Figures 6 and 9 show the emissions of gases that are acidic and contribute to the formation of acid rain. This can be transported over long distances and deposits especially in areas of high precipitation. Figure 9 in particular reveals that using public transport in London releases more SO_2 than commuting to the other sites even where singly occupied cars are the main mode of transport. This arises because of the SO_2 emissions from electricity production.

Figure 8 shows the carbon monoxide emissions from commuting to the different offices. Carbon monoxide is toxic to humans and animals. These results show that minimising car travel makes a major contribution to reducing this category of emission.

3 Progress of TRIP - Transport Implications from Buildings

To-date, this project has identified over 25 potential case studies in the UK across a wide range of buildings and types of organisation (see examples in Table 1). Offices predominate within the sample. The current phase of the project entails reviewing existing data about the building(s) and initiatives taken. The aims of this pilot phase are to define the starting point or reference case, to collate basic data and to determine the likely extent of potential energy savings and environmental impact reductions. The best 15-20 case studies will be evaluated in more detail using questionnaire surveys and energy audit studies-

Table 1 - Potential TRIP Case Studies in the UK

Organisation	**Nature of business**	**Location**
Argent Plc	Developers	London / B'ham
Hertfordshire C.C	County Council	Hertfordshire
Hobart Still	Manufacturers	London
Nat West Properties	Property Investors	Bristol
The Boots Company	Pharmaceutical / Retail	Nottingham
BT Workstyle	Communications	London
Hertfordshire University	University	Hertfordshire
British Airports Authority	Airport Authority	London
Oaklands College	Higher education college	Hertfordshire
Notts. Trent University	University	Nottingham
Hunting Gate Construction	Property mgt/development	Hertfordshire
Oxford Brookes University	University	Oxford
Nottinghamshire C.C	County Council	Nottingham
Surrey County Council	County Council	Surrey
Dr S. Roaf s House	Private, sustainable house	Oxford

Ideally case studies will show economic benefits to business or individuals, personal welfare and quality of life benefits to the occupiers as well as environmental benefits. These can in turn manifest in improved business performance both directly from reduced costs and improved workforce productivity and indirectly by demonstrating reduced environmental impacts from business operations.

Although no firm results from the study are yet available, the indications are that energy and monetary savings and welfare benefits to staff can be achieved, illustrated by:

- one organisation recorded a 13% reduction in car use by introducing flexible working hours with other measures.
- through a car sharing database and a bus service, one company forecasts a 10% reduction in commuter traffic by 2000, with a further 10% reduction targetted by 2005.
- a local authority plans to reduce singly occupied car travel to its main office sites by 30% by 1999, through the implementation of a commuter plan.
- for another organisation, incentives to use public transport have resulted in a 25 % increase in patronage on a number of bus routes, in the first 18 months of implementation.
- an educational institution offered free travel on city buses to staff for a week and recorded a 45 % increase in usage from staff living within the conurbation.
- One organisation is reducing the number of staff in a city centre location by 28 % (for financial reasons) and relocating them at telecentres at the periphery.

4 Conclusions

- The studies carried out at British Council and DL&E offices have examined the environmental consequences of transport and buildings only from an energy, resource and emissions standpoint. They have not taken into account the local environmental impacts of noise, dust, vibration and subsidence damage, traffic congestion and transport infrastructure visual impacts which are highlighted in local planning policies.

- The transport energy and environmental implications of buildings appear to be very significant compared with those for the construction and operation of buildings alone. Decisions made without taking account of transport energy use may result in sub-optimal consequences for the environment.

- Climate change and toxic pollution impacts are worse in buildings which encourage the use of private cars. Acid rain consequences are though, better in buildings that encourage the use of private cars by comparison with commuting to London on electric trains which use a large proportion of electricity from coal.

- Planners, construction professionals, buildings and business decision makers can therefore be highly influential in reducing the transport related environmental implications of buildings.

- As well as the environmental benefits, aconomic and social benefits may be obtained from initiatives that reduce the transport implications of buildings.

- The EC SAVE TRIP project will produce a portfolio of case studies to illustrate successful initiatives. The project will also produce benchmarks of performance for the transport-related environmental implications of buildings.

Sustainability & regional planning: Barcelona's area case study

D. Giménez, P. Alavedra, M. Casals
Department of Construction Engineering, Universitat Politecnica de Catalunya, Terrassa, Spain

Abstract
In this paper the authors have the proposite to study the sustainable concepts which should be priorities in the territorial planning of the Barcelona Metropolitan Area. Underlying the economics and social characteristics of the region studied and the tools of the territorial policy which are available for authorities to achieve the territorial arranging.

The methodology used is based on the general patterns to achieve the sustainable development like as Agenda 21, V Action Program in European view and eco-urban model. The working method applied is going to make up a selection of the most important objectives within local characteristics of AMB. With they, we are going to get a indicators that will be used in strategies configuration with sustainable objectives.

In this paper, we are studied the actual trends and the possible configuration of sustainable strategies.

The authors have considered the usual topics in the regional planning within this area, like as net services, mobility versus accessibility, the urban wastes, energy saving in building, the water and draining, protection of atmosphere, natural parks and humids areas.

The dynamic demographic and sustainability within the territorial planning should dominate the holistic concept in realign of the actual and new occupations, as a consequence of the expansion and dispersion of people in a urban continue, prolongation from the actual Barcelona conurbation to peripheries limits of the region.

The policies of nature protection (forest, fires, drought, erosion, water, flora and fauna) and the protection of the atmosphere should dominate against other actuation which looks like more urgency for the quality life of people.
Keywords: sustainable strategies in regional planning, sustainability and regional planning, sustainability in Barcelona's area,

1 Introduction to Barcelona Metropolitan Area

The metropolitan area of Barcelona is allocated in the north-occidental Mediterranean shore and constitutes the most important economic area in Catalonia, one of the three historical nationalities of Spain, with own government and parliament and also autonomous administration.

Catalonia is a Mediterranean country, but moreover is a European country and in the European union is shaped within the limits of euroregion, it constituted by Catalonia, Midi-Pyrinnes, and Llanguedoc-Rosello.

Catalonia is a mountainous country and its territory is raising from warm plane of Mediterranean coast to Pyrenees Mountains. This geomorphology give a lack of planes territories, with slope lower than 20%, and is essential because population, which is constituted by 6 millions, is allocated basically in planes areas of Mediterranean coast.

AMB is constituted by 7 historical counties with 162 towns and take up a surface with 3325 Km^2 and 4.2 millions of residents that represents the 70% of Catalonia totally people. The density is about 1.3 17 residents per Km^2 and constitute the double of the more urbanisation European regions. The most important urban area is the Conurbation of Barcelona, and it is integrated by 9 towns, with 168 Km^2 of surface and with 2.5 millions of residents, which are concentrated in a small territory, because its density is 14.700 residents per Km^2, higher than the density in the European metropolitan areas.

This density is reflected in the model of territorial occupation and it is, mainly, determined by Conurbation of Barcelona (CB) with its principal focus in the city of Barcelona. Constituting the most important phenomenon in AMB. This urban character determines all the effects over the environmental field.

The boundaries of Conurbation of Barcelona are natural limits constituted by Mediterranean coast in south, Collserola mountains in north, Llobregat river in west and Bessos river in east.

2 Territorial planning in AMB

The territorial policy was born from Territorial General Plan of Catalonia (PTG), on 1983. This plan was born to define the territorial equilibrium and to be the action shape.

The objectives, programs and facts realised during the last years in AMB has been oriented through one referent pattern: PTG.

The metropolitan territorial plan of Barcelona was done in 1987 to find the general objectives within PTC about soil regulation.

The Infrastructures plan of State (1993) determines a different kind of actions until 2007, which the most important are destined in Llobregat river. This activities want to alter the course of this river, to build one logistic area, to extend the Barcelona airport and, finally, to build the infrastructure of the T.A.V.

3 Environmental parameters of sustainable planning in Barcelona Metropolitan Area

The general patterns to achieve the sustainable development are Agenda 2 1, V Action Program in European view and eco-urban model. Work method to apply is going to make up a selection of the most important objectives within locals characteristics of AMB, and with it, to get a indicators that will be used in strategies configuration with sustainable objectives.

Section II of Agenda 21, destined to management and maintain the resources development, it looks the territory as a essential part where is possible developed the sustainable objectives, such as: resources management, avoid the deforestation, drought and blighting, sustainable agriculture, the sea protection, etc.

The V Action Program, in territorial order field, has a indirect effect because is referred to nature protection and biological diversity, environmental quality, based on the Green Book about environment, and also, protect the tourist impact in the offshore.

Eco-urban Model use own elements of the city and it is built from European model which keeps a central position in metropolitan urban.

4 Local limitations within sustainable patterns

The method used in regional planning about sustainable parameters is mainly based on Section II of Agenda , but also in the rest of the section.

The proposite of this paper is not a redact about a Local Agenda 21 for AMB, because the unique objective is introduce and underline the criterions for the selection of the themes which are prioritaries by the autors and should be implemented in sequential advance than the other topics.

A brief reflection about geophysics environment in AMB show as the region participates in general attributes of Spain, and also, in any of Catalonia. Spain has, in European category, a climate relatively warm and its population is concentrated in urban areas. There are so different characteristics through Spanish territory referent about climate, environmental norms and territorial regulations. Catalonia, for instance, has more laws and regulations than others regions in Spain about flora, soil and fauna which represents a advantage situation in sustainable indicators. However, Catalonia is the most industrialisation region in Spain and this industry is centralised in RMB, and it allows a particular characteristics when are determined the main objectives in social and economic sustainable development in the region.

On the territory planning of AMB would be desirable a holistic treatment of these territories that include different focuses and activities with integration, and therefore, avoid sectors more important than others. However, the few extension of AMB, is a limitation, and also, sometimes avoid a totally study and knowledge about this concept.

