20cm steel fibres were spread into the formwork in one step and subsequently infiltrated. Step by step using this method the total heigth was obtained.

Considering the high resistance against abrasion and freeze-salt-attacks SIFCON can be used also very adventageously for repair workson highways, bridges or other public areas. One successful application was the repair work of bus stops in Berlin. Common materials like asphalt and polymer concrete have proven unsuitable on the approaches of bridges due to the braking and acceleration of busses. Also repair work on a highway with a concrete pavement were performed successfully with SIFCON.

Abstract

One important challenge for the industry is to reduce the impact of construction on the global environment, and most of the burden placed on the environment by construction is produced in urban areas. For this reason, there has been much interest in the application of a suitable, long-term method of environmental impact assessment to urban development and urban renewal projects.

The Life Cycle Assessment (LCA) method is believed to be highly effective for such purposes. Several approaches utilizing this method have already been developed and applied to individual buildings, and the results of such analyses have come to be reported in the literature. Yet, there have been very few cases in which an expanded version of the LCA method has been applied to urban structures overall.

The authors have developed a method of applying LCA to the downtown areas of large cities. This method enables comparisons of environmental load between (a) cases of natural renewal, in which the collection of urban structures is merely left as is, and (b) cases of planned renewal, in which various approaches are used to give a project directionality and consistency.

Four quantities were selected as indices for the environmental aspects of the analysis . -- material usage, energy consumption, carbon dioxide emissions, and construction waste discharge. These indices are vital for assessing efforts to prevent global warming, suppress the "heat island" effect in large cities, and, in response to an especially serious problem in Japan, reduce the amount of waste generated at construction sites.

While the authors envision that their method of analysis will be able to be applied in a universal manner to all major Japanese cities, as a first step they elected to apply the model to a specific urban region and, accordingly, chose the western district of Nakanoshima, a big renewal project progressing area in downtown Osaka. The authors then began to analyze the above mentioned life cycle environmental aspects of that district.

Keywords: global warming, LCA, urban renewal

1 Research Background and Conceptual Framework

As the problems of global warming become manifest, there is an increasing interest in societal systems that place relatively little load on the environment. Reducing the burden on the global environment is a vital issue that the construction industry must address in response. Most environmental loading from construction activities occurs in urban areas, where buildings and civil structures are concentrated. Consequently, there has been much interest in the application of a suitable, long-term method of environmental impact assessment to urban development and urban renewal projects.

Our research effort is focused on the analysis of urban renewal projects in the central areas of large cities. As depicted in Fig. 1, it is currently being implemented in three parts -- an environmental assessment system which estimates environmental load by existing urban structures and renewal process, a strategic alternative planning system which proposes low environmental load methods by changing planning variables, and a computer-aided research and development system which handles imformations with user-friendly interface. Presented in this paper is an outline of the . environmental assessment system.

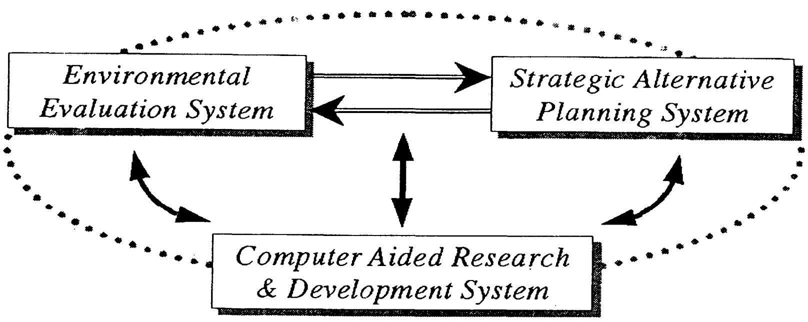

Figure 1. Research Organization

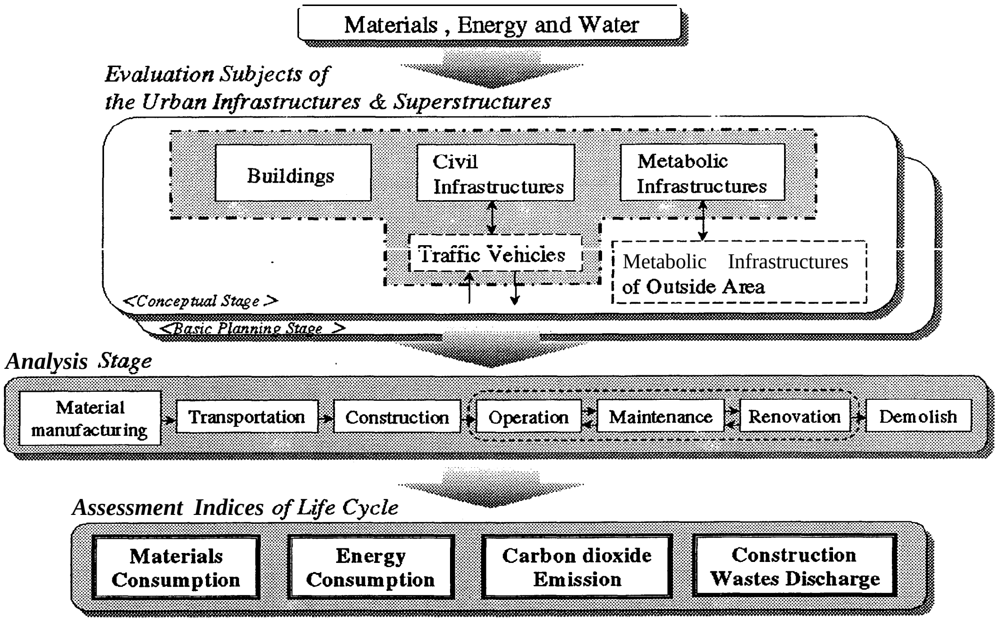
2 Environmental Assessment System

The Life Cycle Assessment (LCA) method is believed to be highly effective for the analysis of long-term environmental loading. Several approaches utilizing this method have already been developed and applied to individual buildings. The results of such analyses have come to be reported in the literature [1], and reports of test calculations for some civil engineering structures are also beginning to appear [2]. Yet, there have been very few cases in which an expanded and general version of the LCA method has been applied to an overall collection of urban super and infra structures.

We have developed an LCA method for application to the downtown areas of large cities. This method enables comparisons of environmental load between (a) cases of natural renewal, in which the collection of urban structures is merely left as is, and (b) cases of planned renewal, in which various approaches are used to give a project directionality and consistency.

As illustrated in Fig. 2, the assessment system is comprised of three components -- an evaluation subjects, an analysis stage, and assessment indices. Into the evaluation subject component, we enteredsuperstructural, infrastructural elements, and the like for the district to be analyzed. We also included taffic vehicles, and a portion of activities external to the district, such as broader infrastructural systems to be borne by that district. The analysis stage was divided into seven steps corresponding to the seven life cycle stages, and the analysis was carried out accordingly.

Four quantities were selected as indices for the environmental aspects of the analysis -- material usage, energy consumption, carbon dioxide emissions, and construction waste discharge. These indices are vital for assessing efforts to prevent global warming, suppress the "heat island" effect in large cities, and, in response to an especially serious problem in Japan, reduce the amount of waste generated at construction sites. Partially because of the difficulties that would be involved in obtaining clear and objective data for other potential environmental aspects, we only included the four indices above in this analysis.



※ "Metabolic Infrastructures" means Supply-Treatment and Communication Infrastructures

Figure 2. The Structure of Environmental Evaluation System

3 Inventory of the Urban Structures Complex

An important prerequisite for the general application of the LCA method to urban areas is that the structural elements making up that area be hierarchically classified. Here, we arranged and classified the collection of structures making up a typical urban area and then created a detailed, hiearchically arranged list of their compositional elements (thereby, in effect, taking an inventory of urban structures). Furthermore, as the results of this research are envisioned for use in the planning stage, it is necessary to be able to perform the actual calculations with only the general data available at the basic conceptualization stage for the district and the basic planning stage for the structures (or, conversely, it may not be necessary to carry out highly precise analyses based on detailed design data for the structures).

Utilizing the arrangement shown in Fig. 3, we created an actual inventory by filling in the detailed data fields one after the other (some of the data is still being collected). The environmental load produced by metabolic infrastructures (e.g., water and sewage systems) is assigned to the district in proportion to demand occurring within the district. To facilitate the analysis of strategic alternative plans, we included manipulable variables in the inventory for those entries likely to have a large effect.

4 Methods and Results of Calculations for Unit Quantities

Several unit quantities have been proposed for the amount of energy consumed and the amount of carbon dioxide given off during the manufacture of construction materials.

As for the unit quantity of carbon dioxide, we utilized values tentatively recommended by the Japan Society of Civil Engineers and shown in Table 1 [3]. These values are utilized as basic data for reference input output table of Japan, incorporate a partial application of simple additive approach, and include ripple effects between industries.

Unit material usage for construction and unit energy utilization (building use) stages was determined by statistically processing past operating data. Energy consumption in the utilization stage accounts for the highest proportion in the entire LCA; and, with an output value sensitively dependent on its input value, much precision is required in its estimation. Here, we developed a database to meet this requirement.

Little data has been presented on unit construction waste generation, and for this reason we prepared estimates using industry statistical values.

Table 1. CO2 Unit Emission

Classification	CO2 Emissions *	Unit	Classification	CO2 Emissions *	Unit

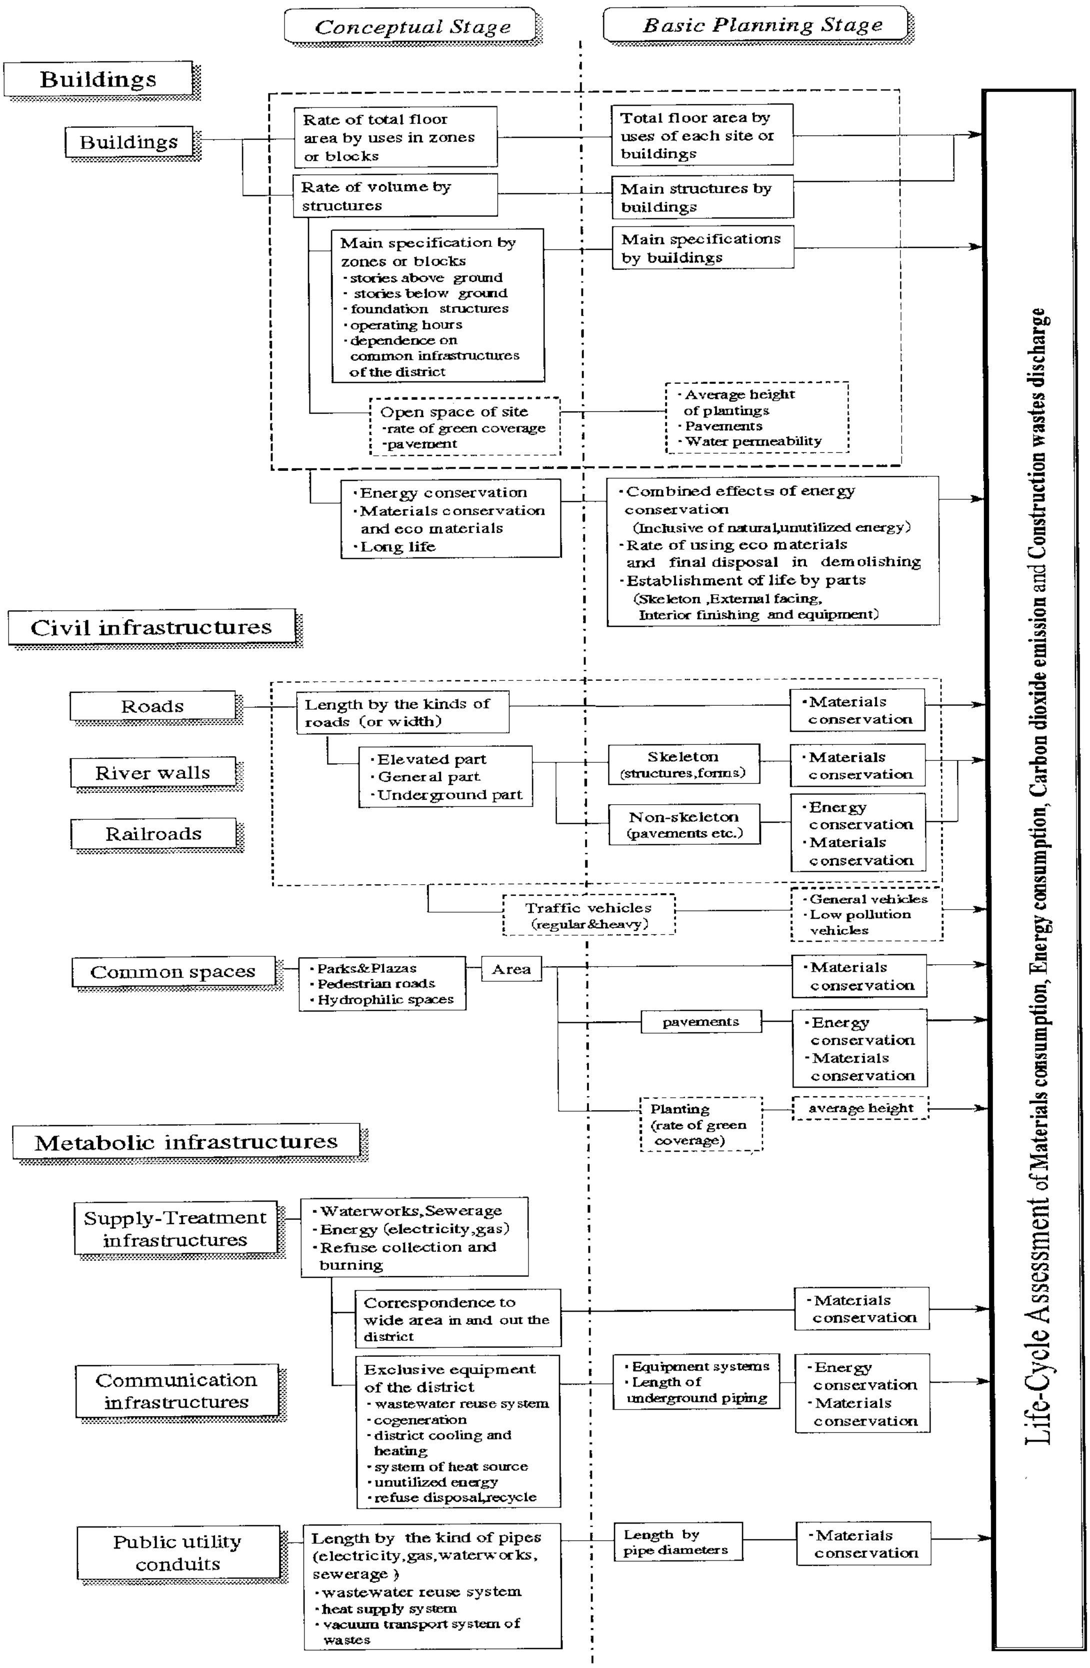

Figure 3. The Inventory of the Accumulated Urban Infrastructures & Superstructures

5 Western District of Nakanoshima -- current state and LCA results

We envision that our method of analysis will be able to be applied in a universal manner to all major Japanese cities. Yet,. as a first step, we decided to select a specific urban region and configure an assessment system modeled on that region. Here, we chose the western district of Nakanoshima, a central business hub in the City of Osaka, a representative large Japanese metropolis.

As is apparent in Fig. 4, the western district of Nakanoshima is enclosed within two rivers and is comprised of (a) an area that contains a great profusion of commercial and business facilities and (b) an area that mostly contains an old college campus , small housings and a number of warehouses. Currently, the state of development in Nakanoshima varies greatly by district; and, even within the warehouse district, several large office buildings are currently under construction.

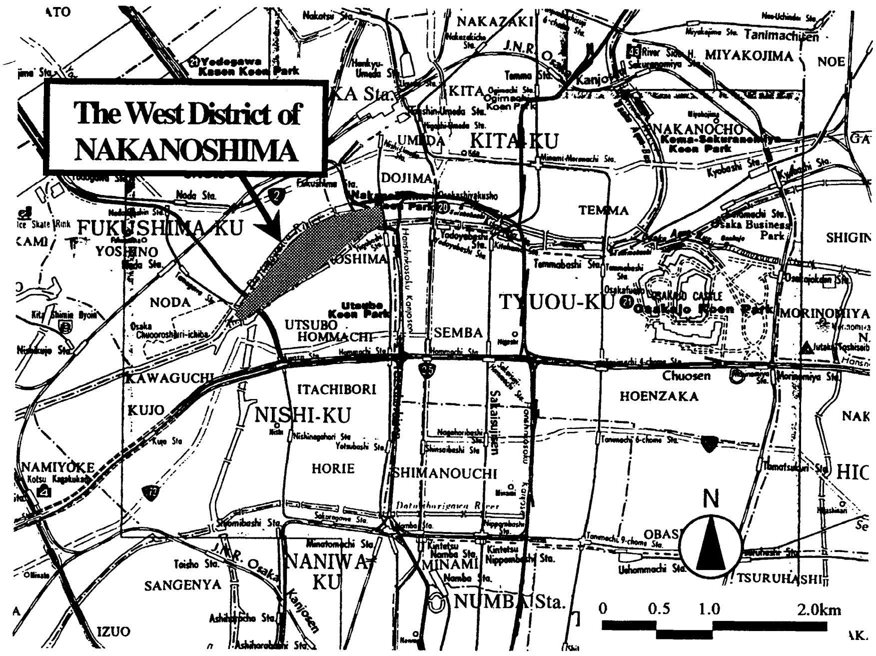

Figure 4. Osaka, the West Distric of Nakanoshima

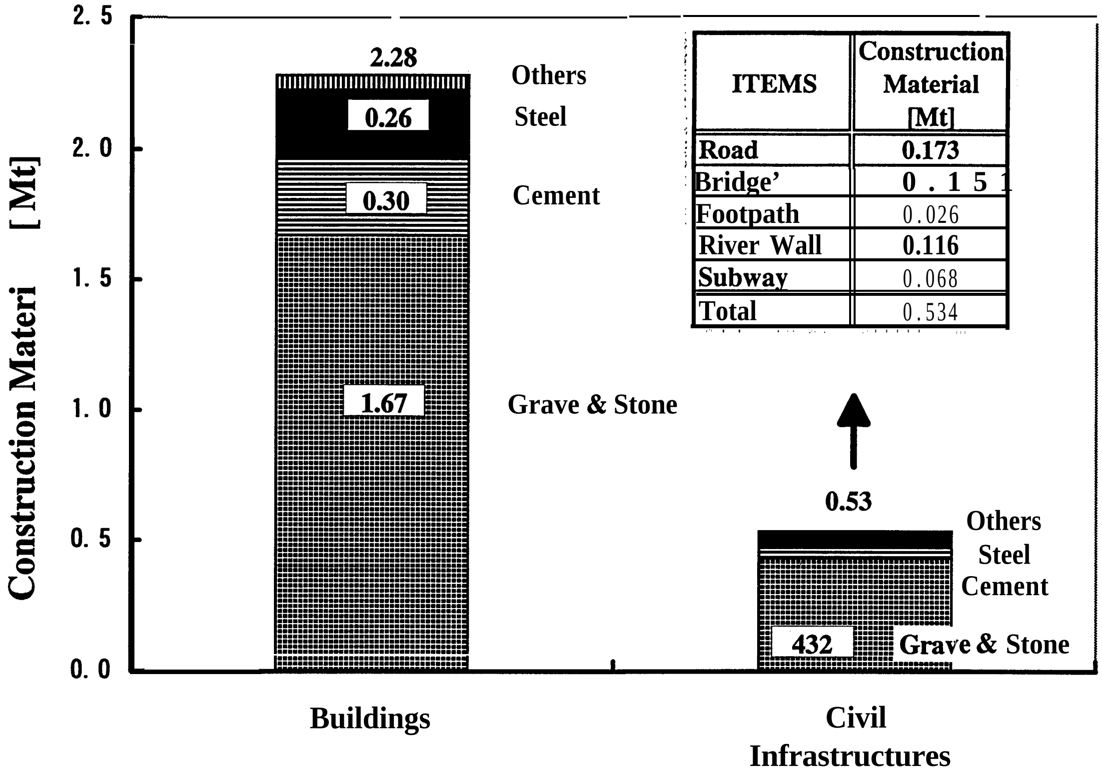
The total area of the district covered in this analysis is 33 ha, the total number of buildings in the district is approximately100, and the total floor area of those buildings is 778,510 m². Also in the district are 1,126 m (total length) of bridges, 4,991 m (total) of general roads, 1,252 m (total) of expressways, 768 m (total) of subways, and 2,843 m (total) of sea walls.