5 Sustainable strategies and actual trends

The last town-planning activities to prepare the Olympic Games on 1992 found a different and traditional type of problems associated within AMB, and specially in its CB.

These problems were solved by authorities used sustainable criterions, but more important was that a culture about territorial planning in quality life was created.

The result of this new policy will be explained in the following points.

5.1 Services nets

Actually, the AMB authorities include, in the territorial planning, the services structure which exchange matter, energy and information. It requires to build a nets that satisfying the transport through the knowledge of the future demand despite of in the territorial planning is difficult to know the future demand and tendencies that will be introduced on 2026.

Actual studies show as the last years, the services sectors had built the nets without co-ordination between sectors, avoiding minimise the occupation in the territory. The lack of co-ordination between sectors, and also, the few interest showed by authorities and politics about it, produces ecological, social and economics problems caused by the extensive occupation in the territory.

Services net reorganisation, represents an important expenditure because a bad planning was applied. In Barcelona, during the last 30 years, each year are opened 20.000 canalisation services. The investment of 180.000 millions of pesetas to build its ring ways, 30.000 millions of those were spent in services reorganisation because were affected by this fact.

The electric lines (more than 66 kV) have a surface of 10.000 Ha. in AMB, and is the same that the surface of Barcelona town. The whole of transport and communication nets occupy 25.000 Ha. within the region, when has 50.000 Ha. of urban soil.

Telecommunications nets must to be replaced every 15 year, energies net every 20 or 25 year and water channels every 30 or 35 year. To reduce urban environmental effect of these actuations, AMB authorities have proposed to build a social ways which will constitute the metropolitan avenue.

5.2 Transport: Mobility versus accessibility

A sustainable policy of transport in AMB must be oriented with equilibrium between cost-revenue analysis of private transport and cost-revenue analysis of public transport. This fact means that the private costs must be internalised (tax over combustible, tax by use of public ways, tax over station-places, etc.) and also the public revenues (advantages over public transport, increase the net, etc.).

The region needs a strategy to reduce the movement in it through a accessibility promotion as a central concept within a sustainable mobility policy. To promote the accessibility means: reduce the necessity and longitude in movements, reduce the inefficient car utility and promote alternatives transport systems. This policy of sustainable mobility needs urban actions, deep changes in town-planning, new technologies and changes in citizens actuations.

In town-planning model, the urban developments should introduce the different utilities and activities in holistic perspective . The new working methods derived from telecommunications may reduce the actual mobility.

Actual mobility treats in AMB are realised without sustainable mobility. For instance, the parameter of mobility raise on 1.2 times the PIB increment, and this fact has created a increment of travels between center-periphery and vice-versa , with raise of cars to CB, more use the private car against the public services, increases the urban congestion, etc.

To avoid these problems, and using the Agenda 21 and V action program models, authorities have introduced a Transport plan (PIT) between 1993 and 2005, and with it create a global transport system based on public services.

Will be important innovations with alternatives combustibles and with transport fashion, the new streetcar is an example.

5.3 The Urban wastes

In these moments the management policies in urban wastes in AMB is carry out by a unique authority, (EMSHTR) which regulates the metropolitan program in waste management. This program find to achieve a more sustainable development than the actual of it, with 10 years of place.

Program objectives include European norms and county legislation which maintain the sustainable development attributes.

In this program will be a important raise of services costs because will appear, step by step, rubbish dump and incinerators to preserve the environmental norms. The volume of this investment is about 47.000 millions of pesetas. This investment will be pay through FEDER and Financial Resources of Cohesion from Europe, County Government and different Towns.

To avoid uncontrollable actions with wastes will be apply a string between plane area and mountain area.

5.4 Saving energy and housing

In Spain, the saving energy measuring never has been successful within authorities and enterprises mentality because, on one hand, there are cheaper energy and on the other hand the climate is relatively warm.

Catalonia is one of the European countries where the industrial activities have a so important weigh within its economy. This fact determined that government five years ago begun renovation industrial programs in according to sustainable development. Thus, very much actions has been centred in optimise the energy use, to reduce the expenditure, and also, to achieve diversification and introduce news technologies in the firms.

The saving in the energetic efficiency field has been more than 275.000 tep/year, and the technology application in new generation has allowed a electric power of 500 MW in 1996.

In renewable energy field the programs and projects are frequents, and now , 7.5% of primary energy consume is cover by renewable energies.

In the building sector, the activities to promote energetic saving are not accept by partners and builders; the indirect revenue available through the investment in termic isolation is not attractive for theirs.

On the other hand, authorities promote technologies in this field. RMB has warm climate, the Mediterranean climate, characterised by short and benign winters, few rain, and with a summer period dry and hot

AMB has been the first region in Spain to substitute the traditional heating system based on coal, and after on gas-oil, by gas. This policy is carry out through the gas arrived from Algiers to Barcelona harbour.

This fact, has allowed measures to combat emissions of harmful gases, provoked by open fireplaces without filters.

Actually, the main calorific energy source on domestic and industrial uses is the natural gas. The last action to increase the consume of natural gas has been the gas pipeline built between Magrib and Europe.

5.5 Water and draining

The water in AMB has been a important objective by government and society, today the region has solved this necessity as consequence of the infrastructures built and the water management policy from the Catalonia rivers. The new necessities will be solved by water from France and other areas of Spain.

Actual draining policy of contaminated rivers, programs to build purifying plant, policies for saving water, eco-taxes, etc. keeps AMB as one of the most important areas in water management in Spain.

5.6 Climatic change

The programs in atmospheric protection to achieve a sustainable development are subsidiaries from the industrial policy in Spain. AMB participates in the increment of the emissions of harmful gases with 17% until 2010.

The industrial growth in the region is 115 Ha by year of industrial soil. This fact means that the region will increase the emissions of gases caused by direct incidence, transport and electric generation, or indirect incidence by consume effect.

In this question, AMB is not going to have sustainability, and authorities will must reinforce the programs with limitations and controls in the Region.

5.7 Natural parks and humid areas

Collserola Mountains constitutes within AMB its natural park. This park is constituted by Mediterranean trees (oaks, holm oaks and beeches,) which are not economically worked but have a town-planning pression. The forest fire is the most important problem. The policy is oriented to sustainable development, and the plans seek the environmental revenue, thus, the forest is used as a genetic reserve to maintain and create soil protected against erosion.

The small lakes in the south of AMB, constitute a special area of birds protection and is situated in the Llobregat river. The infrastructures which are building there, alter the curse of the river, the airport and harbour, can affect the European norms and are being studied now by one European commission.

6 Conclusions

With the study of sustainable and territorial planning of AMB we can talk about different conclusions. AMB is a region with extension limited, high density of population and with a industrial periphery that presents coast and forest attributes with warm and dry climate. This climate allows industrial, economic and social activities with European characteristics.

The infrastructures to be realized in the next future in this area could be irreversible for the territory and it advises to actuate with special care and attention to the ambiental protection.

The demographic dynamics and sustainability within the territorial planning should dominate the holistic concept in realign of the actual and new occupations, as a consequence of the expansion and dispersion of people in a urban continue, prolongation from the actual Barcelona conurbation to peripheries limits of the region.

The policies of nature protection (forest, fires, drought, erosion, water, flora and fauna), and the protection of the atmosphere should dominate against other actuations which looks like more urgency for the quality life of people.

Difficulties into application of the sustainable concepts on construction in Spain

M. Casals, D. Giménez, P. Alavedra
Department of Construction Engineering, Universitat Politecnica de Catalunya, Terrassa, Spain

Abstract
The main aim of this paper is introduce several aspects related with sustainable construction, in order to demonstrate the different points of view about focused actions in sustainability construction depending on the geographic and cultural perceptions.

Another aim is promote a general discussion about the different senses of the construction sector depending on the importance and local influence in each country and the difficulties for the administration to introduce, regulate and apply the general concepts that actually are developing in the international context.

This paper is based on a project developed by our Department focused in the evaluation of the problems and inconvenients on the application of the sustainable construction concepts in our specific country.

This project was divided in a few parts, depending on the subject of study. In this paper we will show the four mean parts of this work.

Concretely we will introduce the state of the life-cycle analysis in Spanish construction, the situation of the environmental impact studies of the building and materials, the construction waste management and the energy aspects of the construction process and the energy buildings efficiency.

All studies was made over several different points of view: designers, public and official institutions, clients, users, general people, builders and contractors, suppliers of equipments, producers of construction materials, etc, and in this paper we emphasize this most relevant aspects of each point of view.

In addition to this general ideas, we are going to comment the mean problems detected in each branch of the project under the different points of view. In case that we would have developed new tools to improve this applicability, we will comment these.

In the last part of this paper, we show a conclusions resuming the mean barriers to introduction of the sustainable concepts in construction discovered during the realisation of this project.
Keywords: barriers to application of practical concepts on sustainable construction, difficulties in practical application of sustainable construction, geographic points of view, problems in application of sustainability concepts.

1 Introduction

We accept that in general sustainable construction must be a respectful with the environment, with sustainable utilisation of energy (in Spain with special focus in solar energy) and taking in account the importance of attention to environmental impact that origin in some construction materials.

This work have an aim to check the applicability and feasibility of the concepts on sustainable construction in a European and Mediterranean country, with their own particular characteristics.

We have been working in the two last years with different approximations and ideas, and we have studied what subjects are more important in our country. The study is based in the perceptions of different involved parts: designers, public and official institutions, clients, users, general people, builders and contractors, suppliers of equipments, producers of construction materials, etc.

We are conscient that in this paper we don't have had in account the quality aspects directly related with sustainability, the performance of the buildings directly related with sustainability, and others basic aspects, but we only want to remark the different perceptions of the different parts involved in the construction process and the different points of view depending on the geographic and cultural characteristics of the country.