The consumption of construction materials in the district covered in this analysis is shown in Fig. 5. Fig. 6 presents estimates of the amount of carbon dioxide given off over the life cycle of these materials based on the average service life of current buildings and civil engineering structures.

Because we are still working to determine unit values for construction waste disposal, we are unable to present corresponding ‘results for construction waste volume at this time.



ITEMS	Construction Material [Mt]
Road	0.173

Footpath	0.026
River Wall	0.116
Subway	0.068
Total	0.534

Figure 5. Construction Materials

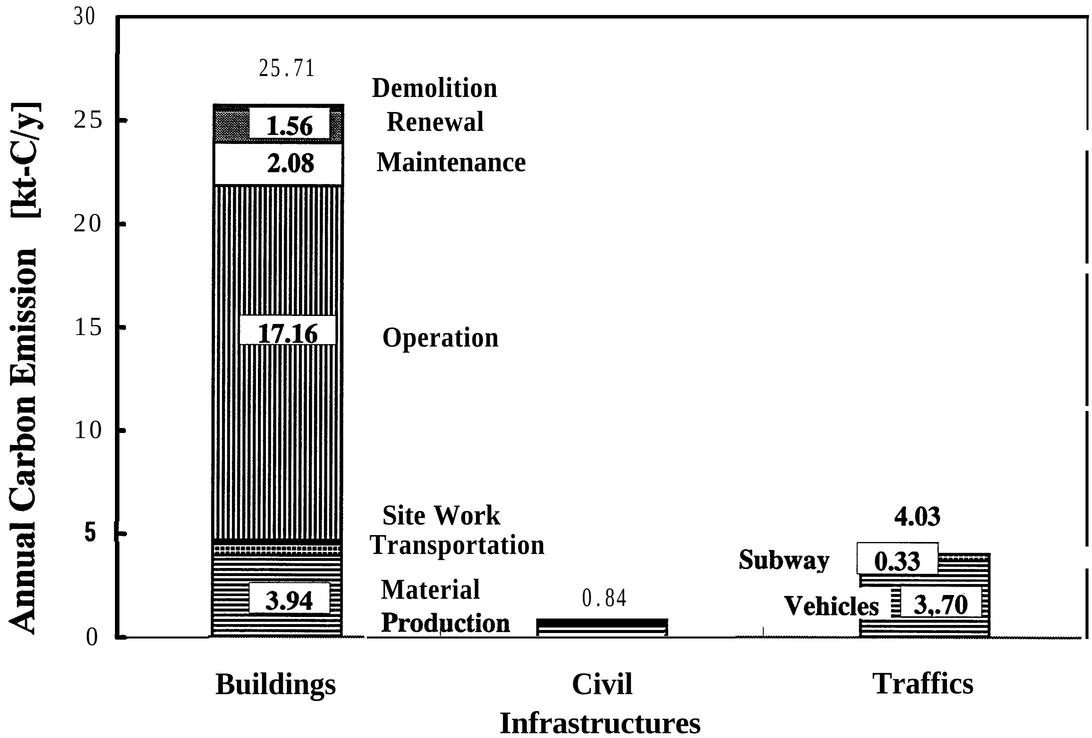

Figure 6. Life Cycle Carbon Emission

6 Conclusion

We have developed a method by which one can easily determine the long-term environmental load imparted by superstructures and infrastructures in downtown areas of large cities. This method facilitates the study and comparison of environmental load in and among (a) cases of natural renewal, in which the collection of urban structures is merely left as is, and (b) cases of planned renewal, in which various approaches are used to give a project directionality and consistency.

Four quantities were selected as indices for the environmental aspects of the analysis -- material usage, energy consumption, carbon dioxide emissions, and construction waste discharge. These indices can serve as a powerful means of assessing efforts to address the environmental problems typically encountered by cities.

While we envision that our method of analysis will be able to be applied in a universal manner to all major Japanese cities, as a first step we elected to apply the method to a central business hub in the City of Osaka, a representative large Japanese metropolis. We then began to analyze the above mentioned environmental aspects of area district over its life cycle. We found that, in the district covered by our analysis, the load relating to the operation(building use) stage accounts for a large proportion of the total.

From here, we plan to expand our numerical capabilities and conduct comparative calculations for cases incorporating a variety of concrete alternative plans for urban renewal projects.

Life Cycle Assessment and Indoor Environment Assessment

Jönsson Å.
Technical Environmental Planning/Centre for Environmental Assessment of Product and Material Systems, Chalmers University of Technology, Göteborg, Sweden

Abstract
Life Cycle Assessment (LCA) is frequently used as a tool for environmental assessment of buildings and building materials. Generally, the main focus of LCA is impact on the regional and global external environment. However, a considerable part of the environmental problems related to the building sector arise locally in connection with the indoor environment, like effects on human health. The study deals with what environmental issues arise for the external and indoor environment, respectively, in the building sector, how these issues relate to each other and whether some issues connected with the indoor environment may be included in an LCA. The study is mainly based on data from an LCA of three flooring materials (linoleum, vinyl flooring and solid wood flooring) and on measurements of indoor air emissions from these flooring materials. Methodological issues are pursued.

Keywords
building materials, buildings, floorings, LCA, life cycle assessment, indoor climate, SBS, VOC

1 Introduction

Life Cycle Assessment (LCA) is frequently used as a tool for environmental assessment of buildings and building materials. Generally, the main focus of LCA is impact on the regional and global external environment. However, a considerable part of the environmental problems related to the building sector arise locally in connection with the indoor environment, like effects on human health.

Research about the environmental impact from buildings and building materials has been performed separately for external and indoor issues respectively, and today this research is continued within two separate disciplines. In the last years, an increasing number of tools for environmental assessment have been developed. When constructing a new building today and when environmental concern is focused, there is generally a desire to minimise the total environmental impact on the external environment and the indoor climate at the same time, but there is a lack of knowledge on how improvements in one area affect the other. Hence, there is a need to map the correspondence between indoor and external environmental issues.

Final results of the study are not yet available. A report containing background data, final results and complete references will be published in spring 1998 [1].

1.1 Aims and objectives

The study deals with what environmental issues arise for the external and indoor environment, respectively, in the building sector, how these issues relate to each other, how they are dealt with in environmental assessment methods used today and whether some issues connected with effects of the indoor climate on human health may be included in an LCA.

1.2 Scope

Some main system boundaries and delimitations of the study are:

- flooring materials were chosen as object of the study
- the study mainly focuses on Volatile Organic Compounds (VOCs) as this is the environmental load most frequently considered when trying to assess the environmental impact on the indoor climate from flooring materials. Also, VOC is a parameter that occurs in several steps of the life cycle of flooring materials, both in connection with industrial processes, transports and the user phase
- non-industrial indoor environment was studied
- only LCA was included of existing methods dealing with impact on the external environment. However, some of the conclusions may also be valid for other methods.

The conclusions are partly based on data from an LCA case study of three flooring materials (linoleum, vinyl flooring and solid wood flooring) and on measurements of indoor air emissions from these flooring materials. Also, existing research in the fields of LCA, environmental assessment of building materials and buildings, VOC, indoor climate and human health was used to answer the questions above.

2 LCA , indoor environment assessment and VOCs

This section gives a brief theoretical background for what characterises LCA, indoor environment assessment and VOC measurements.

LCA is a method for analysing and assessing the environmental impact of a material, product or service throughout its entire life cycle, usually from the acquisition of raw materials to waste disposal. The environmental parameter groups most commonly accounted for in LCA are use of materials, use of energy, emissions to air and water and waste generation. International standardisation work on LCA takes place under the auspices of the IS0 [2]. The methodology of LCA is a systems analysis and generally consists of four steps: goal and scope definition, inventory analysis, impact assessment and interpretation of results. Generally, LCA input data and results have the following characteristics:

- the results are product oriented
- regional/global effects on the external environment are mainly focused
- input data consist of environmental loads (total dose), and mainly quantitative information is used
- in the improvement assessment, inventory data alone (environmental loads) may be sufficient for an evaluation, and when this is not the case the environmental impact of these loads may be assessed.

Indoor climate is a term used for describing physical factors in *the indoor environment,* like temperature, ventilation, humidity, air content of particles and gases, lighting and noise. The *indoor air quality* is one of the factors that affect the indoor environment, and it may be assessed by measuring what substances are present in the air (see for example [3]). Building materials is one of several emission sources that affect the indoor air quality. When, in a specific building, a larger quantity of users than may be expected have certain health symptoms (headache, itching, dry skin, eye irritation etc.) the term *Sick Building Syndrome (SBS)* is used. The indoor air quality is generally considered to be closely related to SBS, and emissions from building materials are often mentioned as one of the reasons for “sick” buildings. However, there is today no consensus on what health effects are linked to building material emissions, and how important these health effects are. Only in exceptional cases has a connection been found between SBS symptoms and the presence of specific building materials or building constructions. Factors that have been shown to influence the rate of SBS symptoms are cleaning conditions, occurrence of copying machines, insufficient ventilation, damage caused by damp and mould and occurrence of putty with a casein content etc.. Primary data and results used in indoor environment assessment may be characterised in the following way:

- the results are building related and site specific
- human health effects are focused
- the aim is often to improve a deficient indoor climate in an existing building

- input data for discovering the problem are generally qualitative and effect oriented, while in the improvement assessment both qualitative and quantitative information is used.

When studying the environmental impact from building materials during the user phase, *Volatile Organic Compounds (VOCs)* are frequently used as a measure, generally defined as those organic compounds that have a boiling point in the interval from 50-100 to 240-260°C. VOCs are regarded to affect the external regional and global environment as well as human health directly. For indoor air the VOC mixture is often expressed as Total Volatile Organic Compounds (TVOCs). As there is today a large variety of ways to calculate a TVOC value and there is no standardised procedure for how to do this, published TVOC data are often not comparable. Odour, sensory irritation and perception of discomfort are the main potiential health effects of VOCs indoors (see for example [4]). According to some sources, no clear difference in VOC concentrations has been found between "sick" and "healthy" buildings. It is today not possible to conclude that health effects like sensory irritation are associated with the concentration of TVOCs at normal exposure levels in non-industrial indoor environments. VOC emissons also have an important impact on the external environment as they contribute to an increased formation of ozone which will affect human health, cause damage on eco-systems like forests and agriculture and also inflict on global effects like the greenhouse effect. Some significant features for assessment of building related VOCs are:

- VOC measurements may be related both to a product (for example one m^2 flooring during a specific time period) and the indoor climate (as concentration in indoor air)
- the parameter is used both in a life cycle perspective and during the user phase
- human health effects in indoor climate and work environment are generally focused.

3 Including external and indoor environment in one method - State of the art

In last years, methods have been developed for assessing and comparing the environmental impact of building materials and buildings. It was studied if and how human health aspects were considered by some of these methods.

According to IS0 among others, the three general categories of environmental impacts that need consideration in an *LCA* include resource use, human health and ecological consequences. It may be concluded that, principally, LCA should include impacts on human health, both regarding occupational and work environments. Several actors working with LCA methodology have tried to include work environment issues in **LCA,** and various approaches are available for doing this [5]. However, not much has yet been done to include indoor climate in LCA. When it comes to the impact assessment step, several weighting methods have indices for VOC emissions, generally with the aim to decrease the impact on the global/regional external environment. Methodologically, it would be possible to include VOC indices based on local human health effects in LCA. Thorough knowledge would then be needed about what is the connection between VOC emissions and specific health effects.

Eco-labelling is one of the methods used today for minimising the environmental impact of building materials. The Svanen criteria document for flooring materials [6] is one such example. The document does not clearly account for what environmental issues are primarily considered. However, the intention is to consider factors that are of *major importance during the life cycle* of the flooring, that are *easy to measure* and that are *relatively easy for flooring manufacturers to influence.* VOC emissions are restricted in one aspect; a limit value is set for VOC emissions per m^2. This refers to the manufacturing process only, and nothing is stated about VOC emissions during use of the floorings.

As an example on the building level, *BREEAM* [7] was developed to set criteria for good environmental performance in buildings. This method seeks to minimise the adverse effects on the *global* and *local* environment while promoting a *healthy indoor environment.* Items are included for which there is *good evidence of the environmental problems they cause,* for which *performance criteria can be defined,* and which *can readily be assessed at the design stage.* The environmental issues covered are grouped under three main headings: global issues and use of resources, local issues and indoor issues. All indoor issues relate to human health, and mostly raise absolute demands on the whole building. No issues take VOC emissions into account, except for one criterium regulating formaldehyde emissions. The functional unit used for the final assessment is the whole building. However, for each criterium a specific functional unit is used (i.e. the environmental impact is assessed per m^2, per kWh, as volume percentage etc.). Also, some credit requirements are defined for the whole building, especially regarding local issues.

It may be concluded that several methods for building related environmental assessment include issues regarding both the external and the indoor environment. It is not always made clear what environmental issues are the main objective of the method and how external and indoor environment issues are weighted for the final results.

4 Empirical analysis

An *LCA **of** flooring materials* was performed at Chalmers University of Technology (CTH), in which the environmental impact of linoleum, vinyl flooring and solid wood flooring during their life cycles was assessed and compared [8]. Only impacts on the external environment were studied, and local indoor effects on human health were omitted. The parameter categories included to present the environmental load were use of resources, use of energy, emissions to air and water and waste generation. Values for VOC emissions obtained in the inventory were sometimes available as specific VOCs and sometimes as TVOC values. According to the inventory, linoleum caused the highest TVOC emissions and solid wood flooring the lowest. However, the difference between the floorings was not large, considering the data uncertainty. The quantitative results of the inventory analysis were then evaluated by using three weighting methods. According to the results from the impact assessment, the impact of VOCs was moderate compared with the total environmental impact, except for solid wood where terpene was the main contributing VOC parameter.

Another *case* study was performed at the Swedish National Testing and Research Institute (SP) [9]. The flooring materials vinyl, linoleum and wood were studied with respect to their *VOC emissions during the user phase*. Measurements were carried on for up to two years, depending on the material. The measurements were performed with a small model test chamber, FLEC (Field and Laboratory Emission Cell). The study was limited to measuring VOC, both as TVOC and as specific main components. Total VOC emissions during the user phase were then assessed, based on some assumed conditions regarding user time, room size etc.. There was a great difference between the floorings regarding what specific VOCs dominated the TVOC measure.

Based on the two case studies, the VOC emissions during the user phase were compared both over the life cycle for each flooring type and related to the total environmental impact of the life cycle of the floorings. It was found that TVOC material emissions during the user phase were of the same magnitude as for the rest of the life cycle. For the solid wood flooring, VOC emissions during the user phase far exceeded VOC emissions during the rest of the life cycle. Three weighting methods were then used to assess the importance of the VOC emissions from the user phase in a life cycle perspective. It could be seen that the user phase had a relatively small contribution to the total environmental impact of the floorings. Only for solid wood did the material emissions of the user phase play a significant role.

Some calculations were made, based on the case studies, literature data and some assumed conditions:

- the relative importance of VOC emissions from floorings for the VOC content in indoor air was assessed
- the contribution of VOCs from indoor air to the external environment was estimated, especially the contribution related to floorings and other building materials
- total VOCs from indoor air were compared with total statistical VOC emissions to the external environment.

5 Discussion and conclusions

Different approaches for building related environmental assessment were compared, and differences and similarities were discussed. Table 1 summarises some main characteristics for LCA, material emissions and indoor environment assessment.

	Life cycle assessment	Material emissions (VOC)	Indoor environmental assessment
Primary data	Dose Quantitative Measurements, calculations Independent of site	Concentrations Quantitative Measurements Site specific	Concentrations, health effects Quantitative, qualitative Measurements, experience Site specific
Environmental problems/effects	Regional, global External environment Contribution Exposure independent	Local Human health Contribution Exposure dependent	Local Human health Whole effect Exposure dependent
Functional unit	Building material, building	Building material	Building, individual
Life cycle steps	Whole life cycle	User phase	User phase
Influencing actors	Whole life cycle	Whole life cycle	Whole life cycle
Influenced actors	All	Users of the building	Users of the building
Results	Loads, effects	Loads	Effects

Table 1. Metodological comparison of LCA, material emissions and indoor climate related effects. Most significant characteristics are presented.

The final results of this study are yet to be published. However, some preliminary conclusions were drawn.

For the studied floorings, the VOC material emissions during the user phase were of the same magnitude as those related to the remaining life cycle. However, the impact of these emissions was marginal in a life cycle perspective when comparing it with the total environmental impact of the floorings.

Some methods for environmental assessment of buildings and building materials include criteria dealing with both external and indoor environment issues. Then for the final results external and indoor environment issues are evaluated either integrated or separated. It is not always made clear what environmental issues are the main objective of the method and how external and indoor environment issues have been weighted in the final results.

Methodologically, it would be possible to include indoor climate issues in the impact assessment step of building related LCA. However, no scientifically verified methods are today available for weighting effects on the external and indoor environment against one another. For building materials there is today no consensus on what health effects are linked to material emissions and how important these health effects are. The indoor environment is affected by the qualities of the building rather than by choice of specific building materials. Hence, issues concerning indoor environment effects on human health may be included in LCA of the whole building rather than in LCA of building materials.

In product related environmental assessment like LCA, environmental loads from processes and transports that may be related to the product are primarily taken into account. Likewise, in human health related environmental assessment like indoor environment assessment, data are primarily used that may easily be related to human health and the indoor climate of a specific building. It is hard to include these two approaches in the same method without making one of the approaches less effective. The method of LCA is not well suited to minimise either local health effects or regional/global total emissions, like national environmental goals.

Acknowledgements

The study is part of on-going research at the Department of Technical Environmental Planning at Chalmers University of Technology in Goteborg, concerning development of LCA in the application of building materials. Thanks are due to Torbjörn Svensson and Anne-Marie Tillman at Chalmers who have supervised the work, to the reference group that has contributed to the report by reading and commenting on drafts and to all other data providers. However, responsibility for the content of the study rests with the author.

Integrated life cycle design of materials and structures

Asko Sarja
Technical Research Centre of Finland (VTT), Espoo, Finland

Abstract
Integrated life cycle design is an important tool for sustainable civil engineering. It aims to concretise the multiple requirements of functionality, economy, resistance, aesthetics and ecology into technical specifications and further into designs of materials and structures. With this objective in mind we have to extend the scope of structural design and develop the design process. The extended design must also include multiple calculation methods in which calculations of life cycle monetary economy are added to those of life-cycle natural economy — in other words ecology. Safety and mechanical serviceability are guaranteed by traditional mechanical design with statistical and dynamics methods. Controlled technical serviceability throughout the target service life is guaranteed by durability design. Health is protected by methods of building physics, including hygrothermal physical and chemical methods. Design for recycling is a special area with its own considerations and methods. The selection of final solutions between alternative structural ideas, materials and products can be done by applying the methods of multiple requirements decision-making. Modular product and performance systematics can be applied at several of the design phases.

The methodology of integrated life cycle design can be used at the design of individual buildings or other structural facilities, as well as in the development of new materials and structures or structural systems.

Many research results exist which allow the introduction of new design methods into praxis. However, new basic knowledge is needed especially in regard to hygrothermal behaviour, durability and service life of materials and structures in varying environments. This knowledge will then have to be put into practice through standards and practical guides. The creation of new types of materials and structures in which the properties can be tailored to each specific need is of vital importance.

Before integrated life cycle design can be introduced into practice, many new guides and standards will be needed. Some such guidelines already exist as international and national standards, but do not yet suffice. Extensive education will also be needed to give practising engineers the required skills in the expanded design process and its methods.
Keywords: Design, life cycle, requirements, environment, integrated design, ecology, service life, durability.

1. Introduction

Our societies are living in a time of rapid change in which old values and traditions are being increasingly challenged Clearly recognisable in the building sector are pivotal changes in the goals and requirements of construction. The main trend is an increase in the basic requirements of buildings and building facilities /1/. Traditionally the four groups of requirements have been functionality, resistance, aesthetics and economy. To these we now to add ecology and general sustainability, and increasingly health aspects.

Sustainability must always be treated according to the life cycle principle — in other words with the application of life cycle methodology to design, manufacture, construction, maintenance, and the management of building projects, companies and other organisations in building. Referring to Fig. 1 we could give a technical definition for sustainable building as follows (Sarja, 1997) /2/: "Sustainable building is a technology and practice which meets the multiple requirements of the people and society in an optimal way during the life cycle of the building facility."