We want to introduce the idea that the final sustainable construction concepts should be developed from an cross-cultural point of view and taking in account the different regional and national perceptions and senses.

2 Study methodologies, current results and discussion

In sustainable construction, the author's origin (geographic origin and professional origin) determines the contribution made for each particular idea or model

According to this influence, we studied the adequacy of the different :international ideas and recommendations from our particular perception like engineers from an European and Mediterranean country.

So, we didn't study the implications looking for the way to change completely all our construction methods and ideas.

The study was made looking for the better ways to improve the environmental implications of the construction works.

We divided the study in five mean parts:

1. life-cycle analysis of materials and buildings
2. environmental impact of the building and the materials
3. construction waste management
4. energy perspectives of the construction process and energy efficiency in buildings

Following we introduce some ideas about each subject and make the discussion about the obtained results and main difficulties detected by the authors during the realisation of the general study.

2.1 Life cycle analysis

The aim of this methods are developing new products, or adapt the existing .products, from an environmental point of view.

Obviously the analysis must include the total life of the product, element or building: from the raw material extraction; the production of elements and their envelopes; the installation of the product; the use of this product and their final removal [1].

The own state of the art related with this aspect implies that would be necessary to evaluate the different life-cycle depending on the particular element or product.

The cultural and historical differences between countries provoke that the most used products in one country would be different than in other nearly country. For instance the evaluation of the ceramic materials life-cycle (bricks or ceramic covering) is a big priority in our country more than in other countries.

Another problems are the different ways to produce the materials, depending on the production technologies. Sometimes this industry is regionally important and is social and politically difficult to influence in it.

We must add to this scenario that this science is growing up from the union of several practical experiences, more than a general and structured strategy.

In the next future is necessary:

- obtain the support of the government in all the related aspects: information, control, regulations, economic incentives, R+D promotion, . . .
- convince to population on the importance of the use of well appraised products.
- introduce this concepts into client and designer strategy and into builder firms management strategy.

2.2 Environmental impact of the buildings and materials

The construction process must be considered like an another pollutant industrial process.

The main aspects are totally commons between construction process and others: raw materials extraction, installation elements, energy consumption and waste generation.

Although, from people point of view in our society, the construction process isn't considered extremely pollutant (less than textiles, metallurgic or another processes) and the environmental impact usually is falsely associated only with visual impact.

Under these general considerations, we can define the following mean single objectives under their associate whole objectives:

- mean single objectives: energy consumption reduction, raw materials consumption reduction, materials reprocessing.. .
- associate whole objectives: decrease CO_2 emission, preserve natural resources,. . .

Some international strategies of reduction of environmental impact could be:

- the use of reprocessed materials to make concrete.
- the general reprocessing of materials and construction waste [2].
- the reprocessing of construction waste from pulled down old buildings [3].
- the reduction of the environmental impact due to materials transport [4].

In this field, actually the designer could be able to introduce some sustainable concepts in the project stage only if the client accept it, due to we don't have regulations related with this subjects.

In relation to the environmental impact of the buildings and materials, the most relevant problems is that the designer would be able to know and master the sustainable concepts related with construction, and at the moment this isn't successful.

Another important subject is to provide effective evidences to the client to obtain the approval of the financial aspects and implications on use and introduction of these points of view.

In respect to the regulations of the construction process, the recent initiatives are in order to increase the health and safety in it.

In the next future, will be necessary to include the environmental aspects in the construction regulations, but this aspect at the moment is in the first stage of their development.

2.3 Construction waste management

In Spain, on 1996 was produced around 20 Kg of waste by person and day, and the 7 per cent of this weight are construction waste [5].

Actually the Spanish strategy in this field seems to be the minimisation of the waste construction production, the promotion of the reprocessing works and the optimisation of the removal of construction waste don't able to be reprocessed.

Furthermore, the existing demolition companies have problems with the new strategies and their compatibility with the current workers, methods and equipments.

Another problem is the different level of waste treatment in the different Spanish regions. For instance, in Catalonia, from 1994-95 we have clear instructions and regulations to realise the pull down of the old buildings [6, 7].

In addition, the regulations force to make the deconstruction project, with the working process necessary to pull down the building, the process liabilities and the final utility for the waste construction.

The main problem actually is to make feasible this objectives with the current dumps and the hardly existing reprocessing plants.

2.4 The relations between buildings and energy.

Under this subject, we consider two different aspects. The first one is the *Energy perspectives of the construction process* and the second one is the *Energy efficiency in buildings.*

Following with this studies, we considered that *Energy in the construction process* involve the energy included (i) in raw materials extraction, (ii) in the elements production including (iii) the energy cost of transportation until the construction site and (iv) in the installation of equipments and components. The total energy involved in this three first points is over the 85 % of the total energy involved in construction process [8].

In Spain the total energy necessary to build a house is upper to the energy consumed during five years.

The solution, obviously isn't in the construction site management. The future trends must go on direction to reduce the energy consumption in the materials production processes.

In respect to the second one aspect, the main energy efficiency objective generally is to design the building with a low energy consumption and using the local climatic and soil conditions of the particular region where is placed the building.

In Spain, this aspect includes the study of the correct location and orientation, the relation with the surrounding vegetation and the natural lighting. Obviously all this subjects are extremely related with the building design and the project, and they are related with the capabilities of the designer.

We can mention initiatives to develop studies related with use of natural cooling and ventilation of buildings, passive heating and cooling systems, solar irradiation protection, etc.

The mean problem is the treatment of the solar influence in the buildings. In the Spanish regulations about thermal conditions, the solar response in buildings isn't adequately treated. So, is necessary by the designers extend the studies during the design stage in order to appraise the future energy consumption in the buildings.

Another big part of this subject are related with the building services: lighting, heating and cooling systems, ventilation, energy management, water supply, draining systems, . . .

The current technologies to use in aim to increase the energy efficiency of the building services are:

- advanced lighting components,
- building control systems,
- air-conditioning (heating-cooling) advanced controls,
- energy co-generation and energy conservation,
- central production and solar production of hot water,
- water-separation between rain water and sewages,
- reprocessing of non-drinking water,
- ♏♦♍📪📪📪

This field is one of the most well-develop actually in Spain, due to the attractive market perspectives for the companies involved in this subjects. The reason is that the energy is directly related to the monetary costs, so, the users are quite interested in the use of this new elements, and another reason is the increasing use of these systems (advanced efficient lighting and air-conditioning systems) in housing, that extend the market for these suppliers.

3 Conclusions

We have explained our perceptions about some sustainable construction concepts and their application in Spain. In order to promote a general discussion between different geographic and cross-cultural research teams, our conclusions will be write only like a resume of the mean problems detected during this study.

We want to emphasise in our particular point of view, promoted by our particular construction needs, and remark that we don't want to develop a closed study and conclusions, and we don't try to export this conclusions to other countries that are working in this subjects.

So, the main barriers and difficulties on implementation of sustainable construction in Spain are:

- lack of information in general about concepts, about the use of this concepts and about the use of this concepts by the professionals involved in the construction process.
- lack of training in technical schools about environmental and sustainable concepts and their use and application.
- lack of culture on sustainable concepts for the people in general.
- lack of responsibilities definition in the construction process from a environmental point of view.
- lack of legal aspects and regulations to promote the adoption of this concepts.
- the point of view too much conservative of this industry, with tendency to use traditional designs and construction methods.
- the benefits from sustainable construction are diffused by general people.
- the difficulties to evaluate and quantify the environmental impacts of buildings and materials.
- lack of financial incentives. In traditional financial appraisals the intangible benefits of sustainable construction aren't usually included.
- lack of general pedagogy about this subjects. In general, people thinks that sustainable buildings are stranges things.
- the green labelled of some products for marketing reasons more than for environmental conditions of these products.
- the non-existent information about environmental responses for the most usual used products of construction-
- the great opposite inertia to change the regulations in order to force to introduce the environmental and sustainable aspects inside the technical information supplied to the designers and professionals.

Fragile networks and robust gates - A view on managing for sustainability

Stephen Emmitt
Faculty of Health and Environment, Leeds Metropolitan University, Leeds, UK

Abstract

As designers and specifiers of building products, architectural practices could be seen as important agents of change. Although a small proportion of architectural practices are leading the way through innovative design and the selection of new materials to achieve a sustainable goal, it has been argued that the majority of practices have been slow to change their behaviour, preferring to stick to well known design solutions and familiar products. This paper presents the findings of two separate but linked research programmes that sought to investigate how management techniques employed by architectural practices limit, and often conflict, with a desire to design for a greener environment. The research has highlighted some of the social and structural issues (often overlooked by the promoters of sustainable design) associated with the adoption of environmentally responsible ideals and practices, drawing on both diffusion of innovations and gatekeeping literature. The summaries of the research have indicated that the management systems employed by architectural practices in the form of both formal and informal gatekeeping systems limits specifiers' exposure to information about new building products. The newer the product to the practice, the greater its perceived risk and the greater the likelihood of it being rejected at formally established gates.

The architect is arguably the only player capable of providing the holistic view required to bring about quality and an ethical approach to sustainable construction, although on the evidence presented above it would appear that inertia to change is restricted through an attempt to manage risk, information overload and the effective use of staff time. Furthermore, the contribution to the specification process from other members of the temporary design team, such as the client, planner and contractor needs to be recognised and researched further since all of those involved in the selection of building products have a role to play in the quest for environmentally responsible building.