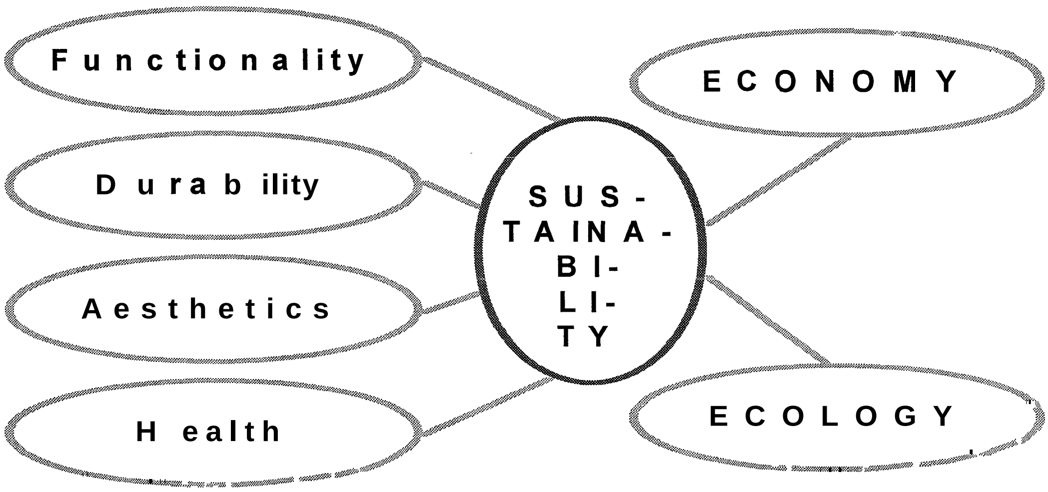

Fig. 1. Multiple requirements for sustainable buildings /2, 8/.

2. Principles of integrated life cycle design

2.1 Interpretation of requirements in economical and technical terms

Sustainability is related to ecology and economy. The ecological aspects include the quantitative goals regarding the consumption of non-renewable natural resources, the production of pollutants into air, soil and water and the qualitative goals regarding non-calculative effects like biodiversity and noise. Ecology can be interpreted as the economy of the nature (Sarja, 1995) /3, 4/. The term gives us a quite concrete starting point for the application of this aspect to materials and structural engineering and it can be concretised in the life cycle methodology in design, manufacturing, construction and management.

Through the principle of sustainability, resistance design will be expanded into durability design to include time as a new dimension in the design calculations. Health aspects are generally related to the control of moisture and thermal conditions and to special subjects like hazardous emissions from materials.

Design for recycling is an important tool for saving natural non-renewable resources and for reducing the environmental impact.

2.2 General framework and design process

The overall scheme of the integrated structural design (fig.2) includes the following main phases of the design process (fig.3): Analysis of the actual requirements, interpretation of the requirements into technical performance specifications of structures, creation of alternative structural solutions, life cycle analysis and preliminary optimisation of the alternatives, selection of the optimal solution between the alternatives, and finally the detailed design of the selected structural system.

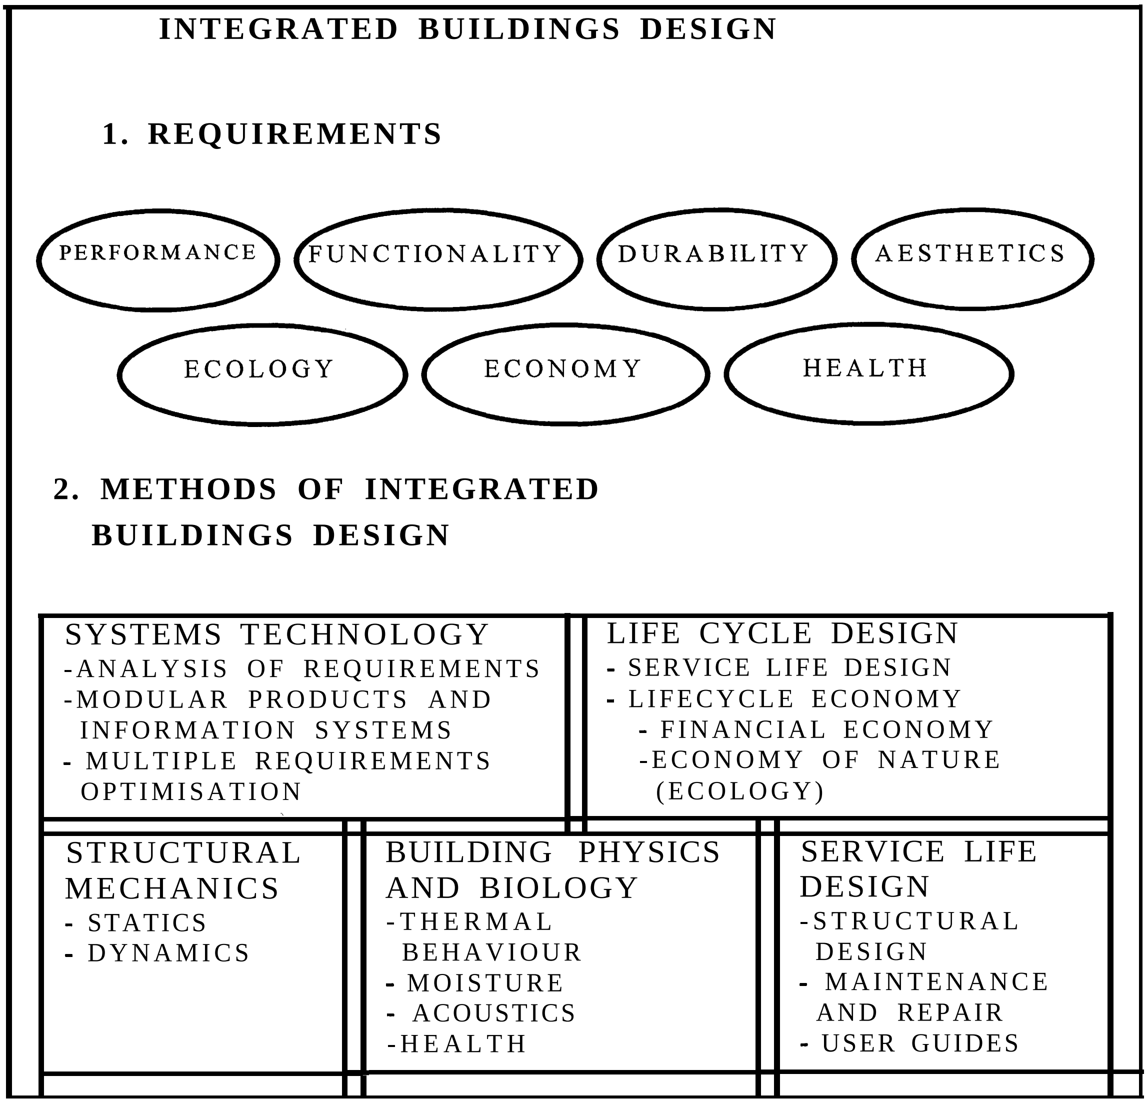

Fig. 2. Framework of integrated structural design (Sarja, 1996) /2, 6, 7/.

The conceptual, creative design phase is very decisive for utilising the potential benefits of the integrated life cycle design process effectively. This is the phase at which the design is done at system level. Modular systematics help rational design, because the structural system typically has different parts, here called modules, with different requirements e.g. regarding durability and service life requirements.

Controlled and rational decision making when optimising between multiple requirements with different metrics is possible through the application of systematics of multiple requirements decision making. All these aspects are widening the scope of structural design and construction to the extent that the entire working processes must be re-engineered. Close co-operation with clients and architects is therefore needed. In design, we can start to establish a new design process, or so-called integrated structural design, which is scheduled and described below.

2.3 Methods of the integrated life cycle design

The key issues from an environmental viewpoint are the life cycle monetary and natural economy, and the service life design.

The conceptual, creative design phase plays a decisive role in the effective exploitation of the potential benefits of integrated design. At that stage, the design works on a system level. Modular systematics greatly help rational design, because the technical systems typically comprise different parts, here called modules, each with different requirements as to e.g. durability and service life.

For life cycle design the analysis and design has expanded to two economical levels: monetary economy and ecology, which means the economy of nature /3, 4, 7/. Life cycle expenses are calculated at present value or in yearly costs by deducting the expenses of manufacture, construction, maintenance, repair, changes, modernisation, reuse, recycling and disposal. Monetary expenses are treated as usual in current value calculations. Those relating to nature are the use of non-renewable natural resources, the emission of pollutants into air, water or soil, and global warming. These impacts dictate the environmental profiles of the structural and building service systems. The environmental impact profile generally includes the consumption of globally and locally critical raw materials like energy and water and the production of CO_2, CO, SO_2, NO,, dust, solid wastes and noise. The aim is to limit and minimise natural expenses below the allowed values. Some ecological impacts, like noise and reduction of biodiversity, cannot be calculated, but must be considered separately during the decision-making process.

Safety and mechanical serviceability is guaranteed through traditional mechanical design with the use of statics and dynamics. Controlled technical serviceability throughout the target service life is guaranteed by durability design /9/. Health is protected through building physics including hygrothermal physical and chemical methods. The final choice between alternative structural ideas, materials and products can be made by applying the methods of multiple requirements decision-making.

The active reduction of wastes in construction and renovation is possible through designing for selective dismantling in renovation and for recycling of new structural systems, components and materials.

Currently, monetary and natural economies may stand in contradiction to each other because of e.g. differences in pricing and taxes between work and natural resources. Such instances lead to valuation problems, which must be resolved by the clients using their defined valuation within the framework of a society’s norms. Besides the calculated expenses are factors which cannot be numerically defined, such as the impact of construction on biodiversity and noise emissions. These must be evaluated and valuated separately by society’s general rules for individual design cases.

Introducing integrated design principles into practical design is quite an extensive process. Not only is the work of structural engineers changing, but the form of their co-operation with other partners of construction and use will have to be developed — particularly if the structural engineers’ expertise is to be maximally effective at the decisive creative and conceptual phases of design. This kind of co-operation also helps clients realise the benefits of investing slightly more in the structural design.

2.4 Factors of sustainability

Much sustainability analysis and assessment work has been done during the last decade. In most cases life cycle methodology has been applied. The results of comparisons regarding all types of main sustainability requirements, generally speaking, lead to the conclusion that differences between different materials and structural solutions of the construction phase are quite small. On the contrary, quite large differences can be found between life cycle sustainability factors of existing entire buildings or other facilities. The differences are caused by differences in the basic factors of sustainability, which are flexibility in design, changeability during use, durability by comparison with the design service life, and the recyclability of components which have quite a short service life. In order to focus on these factors it is necessary take a separate look at the different types of facilities.