Keywords: Change agent, Diffusion of innovations, Environmentally responsible building, Gatekeepers, New product adoption, Risk management, Specification,

Introduction

For a conference concerned with building and the environment there is little need to repeat the well worn argument that something must be done to change the way in which we convert our relatively balanced natural environment into a relatively chaotic artificial one - fuelled through what Samuels [1] has called a lifestyle on the edge of chaos. The keyword here is 'balance' since the majority of literature concerned with the promotion of sustainable issues continues to be largely evangelical in nature and rarely based on examples of what is actually being done in practice [2] Furthermore, many firms are starting to claim through their marketing literature and mission statements that they are acting in an environmentally responsible manner, although research has found that such claims are exaggerated and their actions naive [3]. Indeed, the word 'sustainable', although in common usage is open to a wide variety of interpretations' for example it is used in the business and management field to refer to increasing nnarket segment, thus sustainable in this context has little to do with 'green issues'. Therefore the term 'environmentally responsible' is used in an attempt to convey the notion of individual responsibility for improving our environment, not merely sustaining it. So perhaps it is time to face the difficult questions and actually look at what is being done and how close (or far) we are from achieving some form of environmental balance.

If individuals within the building industry are to work towards environmentally responsible building, then all members of the building team will need to make a commitment, change their existing behaviour and start adopting new products, ideas and practices. But it is frequently argued that the pace of change in building is relatively slow, a phenomenon put down to the fact that people involved in building are uncomfortable with change. To a certain extent it may be true that there is resistance to the adoption of new technologies in the building industry, but the reasons are far more complex than merely being uncomfortable with change. The well established and well respected field of diffusion research helps to provide explanations as to why new ideas and products often take a long time to come into widespread use, or indeed fail to diffuse at all. Getting a new idea or product adopted is never easy, as Rogers [4] has pointed out: this is especially true of building where new products and product improvements, like established products, are all dependent upon decision makers in the industry for their selection, a process known as specification.

The diffusion work is important because environmentally responsible ideals and practices involve the adoption of both new technologies (hardware) and new ideas associated with it (software). Indeed, from the general diffusion model we should not be surprised if the adoption of environmentally responsible ideals and practices is a lengthy business. Diffusion literature has identified a number of factors that are influential in the diffusion of an innovation and although the field has been developing for over fifty years it is only recently that Rogers's model has been applied to the building industry [5]. Central to the diffusion and adoption process is the individual's 'innovation-decision process' during which the individual either ignores or seeks further information about a new idea or product. He or she must be aware of it in order to consider it for adoption.

As both building designers and specifiers of building products, architectural practices could be seen as important agents of change within the built environment. Although a small proportion of architectural practices are leading the way through innovative design and the selection of new materials to achieve a sustainable goal, it has been argued that the majority of practices have been slow to change their behaviour, preferring to stick to well known design solutions and familiar products [6], their palette of favourite products identified in earlier research. [7].

This paper presents the findings of a research programme that sought to investigate how management techniques employed by architectural practices limit, and often conflict, with a desire to design for a greener environment. The paper seeks to address social and structural issues frequently overlooked by the promoters of sustainable design in an attempt to identify the factors which may influence an architectural practice's design approach within a changing environment.

Fragile Networks

The building industry has a poor reputation for communication. A much cited study from the 1960's [8] drew attention to the lack of effective communication and also commented on the gulf between the designers and the producers, a gulf that has widened over the years. Building professionals rarely work together as part of a 'real' team but are brought together as consultants for one off projects, often with conflicting values and goals and also to the detriment of the product. The temporary project network that forms for each project does not encourage a consistent approach to improvement since networks break down when projects are complete, with individuals taking their experience with them to other temporary relationships. As technology has advanced and buildings have become more sophisticated the number of individual players involved in building procurement has increased, all competing for business in a very competitive market and all chasing after, in many cases, the same fee.

The combination of temporary relationships, a multi-faceted industry, and a variety of different technologies has resulted in over complicated procurement systems with associated complex communication routes. When problems have been identified, such as the architect's inability to manage projects, new management disciplines or niches are created to 'solve' the problem, in this case project management firms have claimed a foothold. Unfortunately these new intermediaries add a further strata, or another link to the chain through which information will pass. The large number of links in the product information chain hinders the opportunity for both continuous feedback and continuous evaluation of design and production. The prospect of improved feedback, so often lacking in the building process, will have implications for durability and in turn a serious attempt to look at the total product life cycle.

In recent years the communication field has been claimed by the information technology (IT) advocates who have claimed that communication will be improved by improved technology. An interesting example of this can be found in a paper by Li [9] who calls for radical measures, in the form of re-engineering, to improve the construction process. The paper states that "An important concern in construction re-engineering is to eliminate the delay of information delivery across different managerial and operational levels." and claims that a new intermediary, in the form of the IT manager, is the person to do it. Whilst we would agree with the quotation, the introduction of yet another link, or gatekeeper, to the product information chain is not the way forward. The greater the number of links in the chain, the greater the potential for ineffective transfer of information (regardless of the technology employed) and the greater the potential for gatekeeping of information.

Robust gates

The filtering or management of information is referred to as 'gatekeeping' in mass communication literature [10]. Any person within the information chain will, to varying degrees, control the information that they receive and pass on to the next link in the chain, thus acting as a gatekeeper to the flow of information. The construct of the gatekeeper was introduced to architectural management literature [11] and has since been extended to encompass the product quality chain [12] in which the gatekeeping model is used to explain why communication within the building industry is ineffective. More specifically, the gatekeeping construct is helpful in looking at how information about building products new to the architects office is communicated to the potential specifiers in the office. In a recently completed piece of work [5] the combination of the gatekeeping model and the diffusion of innovations model was demonstrated and supported by observational research. The new model, based on the specifier's innovation-decision process can now be used to assess the adoption of environmentally responsible products. For the purposes of this paper two pieces of research, carried out separately, but linked, are summarised below.

Summary of the gatekeeping research

A small number of interviews with senior partners, their receptionists and trade representatives were carried out, with the objective of trying to identify the gatekeeping mechanisms employed by private architectural practices [13]. The research found that the architectural offices visited were very resistant to information about new building products, concerned about product failure and the legal implications associated with selecting new products.

Trade literature was assessed subjectively and very quickly by the senior partner who threw approximately 80% away every day. The 20% or so of information allowed through this gate was filtered again in all but the very small practices by a less senior member of staff before it was allowed into the office library where it may have been used by the specifiers in the office. The specifiers who actually selected building products were not involved in the gatekeeping process, but were affected by decisions taken by the gatekeepers because their access to, and awareness of, information was restricted.

The partners also reported that they were unhappy with the quality of the literature provided by the manufacturers and did not like being ‘pestered’ by the trade representatives, who were only invited into the office when they were needed. The trade representatives were aware of the difficulty of getting their ‘foot through the door’ of the architect’s office and had concluded that architects were, for the most part, not interested in new products.

The research found that gatekeeping mechanism were in place, regardless of office size, for two reasons. First, to control information from a risk management viewpoint. The gatekeepers hoped that their experience and their professional judgement would prevent the specification of unsuitable products by other, less senior, members of their office through limiting the information and hence choice of products from which to specify. Second, trade information was filtered to manage information overload by reducing the physical amount of literature entering the office - this was a secondary concern but was linked to risk management. The research highlighted the need for some observational research to record what happened to the literature as it came into an office, found its way (or not) to the specifiers in the office and how the specifiers responded to this literature, reported below..

Summary of the diary of adoption

A number of building products, new to an architectural practice, were monitored over a three year period in an attempt to see when, why and how they were specified through participant observation from within the office. The research was important in recording the senior partner’s gatekeeping actions, the action of the technical partner who acted as a further gatekeeper, the behaviour of the staff who were selecting products from filtered information and the contribution to the specification process from members of the temporary project team, external contributors.

The observations supported the views reported in the gatekeeping research above, with regard to the complexity of the gatekeeping mechanisms. It was evident that the specifiers only sought information about new products when their palette of favourite products did not contain information that was suitable, hence leading to an active search for new information. The importance of the palette of favourite products should not be under estimated since it forms a barrier against the consideration of new products. This, combined with the formally established gatekeeping mechanisms provides a strong barrier to the adoption of new products that may have better environmental credentials.

In one of the situations observed, a planning officer put enough pressure on the architect to force a change of material, from timber boarding (from a renewable source) to a manufactured product (non-renewable source), simply because he did not like the appearance of the timber boarding. However, there was no discussion about the environmental implications of such a decision. Furthermore, there was no evidence in any of the observations that the environmental implications of specifying products, changing them prior to the start of a contract or during the contract (specification substitution) had been considered. Instead the pressure of time, observed in both the pre-contract and post-co-ntract programmes was an overriding factor. Although the research was limited in its scope and was based on traditional procurement systems it does provide detailed case studies of the specification process from inside an architect's office, based on observation rather than memory recall.

A view on managing for sustainability

The issues reported in the research above were confirmed in separate observational research [5] As- such it is useful in highlighting the complex issues associated with the adoption of new products, both from architectural offices' use of robust gates and the pressures exerted from members of the temporary project team, the fragile networks.

In both research programmes it was evident that the firm's senior partner, the gatekeeper, was controlling the flow of information to the specifiers in the office, in some instances assisted by a second gatekeeper (a senior member of the office). We should not be surprised by this since senior partners will wish the office to act collectively in his or her image by following certain design approaches, through limiting the use of unfamiliar (thus risky) products and limiting the time spent by staff researching them. Thus it is the partners of the firms who clearly have significant influence over the use of new products and to which the environmentally responsible argument should be directed if an architectural practice's design approach, within a changing environment, is to change.

In the second research programme the importance of external contributors to the process were noted. These ranged from town planning officers requesting changes to external materials, quantity surveyors suggesting cheaper products to reduce the overall (initial) cost of the building contract, and contractors attempting to change products to cheaper alternatives both at the tender stage and whilst construction was ongoing. Perhaps more importantly, the adoption of building products that were new to the office was shown to be a rare event and difficult to observe.