In buildings the energy consumption is economically important and dictates mostly the environmental properties in the life cycle, the differences in environmental economy between different structural systems being otherwise quite small. For this reason, besides well-controlled heating, ventilation and heat recovery, the thermal insulation of the envelope is important. The bearing frame is the most massive and long lasting part of the building, and the durability and flexibility in view of functional changes, spaces and service systems are very important. The envelope must be durable and, as mentioned above, have an effective thermal insulation and a safe static and hygrothermal behaviour. The internal walls have a more moderate length of service life, but they have a requirement of coping with relatively high degrees of change, and must therefore possess good changeability and recyclability. An additional property of an environmentally effective structural system is a good and flexible compatibility with the building service system, as the latter is the most frequently changed part of the building. In the production phase it is important to ensure the effective recycling of the production wastes in factories and on site. Finally, the requirement is to recycle the components and materials after demolition.

Engineering structures like bridges, dams, towers, cooling towers etc. often are very massive and their target service life is long. Therefore environmental efficiency is tied to selection of environmentally friendly local raw materials, high durability and easy maintainability of the structures during use, minimising and recycling of construction wastes, and finally recycling of the components and materials after demolition. Some parts of the engineering structures like water proofing membranes and railings have a short or moderate service life and therefore the aspects of easy reassemble and recycling are most important.

All factors mentioned above are related to the properties connected to the function and performance of the facilities. We know that the decisive factor in our society is financial economy. The budget must always stay within the agreed limits and plays a major role when decisions between design alternatives are made.

Conclusively, the most important sustainability factors in performance for structures with long target service life can therefore generally be defined as flexibility towards functional changes of the facility and high durability, while in the case of the structures with moderate or short target service life changeability and recycleability are dominating. The competitiveness in sustainability between materials and structures focuses on the question of which materials and structures are able to be produced, designed and manufactured with skill and at the same cost, for the best sustainability of the building facility.

2.5 Modular systematics in design

In advanced building we can apply so-called modular systematics /10/. Modulation involves division of the whole into sub-entities, which to a significant extent are compatible and independent. Compatibility makes it possible to use interchangeable products and designs that can be joined together according to connection rules to form a functional whole of the building or another structural system. Typical modules of a building are the bearing frame, facades, roofing system, partition walls and building service systems.

Modular product systematics is firmly tied to the performance systematics of the building. For example, the main performance requirements of floors can be classified as follows:

1. Mechanical requirements, including
   - static load bearing capacity,
   - serviceability behaviour: deflection limits, cracking limits and damping of vibrations
2. Physical requirements, including
   - air tightness
   - acoustics: airborne sound insulation, impact sound insulation, emission
   - moisture tightness (in wet parts of the floor)
   - thermal insulation between cold and warm spaces
   - fire resistance and fire insulation
3. Flexible compatibility with connecting structures and installations
   - partitions
   - services: piping, wiring, heating and ventilation installations
4. Other requirements: buildability, changeability during use, easy demolition, reuse, recycling and wasting.

2.6 Recycling aspects in design

The consumption of building materials can be considerably limited with effective recycling and use of by-products like blast furnace slag, fly ash and recycled concrete. The components of the environmental profile of the basic materials already include the recycling efficiency, which means the environmental expenses in recycling. It is important to realise that the recycling possibilities of building components, modules and even technical systems must be reconsidered in connection with design. The higher the hierarchical level of recycling, the higher also the ecological and economical efficiency of recycling /3, 7/.

3. Research needs

Concerning materials and structures, new basic knowledge will be needed especially regarding hygrothermal behaviour, durability and service life of materials and structures in varying environments. Structural design methods will have to be developed that are capable of life cycle design, multiple analysis decision-making and optimisation. Recycling design and technology demand further research in design systematics, recycling materials and structural engineering. The knowledge obtained will have to be put into practice through standards and practical guides. The creation of new types of materials and structures, in which the properties can be tailored separately for each specific need, is of vital importance. Both strong and soft solutions must be sought, depending on the specific life cycle requirements. New creative innovations for applications of by-products and recycling materials from industry and general consumption are still needed..

Analytical comparison of buildings in terms of environmental impact criteria

M. Aygün
Faculty of Architecture, Istanbul Technical University, Turkiye

Abstract
The basic resource and waste utilization strategies for a sustainable environment in the context of buildings enshrine many exo- and endogenous factors influential to design. These factors implicate or embed the attributes of buildings for comparison. In order to quantify the effects of these building attributes on the environmental quality various parameters on energy and mass flows are designated as medium or effect oriented criteria, indicative of the performance of one or more attributes. The flows manifest cumulative ecological consequences at local, regional and eventually global scales. Some of the criteria pertain to more than one building attribute which may also be appraised by more than one criterion. The interrelated domains involved are the projects, elements and life-cycle of the conceptual building model. An algorithmic comparative method is proposed here for the environmental impact analysis of any one or all of these above. The main consecutive steps of the method are Environmental data acquisition, Synthesis and Result presentation. Any two of the four domains can be explored by each implementation of the method. The evaluation process of each step incorporates value normalization and aggregation augmented by the other supplementary statistical parameters of standard deviation and coefficient of variation beside the average for obtaining a single overall comparative indicator. If all combinations are to be explored than evaluation procedure proliferates and at each step several processes are executed. Alternatively, the procedure is repeated for each pair of the domains. The acquired data is evaluated in two consecutive stages by different sets of criteria. These stages employ the same procedure, but environmental and statistical criteria are substituted respectively. Each stage comprises the following steps: Selection of relevant criteria, their utility functions and weights, Calculation of absolute values of criteria, Conversion to weighted normalized (relative) values. Thus a more comprehensive representation of the environmental performance of each domain component becomes possible.
Keywords: Building performance evaluation, Environmental impact criteria, Life cycle assessment.

1 Introduction

Concerns on the total environmental quality become gradually more significant as natural resources, which are essential for the survival of mankind and his habitat, are being depleted at the current rate. The primary aim is to alleviate the adverse effects of artificial processes on the natural environment for restoring the ecological balance.

In the context of buildings, as a component of the artificial environment, the three interrelated domains involved are the projects, elements and phases of the conceptual building model. These are required to be examined in terms of medium and effect oriented impact criteria based on mass and energy flows which manifest cumulative effects at local, regional and global scales. Some criteria pertain to more than one building attribute which may also be evaluated by more than one criterion.

A brief review of some recent relevant works on this subject is presented as follows. Haagenrud and Henriksen review corrosion assessment studies for materials in the context of built environment degradation [l]. The mechanisms of the latter and the dose response functions are considered in terms of the concepts of critical loads and acceptable corrosion rates. Beccali and Cellura describe the comparative evaluation of energy and environmental performances of constructional alternatives as prescribed by the Electre methodology incorporating surclassment functions [2]. Le Teno and Chevalier modify the conventional life cycle assessment model to obtain an environmental quality evaluation model by redefining system boundaries on the basis of the practitioner's design constraints and goals and introducing environmental quality as an additional attribute [3]. Luetzkendorf describes a building product information system incorporating environmental, technical, health and cost data [4]. Weibel presents the cumulative normalized environmental effects of building materials to allow comparative appraisal [5]. Kohler and Klingele apply the life cycle assessment model in terms of energy and mass flow to the building as an object consisting of elements and phases [6]. Klingele and Kohler investigate the effects of decisions on design alternatives at various project phases on environmental performance in conjunction with a databank [7]. Adalberth presents a method to aggregate the embodied total energy consumption due to material manufacture, waste, replacement and transportation during the successive phases of building [8]. Aygun explores the effect of geometry on the energy performance of building blocks as expressed in terms of design parameters [9].

2 Conceptual building model

For the purpose of representing the building object as a physical entity, in the context of environmental impact appraisal, four distinct domains are prescribed here: Project, Elements, Life cycle and Criteria. These comprise groups of related attributes or components, whether physical or notional, describing various aspects of the building. While the first three, as the independent variables, are assigned nominal values exclusively, the last, as the dependent variable, involves values in ordinal, interval and ratio scales. The term performance refers hereafter to the environmental performance.

The model can be abstracted as a triangulated diagram with nodes representing domains, described below as synopses to examine their effects on the eco-balance, and edges representing relationships (Figure 1).

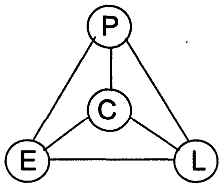

Figure 1: Nodal Representation of Domains

2.1 Project domain

Before taking any decision to proceed with a new building project the primary consideration should be whether this is absolutely essential. The overall properties are specified of those buildings to be compared in terms of their ecological implications.

Location: Rural, urban, suburban. Orientation, exposure, topography. Type: Existing, prospective. Historic, refurbishable. Form: Low or high rise. Compact, slender, irregular. Function: Residential, public, industrial, commercial. Chemical processes. Intensity, duration.

2.2 Element domain

Every building consists of functional elements which are reviewed in 3 categories and contain many physical components with different influences on the environment.

Infrastructure: Roads, paved areas, pipes, cables. Substructure: Excavations, foundations, basements. Superstructure: External, internal. Floors, walls (opaque and transparent parts), roofs. Configuration of elements inclusive of finishes and fit-out. Structure: Monolithic, loadbearing, frame, studwall, membrane. Services: Supplies of air (ventilation), water (cold/hot), space air conditioning (heating, cooling, humidity control), lighting (natural, artificial), power (electricity). Discharge of drainage (precipitation and waste water), garbage disposal and gas removal. Active, passive or combined systems. Distribution networks of ducts, pipes or cables. Mechanical devices of solar collectors, heat pumps, heat exchangers, energy converters, filters, HVAC. Local or regional services.

2.3 Life-cycle domain

The consecutive phases of the building life-cycle as transient states have different environmental consequences, which are determined by the building attributes. The type and quantity of energy consumed and waste produced affects the performance of each phase each of which also embodies energy due to extraction, transportation (horizontal and vertical) and replacement.

Manufacture: Raw or processed materials. Construction (erection): In-situ, prefabricated. Equipment. Preservation of natural assets. Occupation: User behaviour patterns. Efficiency devices of optimal start controls, sensors, thermo- and humistats. Maintenance and Repair: Durability(economic service life). Replacement. Chemicals. Refurbishment (renovation): Recycle, reuse. Demolition: Recycle, reuse.

2.4 Criteria domain

The basic resource and waste utilization strategies for a sustainable environment in the context of buildings are listed here as: Restriction on resources, Reduction of waste, Implementation of passive systems, Exploitation of renewable resources, Reuse or recycle of resource and waste.

These strategies enshrine many exo- and endogenous factors pertaining to the design of buildings: Orientation and location, Geometric form, Disposition of internal spaces, Primary function, Occupation pattern, Mechanical HVAC systems, Air infiltration and ventilation, Attributes of the external envelope, Waste recycle, Maintenance.

These factors implicate or embed the attributes of buildings in question. In order to quantify the effects of these building attributes on the environmental quality various parameters on energy and mass flow are designated as effect or medium oriented criteria which indicate the performance of one or more attributes. Some criteria may pertain to more than one attribute, which may also be evaluated by more than one criteria. The type of numerical criteria can be quantity, ratio or coefficient. Within the scope of this work the medium oriented criteria in the form of energy and mass are reviewed here in the two groups of Resources and Emissions. The former comprises those supplies obtained from the environment and the latter discharges from the building. The two sets of criteria below are non-exhaustive. Either one of them may be adopted for evaluation.

Medium-oriented Criteria

- Resources
  - Energy (embodied)
    (primary, delivered, useful)
    - Fuel
      (Renewable, Non-renewable)
    - Electricity
  - Air
  - Water
  - Materials
    - Natural (Organic, Inorganic)
    - Synthetic
- Emissions (Solid, Liquid, Gas)
  - Toxic/pollutant
  - Biodegradable
  - Non-toxic

Effect-oriented Criteria [10]

- Acidification
- Aquatic and terrestrial ecotoxicity
- Bio- and abiotic resource depletion
- Global warming
- Human toxicity
- Noise
- Nutrification
- Odor
- Ozone depletion
- Photochemical oxydant creation
- Waste heat

3 Method description

The main consecutive steps of the method are Environmental Data Acquisition, Synthesis and Result Presentation (Figure 2). Any two of the four domains can be explored by each implementation of the method. The evaluation process of each step incorporates value standardization and aggregation augmented by multiple statistical parameters. If all combinations are to be explored than evaluation procedure proliferates and at each step several processes are executed. Alternatively, the procedure is repeated for each pair of the domains.

Step 1 (Data Acquisition): The value of each criterion for all domains in a 3-dimensional matrix or a series of tables for all building alternatives.

Step 2 (Data Synthesis): Subsequently the individual values are aggregated, supplemented by multiple statistical criteria, to obtain average criterion values for the corresponding domains. For aggregating values with different units of measurement a normalization process is used as described later.

Step 3.1 (Inter-domain Results): The values from the previous step are aggregated for the pair of domains in question and presented in tabular form.

Step 3.2 (Intra-domain Results): The values yielded above are further aggregated in rows or columns, as appropriate, to obtain the average performance for each component of that domain. Finally, the components can be ranked for each domain.

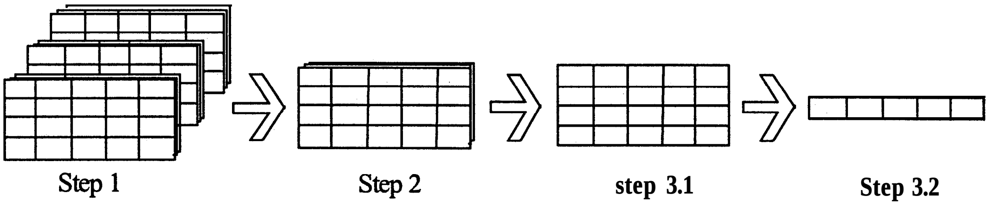

Figure 2: The Method Sequence

Whenever aggregation is to be carried out across different criteria at each step the values are standardized through interpolation prior to aggregation. Additionally, performance functions and criteria weights are applied. Beside the average, the process takes into account the supplementary statistical parameters of standard deviation and coefficient of variation for obtaining a single overall performance indicator. Consequently the initial average absolute criterion values are converted to absolute performance values and then to weighted relative statistical performance values. Thus a more comprehensive representation of the environmental quality of each domain value becomes possible. The acquired data is evaluated in two parts by different sets of criteria. These parts employ the same procedure, but environmental and statistical criteria are substituted respectively. The steps of each part are described below. The numbers in parentheses refer to the step in the flowchart (Figure 3).

3.1 Environmental criteria evaluation (B1)

1 Environmental criterion functions (1.1): Express the relevant environmental criteria as functions of exogenous and endogenous independent design variables for achieving the preset objectives

2 Environmental performance functions (2.1): Establish the appropriate environmental performance function for each criterion in terms of that criterion. This process can be concurrent with 2.2 as well as with 2.3. and 2.4.

3 Environmental criterion weights (2.2): Rank-order and draw hierarchical tree for objectives in order to set the relative weights of the environmental criteria with

respect to their contribution to achieve the objectives. This process can be concurrent with 2.4. as well as with 2.1. and 2.2. of the previous part.

4 Environmental criterion values (3): Calculate the environmental criterion values through that function for each domain component.

5 Elimination of building alternatives (4): Identify those eligible alternatives which satisfy all mandatory limits of criteria stipulated by standards, codes and regulations, directives, etc. or which attain above-average values for all criteria.

6 Absolute performance values (5): Calculate the absolute performance values through that functions of each criterion for the domain component.

7 Weighted relative performance values (6): Normalize environmental performance values by converting them from absolute to relative through linear or non-linear interpolation as required and apply the weights.

3.2 Statistical criteria evaluation (B2)

1 Statistical criterion functions (1.2): Select the suitable statistical criterion functions or approve defaults, i.e. standard deviation and coefficient of variation.

2 Statistical performance functions (2.3): Establish the performance functions in terms of statistical criteria or approve the defaults, i.e. linear function.

3 Statistical criterion weights (2.4): Set the statistical criterion weights to reflect the environmental objectives. The default weights are all equal.

4 Statistical criteria values (7): Calculate the statistical criterion values through that function for each alternative.

5 Absolute Statistical Performance Values (8): Calculate the absolute statistical performance values through that function of each criterion for the alternatives.

6 Weighted relative statistical performance values (9): Normalize statistical performance values by converting them from absolute to relative through linear interpolation and apply the weights.

7 Ranked shortlist (10): Prepare a ranked shortlist of satisfactory alternatives which attain above-average pre-normalized values for all statistical criteria.

8 Correlation between variables and ranks (11): Ascertain any effects of design variables on the rank of alternatives by correlation.

4 Discussion

The results in the penultimate step of the evaluation procedure are tabulated for any combinatorial pair of the four domains, namely project, elements, phases and criteria so as to compare the performances of their components. Consequently, six different tables can be obtained, each of which exploring the effect of one domain on an other. Furthermore the cumulative effects of the element and phase domains at different hierarchical levels can be investigated.

In the ultimate step of the procedure the components of one domain can be ranked in order of their overall performance , allowing the most satisfactory ones to be identified. For example, that building design alternative with the highest performance in any given set can be selected for further development. As for the other domains, those elements, phases and criteria relatively efficient or deficient in environmental quality can be ascertained.

5 Conclusions

As apparent from the preceeding description the proposed method of environmental appraisal relies on comprehensive acquisition and compilation of accurate data for all domains as a prerequisite. In view of the diversity of the various criteria involved in the process the practical constraints of obtaining this data in standard format and the absence of adequate database facilities inhibit as yet any effective large-scale application of this and other methods involving quantitative analysis. In this respect the direct use of ordinal values for the impact criteria may expedite the application process.

At present there is sufficient technical knowledge available for achieving improvement in environmental quality. However the main task remains to be the implementation of this knowledge in actual practice according to guidelines [11] and the immediate enforcement of current standards regulating environmental management and life cycle assessment [12].

Resolute and collective support of all efforts by scientific, professional, industrial, legislative organizations as well as individuals will contribute towards more sustainable natural and artificial environments through a balanced interaction.

Environmental relevant product information in the Dutch building industry

Agnes Schuurmans-Stehmann. and Joep P.R. Meijer
Environmental Department
INTRON BV, the institute for quality assessment in the building industry
Sittard, the Netherlands

The importance of environmental relevant product information as a tool to achieve product improvement is broadly recognised by the building industry, designers, commissioners and governments. It is also recognised that the information provided by the building industry must be based on a reliable standard method presented in a standard format.

The Dutch building industry has recently started the ‘MRPI-project’ (MRPI is the abbreviation of environmental relevant product information) in which a format is developed for the harmonisation, on the international consensus on Life-cycle assessment (LCA) and is adjusted to the specific needs of the building industry. Guidelines for LCA practice and communication of the results are developed.

The information is useful for several partners. Governments use this information for policies regarding sustainable building, researchers dealing with LCA in the building industry are supplied with well documented and reliable inputs for their databases and the building industry can focus on real product improvement rather than dissipating their energy in disputes about methodology, assumptions and reliability.

In this contribution the format and use of the format in the building industry is explained. The importance for international discussion as well as international projects dealing with this subject is mentioned.

Keywords: building industry, environment, LCA, MRPI, product information

1. Introduction

In the Netherlands the Ministry of Housing, Physical planning and Health (VROM) has developed a policy plan for sustainable building in 1995 [1]. One of the aims of this policy plan is the introduction of reliable standardised and quantitative information of building materials, products and elements. This information should be based on an integral life cycle approach. For this purpose the most appropriate and widely used tool is the Life cycle assessment, the LCA methodology. This aim is communicated, constructed and implemented in co-operation with the Environmental Council for the Construction Industry, the MBB, in which the building industry is organised. In 1997 the succeeding second policy plan for sustainable building strengthens the importance of environmental relevant product information for building materials [2].
As a result of this strengthened importance the building industry in the Netherlands, organised in the Dutch council of suppliers of the building sector (NVTB) has committed itself to make this information publicly available.
For this purpose in the first half of 1997 the NVTB has started the 'MRPI' project. MRPI is the abbreviation of environmental relevant product information.

2. The MRPI project

In 1995 the NVTB committed herself to provide reliable quantitative environmental relevant product information for all building materials applied in the Netherlands. The NVTB recognised that LCA is the most appropriate tool for this purpose. The choice for LCA is based on the policies from the national government and the MBB. Several producers have already carried out LCAs for their products. From experiences of these LCAs the NVTB learned that harmonisation of LCA practice is of vital importance when LCA results have to be compatible. The NVTB aims at a broad participation of it's members. Therefore the NVTB started the MRPI project in which interaction with it's members is the basis for this harmonisation.
The MRPI project aims at providing environmental relevant product information to several users in society. For this purpose it is agreed upon that a uniform format must be developed. This format must comprise guidelines to construct and present MRPI. MRPI is defined as *verified* information on environmental aspects of a building material, product or element that is constructed on the *initiative* of *the producer*, that can be used for communication to specific target groups. MRPI will be verified. This verification is still to be outlined. IS0 describes verification as a 'peer review', within MRPI it is thought of in terms of environmental declaration with a MRPI-label.