The research summarised above has practical implications for specifiers and for manufacturers of new products given the emphasis on sustainable design and the selection of 'green products'. Since these products will be perceived as innovations by specifiers (and therefore assessed against existing behaviour, represented by the palette of favourite products) the adoption of such products is likely to take longer than the proponents of environmentally responsible design would like to believe. Indeed, it is likely that many of these products will be stopped at the architectural office's formally established gates because of both their unfamiliarity and the perceived risk of using them. Furthermore the research highlighted the pressure put on the specifier to change products that were unfamiliar to them, to ones that were. Again it is reasonable to assume that 'green products', if specified by the architect, may be substituted by more familiar products during the detail design and construction phases, the innovation-decision process.

The use of electronic media, such as CD ROM and the internet may help the manufacturers to overcome (or get through) the gatekeeping mechanisms employed. But firms are reluctant to pay for a service they can get free through the post in the form of paper literature. The Building Research Establishment have pioneered the 'Information Gateway' [14] although there are problems here in policing the information provided on the inter-net for accuracy. If manufacturers could get together to provide reliable, up to date information that clearly identified the product's environmental credentials (rather than marketing hype) via the internet they will have an ever open gate to the specifier. However, it should be noted that such a system is, according to the research reported above, still reliant on specifiers looking outside their palette of favourite products.

Conclusion

This paper has attempted to highlight some of the social and contextual issues associated with the adoption of environmentally responsible ideals and practices, drawing on both diffusion of innovations and gatekeeping literature. The summaries of the research have indicated that the management systems employed by architectural practices in the form of both formal and informal gatekeeping systems does limit the specifiers exposure to information about new building products. The newer the product to the practice, the greater its perceived risk (consistent with diffusion research) and the greater the likelihood of it being rejected at the formally established gates. As such the actual specifier is, for the most part, denied access to information about new products unless awareness comes from a source that has by-passed the formal gates.

The- architect is arguably the only player capable of providing the holistic view required to bring about quality and an ethical approach to sustainable construction, although on the evidence presented above it would appear that inertia to change is restricted through an attempt to manage risk, information overload and the effective use of staff time. Furthermore, the contribution to the specification process from other members of the temporary design team, such as the client, planner and contractor needs to be recognised and researched further, since all of those involved in the selection of building products have a role to play in the quest for environmentally responsible building.

Research for Sustainable Development in the Construction Processes

J. Borgbrant
Department of Construction Management, Lulea University of Technology, Lulea, Sweden

Abstract

A lot of good technical research is produced, unfortunately the results are not always used properly in the construction processes and resources are wasted. This implies that more attention must be focused on implementation and change.

There is also a need for clear communication and agreement between different interested parties and participants to achieve research that provides a contribution to the sustainable development of society. An increased understanding and respect for different types of research and research processes will also contribute to a sustainable development in the construction processes.

The purpose of this paper is to describe four different research processes depending on the different aims for the research. The model presented, hopefully, can be a frame of reference in discussions between research departments, customers, clients and researchers.

This paper is based on a report produced in co-operation between the Productivity Group at the Danish Building Research Institute, the Department of Construction Management at Lund University and the Department of Civil and Mining Engineering at Lulea University of Technology.

The intent of the design description is to clarify the profile of the research project as a whole. This includes decisions regarding type of research, i.e. whether the project shall be given a descriptive, evaluating, change directed or theory building design. It is also done in order to judge the research question relative to cost, time and available resources as well as its practical application.

All types of research (technical, economic, behavioural.. .) must be used to contribute to sustainable construction. All partners in the research process must understand the limitations for each type of research.
Keywords: Change, design, development, evaluation, process, research, research methods, scientific society.

1 Introduction

Research contributes to changes and development of various functions in society. At the same time, research is influenced by the society such as changes in business activities and political decisions. With research departments as a part of the society, there is a need for clear communication and agreement between different interested parties and participants to develop research which makes contribution to sustainable development. Constant changes in society mean that researchers are continually faced with new demands and challenges. It is important that the research process supports a sustainable society from the perspective of environment, technology, economy and humanity.

Much technical research is produced, but unfortunately the results are not always used properly in the construction processes and resources are wasted. This implies that more attention must be focused on implementation and change.

The purpose of this paper is to describe four different research processes depending on the different aims for the research. The model presented hopefully can be a frame of reference in discussions between research departments, customers, clients and researchers. At best the model should increase the understanding of each others roles and responsibilities in decision making, planning, producing and reporting the results of research and it will be clear what contribution research can make.

This paper is based on a report [1] produced in co-operation between the Productivity Group at the Danish Building Research Institute and the Department of Construction Management at Lund University. Both institutions have a common interest in strengthening the development of the construction process. In the final stage of the work, the author was appointed Professor at the Department of Civil and Mining Engineering at Luleå University of Technology, and then this department also become involved in producing the report. The methodological literature used in the process of making the report is printed in chapter 5 [2-14].

The research at the various institutions is focused on different phases of the construction process; design, planning, production and maintenance. Research questions which are dealt with are found within different areas such as housing costs, cost development, choice of materials, building physics, load bearing structures, questions on quality, structural design and environment.

The departments also look into how research results are adopted to contribute for sustainable development in the construction area and what are the consequences for new knowledge within the building process. Examples of research areas are:

- How to evaluate the developing process of construction business
- How different areas in the production process interrelate

The common starting point for research activities has to be to achieve a better insight into the building process. A holistic understanding is reached by collaboration and teamwork between researchers and the partners of the building process. This also contributes towards research that is easily applicable and useful. An ongoing development of knowledge about the building process is undertaken on the personal initiative of the researchers as well as through communication and co-operation with the industry, other researchers and experts in the areas of specialisation that are affected. In this manner, the building process is in focus from both an economic, technical and social perspective. Research should be given the direction and status it needs in order to gain the respect of the scientific world. At the same time, it should be easy to understand and to apply within the building sector.

2 Research design

To provide relevant results, the research projects has to be properly designed. A comprehensive view regarding the intent, planning, conduct, expected results of the research project as well as aspects of implementation must govern the project work.

The intent of the research design description is to clarify the profile of the research project as a whole. This includes decisions regarding type of research, i.e. whether the project shall be given a descriptive, evaluating, change directed or theory building design. It is also done in order to judge the research question relative to cost, time and available resources as well as its practical application. The research is also influenced by ongoing international research. This means that when creating the research design, the researcher defines activities, target groups for collection of data as well as economic and time frames for the research project. Research design also includes an estimate of the accessibility of data along with a description and reasons for focusing and scooping the content at the research. Pre-studies and reference groups, if any, are described by function and planning/disposition together with the organisation and available resources of the project.

The research design has to be realistic in relation to prevailing economic frameworks, accessibility of information and other prerequisites for the project. The research design created by the researcher is analysed together with customers, clients, researchers and representatives from the management of the department, instructor/supervisor and financial suppliers. It is important that the researcher has an understanding for both the building process and the research process when choosing research method. The choice ought to be done in relation to both the object being built or the production process which will be studied, as well as the type of research which is intended. Qualitative methods are often most suitable, when doing research related to the process of change, as this type of research involves questions which are described using a large number of non-quantitative variables.

3 Four types of research designs

The matrix in table 1 describes the intent and direction of research relative to choice of research question, choice of method, collection of data, analysis and presentation of results. The horizontal axis of the table describes the research process and the vertical axis the type of research. The research design describes the type of research and all steps in the research process.

		Research process				
Type of research		Research question	Choice of method	Collection of data	Analysis	Presentation of results
1	Change/ Influence	What and how to change	Case studies of change in the organisation/ work-site	Observations and questions	Data feedback, expanded collection of data	Work material, Seminars, reports
2	Evaluate/ Describe	Characterise study of material, behaviour and processes	Surveys at different study objects	Quantitative/ qualitative surveys	Description (part, whole) connection/ reason	Pedagogic presentations
3	Theory or model development	Develop new theories/ models	Studies of published results	Collecting results of empirical and theoretical studies	Combine known knowledge into new structures	Models or theories presented in articles
4	Tests/ Examinations	Behaviour of material/ people in controlled situations	Laboratory tests, experiments	Measurements, simulations	Testing of hypothesis	Scientific papers

Table 1. Type of the research and the steps of the research process.

An analysis of the type of research has shown that, it can be divided into at least following four categories (1) change/influence, (2) evaluate/describe, (3) theory or model development and (4) testing/examinating. Table 1 shows principle relations between the type of research and the research process.
There are no strict boards between the four research types. Some projects can be hard to specify into one research type. The results from one project can and should be used in another project with another type of research. For example, results from tests/examinations regarding toxic materials can be used as input in a project directed to change. An evaluating research can be used in order to find the effects of a change process that are supported from researchers work inside an organisation.

The combinations of different research types will together contribute to a sustainable development. The four types of research will be described below.

3 .l Change/Influence directed research

A research process whose main intent is to contribute to changes in a daily activity is closely related to a work situation. Often, it is the activity which constitutes the focus in a change situation. The aim of the change could be to implement material, work-processes and values that supports a sustainable development. Examples of the variables for investigation are the economic situation, seasonal variations, rules for handling capital, market demands, and teamwork between various partners in the building process or production methods.

To investigate this matter, it would be natural to choose some form of case study. Specific variables are studied as well as how these in various ways influence the target of change; pro and con. How the problem is expressed is to effect change. The choice of method has to be done in such a way that people who are affected by the change are engaged in the research work. Methods for collection of data are focused on both structures and processes in the activity. The amount of quantitative data is often very large. “Feed-back” of collected data is important when making the analysis. Its goal is to create insight and understanding of questions regarding change and research.

For work on change to be successful it is necessary that the collection of data contributes to increased understanding of processes of change. Documentation contains information regarding variables which could contribute to changes. A great deal of the critical examination and the scientific contribution is validated directly by those involved in the process of change. Models and theories could be created through analysis and processing of many case studies/ change projects from a scientific point of view.