Another important aspect of MRPI is that it is constructed on the initiative of the producer. The MRPI shall therefore reflect, with the best possible data, at least the processes, which actually take place at the production site of this producer.

In the MRPI-project representatives of all different sectors in the building industry participate in three Working groups. In Figure 1 you see that the project is split up in three phases and a Working Group Data / format, Communication and Verification.. In this paper we will focus on the work of the Working Group Data / format.

Working Group Data / Format	**Working Group Communication**	**Working Group Verification**
Concept manual for MRPI Pilot projects Final manual for MRPI	Communication plan Format for presentation and communication of MRPI	Development of a verification structure

Figure 1. The Working groups and tasks of the MRPI project

Task one of Working Group Data / format is the development of guidelines to construct MRPI. Since MRPI is based on LCA the guidelines are based on the draft IS0 14040-series and the international developments from SETAC and SPOLD. The general guidelines are adapted to the specific needs and characteristics of the building industry.
The manual leads producers through the most important points of attention and choices to be made within LCA. Some choices are fixed based on consensus in the Working Group. For the elaboration of other choices checklists are constructed. In several cases the possibilities are indicated.
For example the target group for communication of MRPI must be chosen. The choice of the target group can differ from the National Package Sustainable Building from the Dutch national government to architects or researchers. All target groups have their specific needs and goals. Within MRPI it is tried to follow those needs as far as possible. This can imply different elaboration of the other choices within LCA.
The important items are listed in Table 1. As you can see some items still need to be discussed and elaborated. One item is the life expectancy of building materials, products and elements. Two directions are discussed, e.g. following the life expectancy guaranteed by the producer, or choosing the empirical life expectance. The discussion tends to the latter.

Table 1. Guidelines for LCA choices within MRPI:

Important items within MRPI	Guideline
• Identification of the goal and target group	Choice indication
• Construction of the functional unit	Checklist
• Description of the product	
Material list	Fixed
Replacements	Choice indication
Maintenance	Fixed
Life expectance	Fixed
• Choice of the system boundaries	
Phases f the life cycle	Checklist
Processes within the life cycle	Checklist
Process tree	Fixed
• Data categories	
Data categories	Fixed
Completeness per category	Fixed
• Allocation	
Multi-output and multi-input allocation	Fixed
System boundary allocation	Not elaborated yet
• Data collection	
For the production site of the initiator of the LCA	Questionnaire
Outside the production site of the initiator	Fixed
Literature data	Fixed
• Data quality	Fixed
• Calculation of the environmental impacts	Fixed

When the manual is followed the LCA results can be calculated and are ready to be presented to the identified target group.

Working Group Communication is working on a format for the presentation of MRPI. It is thought that MRPI can be presented as an A4-form, or environmental declaration. This declaration contains three levels of information:

- MRPI itself
  This are the LCA results expressed in several environmental use classes
- Scope
  The most important choices and system boundaries
- Qualitative information
  Optional space for verifiable producer specific environmental information, e.g. return systems, EMAS, etc.

The second task of Working Group Data / Format are the pilot projects. The members of the NVTB are invited to join these so-called pilots. In the pilots the producers and their associations are invited to screen the concept manual for practicability and to try to fill out the non-fixed items (see table 1). Four product groups are chosen:

- Roofing;
- Walls and floorings;
- Constructions;
- Window frames.

In each product group different producers participate. For example the choice of the functional unit is outlined. According to the experiences of producers, other projects in the Netherlands and the checklist form the concept manual it is tried to form consensus over the functions and quantification of these functions. Related to this functional unit the system boundaries and the material input is filled out. Per product group is determined which maintenance, replacement and life expectance are needed. In the pilots it is tried to find those material inputs and processes that are discriminating between different products which meet the functional demands of the functional unit.
For all items in Table 1 it is tried to seek for possibilities, solutions, or adaptations. The experiences of the pilots are used to adapt the concept manual and to elaborate the verification structure and content.

When the manual is adapted and the most important choices are filled out for the different product groups of the pilots, the producers and associations can start with the construction of MRPI. In order to guarantee that the MRPI provided meets the demands and consensus of the manual a verification structure will be developed. This verification guarantees that the MRPI provided is of the prescribed quality. The elaboration of the verification structure is still under study.
The verification will be based on the balancing the harmonisation principles within the manual with the accomplished choices within MRPI. This is essentially the same as the way that IS0 standards prescribe certain actions. However, the MRPI verification will be broadened and will not necessarily include a complete 'critical review'. For example the verification will be extended to the used data sources. For generic data such as energy generation and transport, but also transport distances, agreements will be made and will be verified. The result of the verification can be a label or certificate.

3. Related projects

The MRPI project goes in front of the developments. Throughout the world there is an explicit need for international discussions in the field of harmonisation of environmental product information. The MRPI project does not stand all by itself. In the Scandinavian countries analogous projects are initiated. For example by the SBI, the Danish Building Research Institute, in Denmark.

4. Conclusions

The MRPI project has two main accomplishments. The first accomplishment is the obtained participation of the producers and associations in the building industry. They have been introduced in LCA practice in with central focussing on discussions and consensus. They have been enabled to learn about the merits and possibilities of LCA for the elaboration and communication of the environmental performances of their products.
The second accomplishment is the obtained harmonisation. Harmonisation is accomplished with the construction of the manual. Also the pilots have contributed to further harmonisation of product group specific items which could not be standardised over the whole building industry. Therefore harmonisation is accomplished not only in LCA practice throughout the building industry but also for the product group specific needs and characteristics.

Structuring of data for LCA of buildings

T. Björklund
Technical Environmental Planning, Chalmers University of Technology, Goteborg, Sweden.
R.Carlsson, A.C. Pålsson
Center of Exellence, Chalmers University of Technology, Goteborg, Sweden.

Abstract
Inventory work for large life-cycle assessment may be facilitated by organizing data according to certain needs. A data structure for life-cycle assessment of Swedish building production is presented in this paper. The basis for the structure is the building component and activity table “the BSAB-system.” A combination of the structure and a computer based analysis software, which is able to support linking of data sets, may be a good support when enforcing system boundaries and performing hot spot analysis.

Keywords: LCA, Building, Environmental Assessment, LCA-data, database, data structure.

1 Introduction

There are several actors in the building industry engaged in different lines of work, but all related to the building. The view of the building as a system, that each actor holds, is not the same throughout the entire industry. The contractor may view the building as a collection of building materials and components that systematically have to be in-stailed to achieve a meaningful structure with agreed upon qualities and functions. On the other hand, the user of the building may see the building as a shelter with thermal, aesthetically and spatial qualities in focus. How the building is viewed, depends on the relationship that the actor has to the building [0], i.e. which life-cycle phase, of the building, the actor is involved in.

When looking at the environmental impact of a building and the process of producing and maintaining the building, the difference in view of the building as a system is important to have in mind, particularly when using Life Cycle Assessment (LCA) [1] as assessment tool. Two case studies [2],[3] which have studied the environmental impact of altogether eleven building frames, have been performed at Technical Environmental Planning, Chalmers University of Technology, Göteborg, Sweden. To be able to perform these studies, a structure for LCA-inventory data was developed. The systems view of the building which this structure supports, is the one of technical designers and the Swedish building material producing industry, hence viewing the building as a production process where flows of matter and energy enters and leaves the building over its life-cycle.

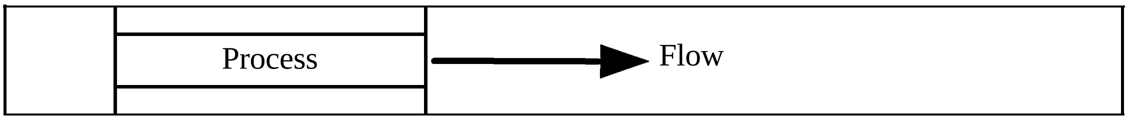
2 The data structure

The data structure had to fulfil1 some primary needs. They all sprang from one of the objects of the case study [2], which was *"...to create a computerized model structure for environmental assessment of frame structures, that may be used as a tool for improvement analysis."*

The structuring of data belongs, from a LCA methodological point of view, to the inventory stage. This stage is in LCA commonly subdivided in three phases: production phase, user phase and the demolition and waste handling phase. The structure primarily handles data in the first phase of the inventory, the production phase.

When contemplating on how to achieve a suitable data structure for a large LCA of a product system, it is important to recognize that there are at least two conceptual models [4] that have to co-operate. First the one of the production system and second the similar of the analysis tool, i.e. the formalized and interpreted model of how global environmental impact occurs. The building production system is a hierarchical system where materials are assembled to products that works with other products to achieve an even more complex product or function. This production system translates into material flows needed to fulfil1 the production phase (cradle to gate) part of the functional unit. As LCA is a flow analysis method, there was basically no conceptual difference between the production system and the tool, which the production system were to be analyzed with. This meant that the basic elements of the LCA (processes and flows, figure 1) worked well as basis for the environmental analysis of the production processes involved in the production phase.

Figure 1 Basic components of the Life Cycle Analysis method.



The data structure were designed to meet three different needs. The first need to met was to organize LCA-data in a pedagogical and “easy to find” fashion that is customary to the building materials industry and technical designers of buildings. The second need was to make the structure expansible and general for data to be added in the future. Finally, the third need to met concerned the organization of LCA-data for production, energy and transport processes in such a way that data would:

- not be redundant,
- be consistent,
- be easy to update,
- easy to use in the inventory process when ever needed,
- be independent of the goal of the study.

Since 1972 a system for describing the building and its components and materials has been a standard in Sweden [5] . The system is called the “BSAB-system” and it consists of two tables: one table classifying the building products by the technical composition of the product, the other table classifying the products by the technical function. For the structure, the latter table was selected as the organizing component to meet the need of information to be customary organized. However, an adapted version of the table was used (figure 2), developed by SBEF (the Swedish Building Contractors Federation). The SBEF-table solely classifies products and activities related to the production process of buildings while the BSAB-system is valid for all types of construction activities.

The need for a general and expansible structure was granted by the product classification table as well. The categories 0 to 2 belongs to activities connected to the building site, categories 3 to 5 belongs to the building envelop and load-bearing structure, while categories 6 to 9 are related to the specific use the building is designed for. Products and activities are being divided in categories by the classification, independent of what building actually is being built, thus making it general and expansible for all types of buildings, components and materials.