3.2 Evaluating/Describing research

Research meant to evaluate ought to have a very clear description of what is being evaluated. The aim of the evaluation could be to find out how waste are managed, what criteria to use when choosing building materials and what impact the concept of sustainable development has in the process of tendering.

These target descriptions direct the choice of the research process, i.e. choice of target group, variables for study and methods for analysis of collected data. Documentation of research results has a primary function as different parties avail themselves of the research result from their background and specific needs.

The pedagogic design and structure of research reports determines how different parties avail themselves of the result of the evaluation. Many evaluations are presented in such a way that results do not reach the parties of the research area. A scientific examination of presented results could be made by other national/domestic or international experts and research groups. From a scientific point of view, there is general knowledge to be gained by processing and analysing complementary investigations and research.

3.3 Theoretic or model building research

Research directed towards theory building is intended to advance the frontiers of knowledge within clearly defined areas. It might involve particular questions within for example structural design and strength of materials, but also building models around specific functions of the building process that support sustainable development. Therefore, the research question is focused on specific models or systems to make specific processes or part processes more effective. In turn, these specific areas of knowledge could be integrated into a wider area of knowledge, i.e. CAD/CAM-models and other IT-tools for specific parts of the building process.

Methods used are very specific to subject and are often carried out by experts within very narrow areas of specialisation. Collection of data is done through a systematic search of previously conducted research studies and constant exchange of experiences with international partners. Empirically defined investigations might also complement the collection of data. Collected data is mainly analysed through combining known knowledge into new structures. Experiences and results that have been achieved are primarily intended for researchers within the area of specialisation and would be published mainly in scientific papers in journals of good renown.

3.4 Testing/Examining research

A fourth area of research is testing research. Its primary intent is to investigate and explain the function of specific components or materials, often made in a laboratory environment.. The research question might be strength, types of cracks in concrete or steel etc. The laboratory can also be used to arrange a specific situation where persons or groups are discussing ore making analyses of there values and how these values supports or hinders a sustainable development.

To get answers to the questions, a research process is chosen in which a single variable is isolated and manipulated. Formulation of problems is often expressed as hypotheses which are tested by experiments. The data acquisition is quantitative with a precision sufficient for the purpose. Computer simulations are used first to reproduce the test and secondly to widen the database. Statistical methods are used for the development of design formulae and also for reliability analysis. The international publication is an important part of the scientific contribution.

4 Conclusions regarding choice of research design

Within technical research different institutions and departments have strongly varying types of research. You will find very qualified experimental studies, evaluation of both building processes and building products and action research. Certain departments work very close to companies and various organisations with the intention to contribute to measures that can increase the quality as well as productivity in the building process. Others carry out experimental studies on material and technical questions on function.

In order for different types of technical research to become successful within its respective field there is a need for increased understanding and respect for different types of research and research processes. Often, qualitative aspects turn out to be worth taking into consideration during implementation of results obtained from experimental situations that focus on quantitative aspects. Simulated experiments and statistical analyses often give an active contribution towards insight and understanding for different needs regarding changes.

All types of research must be used to contribute in sustainable construction. All partners in the research process must understand the limitations for each type of research.

Environmental Cost, a decision support model

Marcel Dewever
Chief Inspector of Environmental Affairs, Government Building Agency,
The Netherlands.

Abstract
The budget plays a major role during building design and construction. How to keep a project within budget is a source of endless discussion. The Dutch Government Building Agency also maintains a so-called 'environmental budget' to take account of the environmental aspects of each project. This enables us to monitor the 'environmental costs', in a similar way to the financial budget, to ensure that they too stay within their allotted budget. By 'environmental costs' we mean what it would cost to prevent or repair the environmental impact of the construction and use of a building.
An environmental budget is drawn up based on the Schedule of Requirements and the client's environmental ambitions. This indicates what environmental costs the project may involve. An estimate is then made of how high the environmental costs of construction and use of the building would be if the proposed design were carried through. The methodology runs parallel to that of commercial cost control systems. At the start of the project, the environmental cost estimates are only approximate; as the project proceeds, these figures become firmer. On completion, an overall costing is done. The technical data that result from this are used as a basis for initial estimates when preparing the next project.
A practical example of an environmental cost calculation is included.
Keywords: environmental costs, environmental budget, environmental economy, cost control.

1 Introduction

There is a growing interest in the Netherlands in sustainable building, and the concept has attracted considerable government attention. A few years ago Parliament adopted a plan of approach for sustainable building, the results of which were recently evaluated. They indicate that the concept is beginning to have an impact in residential construction. A second plan was approved at the end of last year which included a significant emphasis on commercial and industrial construction, and sustainable town planning. Many local authorities are now also actively pursuing sustainable building policies. Discussions in the construction industry have led to agreement on a package of environmentally friendly measures that have practical application in residential construction. A similar set of measures for commercial and industrial construction is now in preparation. Utrecht, a city in the heart of the Netherlands, has had an information centre for sustainable building for some time. The centre is a focus for a lively exchange of knowledge and ideas between commercial concerns, universities, and national and local authorities.
The Dutch Government Building Agency has played a pioneering role in these developments. As one of the biggest commercial and industrial construction clients in the country, the Agency has been able to encourage the implementation of a national sustainable building policy. When we started doing this in around 1990, lists of all kinds were circulating in the Netherlands giving details of environmentally friendly materials and others deemed much less desirable. Timber, for example, was presented as a building material which had less impact on the environment than aluminium. This, however, ignored the way in which timber and aluminium are used in construction. Timber structures are usually relatively heavy, whereas thin sheet aluminium can be

applied as a facade cladding. This leads us to ask what is better for the environment: large quantities of timber or much smaller quantities of aluminium? This whole question prompted us to start looking for a quantitative evaluation system. We eventually came up with the TWIN model. Further details of the model can be found in the paper given at the CIB World Building Congress 1998 [1] by Michiel Haas, the model's spiritual father.

2 An integrated standard for sustainable building

The introduction of the TWIN model alone is not enough, however. There is more to sustainable building than simply the environmental qualities of building materials. We also have to consider energy and water consumption, and the environmental impact that is linked to choice of location. It makes a considerable difference, for example, whether an office building is placed near a motorway and given generous car-parking facilities, or right next to a railway station with hardly any parking spaces at all. In the latter case, the office staff will make more use of public transport, with consequent beneficial environmental effects from reduced private home/work traffic. If we want to evaluate the environmental aspects of a construction plan, therefore, we need to examine a number of factors, such as:

- choice of building materials
- energy and water consumption
- environmental impact of home/work traffic

In practice, these factors are interconnected - for example, if we wish to compare an energy-efficient new building situated next to a railway station with the renovation of an existing building located some distance from the station. The energy-use and mobility factors associated with a renovated building often have a greater environmental impact than those associated with a new building, whereas the materials input, by contrast, is substantially lower. The question then is: which solution causes the least environmental impact — new construction or renovation? In answering this question, it is useful to have some way of adding up all the various individual factors to enable us to compare the total environmental impact of each alternative.

We decided, therefore, to express all environmental effects in financial terms. We do this by first ascertaining the scale of the environmental effects and then calculating how much it would cost to prevent or repair those effects. We published guidelines for this method of evaluation in a so-called 'Easter letter' in 1996 [2]. Following this, a foundation was set up[1] which developed the concept into a fully-fledged professional programme, that is now on the market in the Netherlands under the name 'GreenCalc'.

3 GreenCalc, a calculation in three steps

1. The calculation starts with a quantification of the environmental effects. This involves ascertaining the environmental impact of a building's construction and use.
2. This environmental impact is then accorded a monetary value. To do this, we calculate what it would cost to prevent or repair the environmental impact concerned. These prevention-or-repair costs are referred to as the 'environmental costs'.
3. The calculations we subsequently carry out based on the environmental costs give us a total figure for the environmental impact of a building and its use.

In summary, the calculation model looks like this:

---

1 Sureac Foundation (Sustainable Real Estate Accountancy & Certification)
PO Box 229, 1400 AE Bussum, The Netherlands. Tel. +31 35 6946204, fax +31 35 6950042

Q → **$** → **Σ**
quantification → monetary valuation → balance calculation

It would be beyond the scope of this paper to elaborate on these three steps in great detail. We shall instead limit ourselves in the following sections to a few general guidelines, and then expand on the way in which we use the model in practice.

3.1 Quantification

The calculation method starts with a quantification of the environmental effects. Life-cycle analysis (LCA) is the most widely known method for doing this. This analysis surveys the environmental impact of, for example, a building material over the whole life-cycle of that material: from the extraction of the raw materials through to the processing of the demolition debris. In so far as the data needed are available, the method gives a reliable picture of the environmental impact. The fact that this LCA picture cannot be complete because the required data on some environmental effects are not known led Michiel Haas to develop his TWIN model [1]. Using a specially developed system to produce qualitative estimates, he is able to fill in the gaps left by the life-cycle analysis.
Besides the TWIN model we also use other, less recently developed quantification methods for (anticipated) energy and water consumption. An estimate is also made of the fuel used by related home/work traffic. The picture we arrive at shows us the extent of the environmental impact of:

- building materials
- energy and water consumption
- mobility (home/work traffic)

3.2 Monetary valuation

The second step in the GreenCalc method is the conversion of the environmental effects into monetary values. We do this in collaboration with the Erasmus University in Rotterdam. The university's Faculty of Environmental Economics is a centre of expertise in the monetary valuation of environmental impact. Together with the Faculty, we determine what it would cost to prevent or repair the environmental impact of a building.
The following is an example of this approach: the energy used in the production of building materials contributes to acidification of the atmosphere, and this pollution in turn damages buildings and natural areas. The costs of repairing this damage are not included in the price of the building materials. These costs are quietly passed on to others. In maintaining historic buildings we encounter damage to facades and ornaments caused by acid rain. The repair costs have to be paid by the proprietor of the building, while those responsible for the damage are well out of range. Within the Government Building Agency these, 'hidden' environmental costs are brought to the attention of the decision-makers. They are not yet being asked to pay these costs, but in the longer run that is perhaps the way we have to go. The decision-makers are currently only being asked *to justify* these environmental costs, but they need to investigate the possibility of other solutions to lower them.

3.3 Balance calculation

The GreenCalc method is highly analogous to the traditional calculations made in the real estate sector. The use of building materials, for example, is seen as an investment in environmental goods. As in the commercial economy, this investment is gradually depreciated over time. One striking difference, however, is that commercial calculations depreciate an investment over its *economic or functional life-time,* whereas environmental investment *takes the technical life-time* as the basis for depreciation. This was a conscious choice, because we believe that sustainable building is not just about the design and construction phases, but includes a building's period of use too. In this utilisation phase it is advantageous to maintain a building's functionality as long as possible. There is a certain wastage when a building is demolished before the end of its technical life; the technical usage value of the invested environmental goods is not fully realised. This necessitates the premature use of additional environmental goods for new construction, and is another cost item on the environmental bill, This effect can be brought into the overall picture by depreciating environmental investments over their technical life-time.

Future environmental costs are also calculated in the same way as they would be commercially. From these costs we calculate a monetary value over the anticipated period of a building's use, and this figure is taken into account when evaluating an investment. It is then a matter of looking at the environmental costs of expected energy and water consumption and mobility.

4 A common language

Many of the decisions taken in the construction industry are based on commercial considerations. The decision makers think about lines of money. We want to follow this line of thought by making our calculations, using currency. Environment and economics are then speaking the same language, and this simplifies the decision-making process.

Environment & Economics

5

a common language

As with economic judgements, environmental aspects are not assessed purely on the basis of the costs, but also in terms of the cost/quality ratio. The environmental costs provide a 'price tag'; they do not say anything about quality. As with the other aspects of a building, the axiom that the cheapest solution is not always the best solution also holds for the environmental aspects. The environmental costs do not, for example, tell us anything about the functionality of a building, nor the way it is experienced by those using it. It is therefore important that the environmental costs are always weighed up in combination with the quality of the design in question. For a discussion of the quality assessment of a building plan, we refer to the paper by George Ang [3]. The performance concept - which he discusses - and the environmental costs - which are discussed here - are, as it were, two sides of the same coin.

5 Consecutive calculations over the whole life of real estate

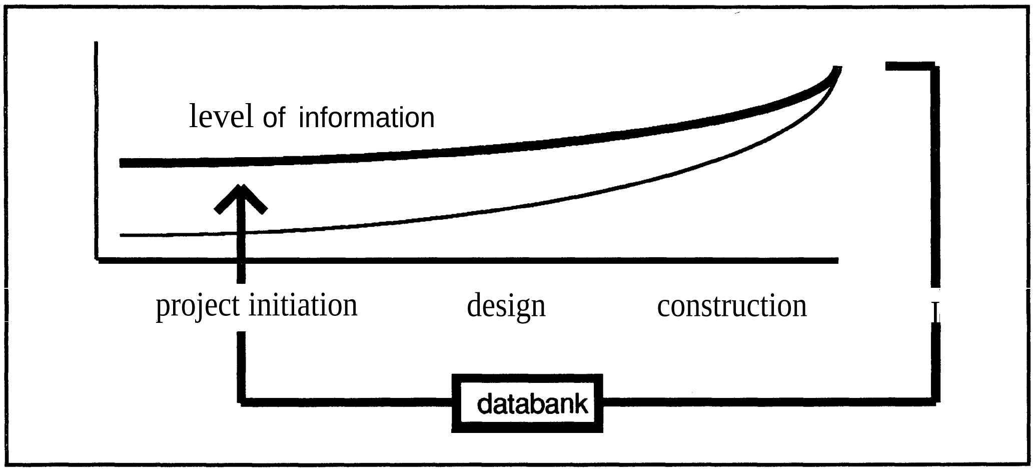
The construction process entails a whole chain of decisions. From the very first initiative right through to completion, choices continually have to be made — as George Ang demonstrates in his presentation to the CIB World Building Congress 1998 [3]. The task each time is to match supply to demand. What does the client want and what is feasible in practice?

In order to gain a clear picture of the environmental aspects of supply and demand, the Government Building Agency calculates the environmental costs several times during the course of a project. This begins with the initiation phase, and continues through design and construction and on into the utilisation phase. GreenCalc has sets of calculation results relating to each phase of a project. This can be summed up as follows:

Project phases	GreenCalc calculation results
initiation phase:	establishment of environmental budget
design and construction phase:	environmental costs versus budget
utilisation phase:	environmental profit and loss account

5.1 Initiation phase

An environmental budget is drawn up based on the Schedule of Requirements and the client's environmental ambitions. This indicates what environmental costs the project may involve. In this initial phase, when relatively few details of the project are yet available, estimates have to be made. Here too the methodology runs parallel to the commercial approach. At the start of the project, the cost estimates are only approximate; as the project proceeds, these figures become firmer. On completion, an overall costing is done, The technical data that result from this are kept in a databank and used as a basis for initial estimates when preparing the next project. This technique makes a more sophisticated level of information available at the beginning of a project, something which is very important given that it is during this early phase that the most radical decisions have to be made - think, for example, of the consequences of the choice of location and the choice between renovation and new construction.



5 ● 2 Design and construction phase

A 'do-it-yourself' version of GreenCalc is available which enables a project team to make its own estimates of environmental costs, At a suitable stage — but in any case before the tender — official calculations are made, and the input data verified as correct. The results are presented to management in the form of a so-called 'Environment Chart', an example of which is attached. On completion, the final results are set out on another Environment Chart. If these results meet certain specified requirements, a certificate can be issued.

5 . 3 Utilisation phase

Commercially, in the real estate utilisation phase a profit and loss account is kept in which the annual operating costs are set against annual income. Costs include depreciation, interest charges, maintenance, management, and so forth, and are set against benefits such as rental income. In environmental accounting we also have costs, but the income side is less clear. Here the profits consist of the social functions that the buildings perform which are valued by the community. Consider, for example, the social function of courts and prisons. We can deduce from the environmental budget which the government maintains for these buildings how much they are worth to the community.The use of environmental profit and loss accounts is still in the development stage. The first such account will be drawn up in 1998 for an office building.

6 A practical example

The results of a calculation of environmental costs are presented on an 'Environment Chart*. An example of one of these is included as an appendix. It refers to the renovation of an Amsterdam convent and attached school. These now form a complex which houses an employment office and a temporary employment agency.

GreenCalc modules	environmental budget	environmental costs	result
floor area (gfa = gross floor area)	1.715 m² gfa	2.448 m² gfa	
environmental book value of existing		NLG 750.000	
building		NLG 1 .000.000	
building materials for renovation	NLG 3.900.000	NLG 1.750.000	45%
total building materials	NLG 2.700.000	NLG 4.500.000	170%
energy consumption*	NLG 20.000	NLG 20.000	100%
water consumption*	NLG 900.000	NLG 700.000	80%
mobility (home/work travel)*	NLG 7.520.000	NLG 6.970.000	90% of **the budget**
TOTAL			
* cash value over the period of use			

This table has been formulated using a calculation model which is still under development; the figures are indicative.

In the above table — taken from the Environment Chart - the environmental costs are compared to the environmental budget. The budget is based on a new building, efficiently designed according to Government Building Agency guidelines. The table shows that the environmental cost of building materials is only 45% of the budget. The figure is so low because the building is *60* years old. Hence the environmental investment has been written off to a large extent. The project architect, Wim van Rijn, also managed to adapt the building to its new function with minimal alteration.
Against the plus of the very low materials requirement, we have the definite minus of high energy consumption. The building is very generously proportioned and the employment office takes up far more space in this building than it would in a new building *(2,500* m2 as opposed to 1,700 m2). The energy required to heat and light this extra space pushes consumption way up, and works out at 170% of the norm for new construction. This cancels out the advantage of low materials input.Taken altogether, the environmental costs are 90% of the norm for new buildings. On these grounds it might be assumed that it makes no real difference to the environment whether we renovate or put up new buildings. On the contrary! The building concerned had been empty for years. A great sombre colossus, covered in graffiti, that dominated the whole square in which it stands. It takes up one whole side of the square and affects the atmosphere of the surrounding area. The renovation has not just revived the building, but has brought the whole square back to life again. The shops and houses around the square have increased in value, with houses being improved one after the other. By renovating the convent we have also indirectly extended the useful life of dozens of adjoining buildings. The environmental gain of this effect on the surroundings is not yet factored into the calculation of environmental costs. We are working hard to expand GreenCalc to include a module on 'space utilisation', which attempts to assess a building's effects on its immediate environment. We are not there yet, but it is clearly evident that this type of renovation actually has no environmental *costs.* If we add in the effects on its surroundings, we are undoubtedly looking at a substantial environmental *profit..*

Basic approach methodologies for buildings' management in mountain environment. Case study.

A.Frattari, I. Garofolo
Department of Civil and Environmental Engineering, University of Trento, Trento, Italy

Abstract
Sustainable development is more and more the keyword according which every efforts must be made to assure the maintenance and a suitable transformation of the mountain territory and of the cultural and historical heritage represented by its settlements, to allow the development and the fulfilment of requirements of the modern life.
The belonging to sites with specific geographical and morphological features, which have deeply influenced the existence and the availability of natural resources for long time, affects as a determining factor the built objects and the technical infrastructures, for what concerns as the choices related to the building materials as the building systems employed into their construction.
The paper deals with the case study of the residential buildings of the mountain communities of the eastern Alps in North Italy, with particular reference to some peculiar building typologies of the vernacular architecture.
The study aims to set out the basis to fix operative tools for the maintenance management of such built estate, and to point out some sustainable design choices as for the reuse and the rehabilitation of old buildings as for the new buildings, this aim could be pursued throughout a reappraisal, even from an economical standpoint, of these areas which potentially offer the opportunity of a wider exploitation to shrewdly managed for the safeguarding of the cultural values to be transferred to future generations.
The analysis of the area showed some recurring situations, summarised as following : the progressive abandonment of large areas, the development of new settlements for residential/productive purposes close to ancient historic towns, the building up of totally new urban centres. A basic methodological approach to the management of the building stock is given as answer by the study, according to the following criteria : the development of the knowledge and the transmission of the cultural heritage belonging to the mountain environment, with particular reference to the building stock ; a "guided" transformation of the most meaningful sites and built areas still important for the territory ; the reappraisal of the use of local resources and traditional building technics, as in the rehabilitation of existing buildings as in the new constructions.

Keywords : maintenance management, reuse, sustainable materials, wooden buildings

1 Introduction

Mountain territories are rich of scenic and environmental values ; since they were for such a long time uncontaminated places, or affected by slight changes, due to the human settlement and the related activities, today they are much more sensible to whatever intervention. Sustainable development is more and more the keyword according which every efforts must be made to assure the maintenance and a suitable transformation of the mountain territory and of the cultural and historical heritage represented by its settlements, to allow the development and the fulfilment of requirements of the modern life.

Geographical and morphological features of alpine territories have deeply influenced every intervention carried out by men to develop any activity to maintain acceptable living condition and to establish permanent settlements. Mountain economies have been generally characterised, during the past, by poor activities (farming based on the growing of limited vegetal species, aimed to fulfil the requirements of small communities, stock /sheep - rearing characterised by the seasonal moving to different heights, limited productive activities mainly related to the milk transformation process).

Even the social organisation has bees for long time influenced by the territory's severity : the much more diffused model for the settlement in these areas was that of small autonomous communities, gathered in small / medium size blocks of houses (*masi* or farms), spread out on the territory. This typical settlement remained practically unchanged for many generations, even thanks to the existence of strong social-legal institutions such as, i.e., the *maso* ***chiuso*** diffused in the South-Tyrol area since from the middle of the XVIII century.

The diffused architecture of these regions was also characterised by the use of local resources and from archaic forms, by the use of traditional and simple building technics handed down from father to son by carpenters and builders who deeply respected the environment by employing only what the place allowed to use as building materials ; up today this architecture has suffered deep transformations even due to the coming of the so called modernity, able to exceed the natural barriers, which also allows the building of every kind of construction, with whatever material and advanced technologies, even if with high economical and environmental costs.

In this frame we face today the problem to reconcile the respect and the maintenance of typical features of the mountain environment with the need of its sustainable development ; this aim could be pursued throughout a reappraisal, even from an economical standpoint, of these areas which potentially offer the opportunity of a wider exploitation to shrewdly managed for the safeguarding of the cultural values to be transferred to future generations.

2. The knowledge and the analysis of the building stock

At the Laboratory of Building Design of the Department of Civil and Environmental Engineering (University of Trento, Italy), researches are carried out dealing with different aspects related to the building stock in the mountain environment. A first research line is about the study of the traditional building heritage, strongly characterised by the stone vernacular architecture, recurring in the lower valleys, and by the wooden architecture diffused in the medium/high level areas (1). A second research line deals with the more recent building estate, as an answer to the modern living requirements which developed new formal and building typologies not always respectful of the surrounding environment : they didn't either become integrated it or respected traditional use of local materials, giving rise to problems related to their maintenance especially for what concerns the performances of materials and technics not suitable in a so strict environment (2).

The aim of the researches is to point out interventions' methodologies and tools for the management and sustainable transformation of this building stock, with the safeguarding and the maintenance of its cultural heritage ; moreover, the aim is to point out building systems and technics compatible with the delicate balance of the mountain environment, and which can also reclaim the building experience from the past as for materials and technics. Nevertheless, this doesn't exclude the possibility of a new understanding and a supplementing of the last with even strongly innovative materials, on condition that they have a high level of adaptability to the mountain environment and recycling possibilities when different users' requirements ask for a change in the use destination.

The studies carried out at the Laboratory in Trento are part of a wider discussion at the international level on the reappraisal of the technical and building solutions of the traditional vernacular architecture, seen as a man's product able to reach a good balance between the exploitation of the environment and the vital needs of nourishment in acceptable comfort conditions (3).

To fix basic approach methodologies for the management of the building stock in mountain environment, to be followed as guide lines as in the rehabilitation and renovation process of the existing buildings as in the choice of formal, functional and building typologies for new interventions, a starting point has been the analysis of the present situation on a share of sample - territory Some valleys belonging to the territory of the Trento and Bolzano provinces have been examined, in the north-east part of the Italian Alps and pointed out as representative of the changes which interested the mountain habitat following the coming of the modernity with all the related needs and requirements. Meaningful examples of the last are the two opposite conditions of the abandonment and the depopulation of underdeveloped areas and, on the other hand, the extreme exploitation and the transfiguration of the areas with strong touristic bend.

The collection and the arrangement of data concerning the built estate has been carried out by means of recording charts used as analysis tools appropriately studied to enhance and to evaluate some features which strongly characterise the place and its prevailing architecture, and to stress the influence that the first had on the second. These features are : the configuration of the buildings' surrounding ground and environment ; the sides exposure in the valley ; the land arrangement ; the human scale of the settlements ; the access routes ; the recurring formal and building typologies ; the search for their original matrix ; the materials and the technics employed in the production of the building components which are seen as strong marks of the settlements. Moreover, transformations at functional, formal and building level have been examined ; the analysis focused the strong tendency to the change of the original use destination which deeply affected the original building type.

The analysis showed some recurring situations which is important to focus when drawing up intervention proposals for the safeguard and a right management of the territory and its building stock. A first case is represented by the progressive abandonment of large areas with prevailing agricultural bent, with the following advanced decadence of the living centres and oblivion of the cultural value represented by the traditional architecture. The main need is in this case the complete conservation of the sites and their building blocks as authentic witness of the past.

A second case, much more diffused, is represented by the development of new settlements for residential/productive purposes, close to ancient historic towns and the following alteration of the last to the modern requirements for what concerns living standards and fitting with new services and infrastructures. From the analysis of these situations some warning signals must be kept in mind as meaningful of the current way to operate the transformation of the buildings, without respect of their inner cultural values : very often the lacking in the knowledge of the values of the built estate, in the knowledge of the traditional technics and the use of local resources, on which now the modern materials take priority because of less expensive, easy to build up and more "secure" for performances and given comfort, all these reasons lead to the transformation of the traditional features of the vernacular architecture and to the settling side of modern buildings deeply conflicting with the surrounding environment.

The last even less recurring situation is the building up of totally new urban centres or specialised buildings in areas with strong specific bent, as productive as touristic. Problems in this case are related to the need of integration of the new object with the surrounding territory which can be seen as a non renewable resources with peculiar cultural and environmental features to preserve.

3 Methodological proposal for interventions

In a preliminary phase some methodological proposals for further interventions have been promoted for the rehabilitation and the renovation of vernacular architecture, for the cultural values handed down by it, and of its capabilities to become integrated with the surroundings thanks to the sustainable use of the territory and its resources. Criteria for interventions have been therefore pointed out aimed to :

- the development of the knowledge and the transmission of the cultural heritage belonging to the mountain environment, with particular reference to the building stock ;
- a "guided" transformation of the most meaningful sites and built areas still important for the territory ;
- the reappraisal of the use of local resources and traditional building technics, as in the rehabilitation of existing buildings as in the new constructions.

For the areas with an high level of decadence and strong tendency to the abandonment, to maintain built object in situ until it is possible could be a sustainable choice, within a "museum" structure ; to maintain the building heritage could imply the conservation of functional, building and formal typologies, without modifying or changing the original use destination. Basing on the experience in the analysed territories, this can be achieved as for small built areas as for larger areas, through the arrangement of open air museums or eco-museums seen as the pointing out of main ways with landscape and cultural values crossing the built areas, isolated or gathered into groups, with particular cultural interest and meaningful of the vernacular heritage of the region. If this is not possible, but on the other hand it is favourable to keep only few examples, more representative of the past, the possibility can be evaluated to move these buildings in other places than the original, were some totally new "open air museums" can be established, thus recover land in the original areas for new destination.

These proposals can be accepted if supported by strict conditions, such as the accessibility of sites and the available financial and technical resources to maintain, to run and make these places interesting for tourism, thus transforming them into a fruitful activity able to revalue from the economical standpoint the area by bringing new resources to the local community.

A different proposal must be made in case of the renewal the rehabilitation of a building stock with high potentiality for exploitation even if it requires the adaptation to modern standard and the integration with new buildings. This is the case related to the mountain areas which moved from the agriculture and farming bent to the tourism and the tertiary activities, asking more and more for a renovation and enlarging of the building stock.

Looking to similar project developed in rural areas of side regions (4), with similar problems for what concerns the maintenance and respect of landscape and environmental values, some proposals have been pointed out for the control and the management of transformations, such as "guide lines" to be used as executive tools These are intended not as strict rules or "how to do" models to be used in every situation as acceptable building solutions, but rather as "like to do" suggestion among which the user or the owner of the building can choose and adapt to his building that which suits more his needs according to present situation or can be easily adaptable to future changes, limiting the economic and environmental costs.

In this framework the reappraisal of the use of traditional materials and technics take importance, which could allow, as in the past, the suitable exploitation of the prevailing local resources and at the same time an incentive to the recycling as much as possible of materials belonging to old buildings which would be dismantled or deeply renewed. Nevertheless, during the past it was a diffused way to act to recycle and reuse of wooden components from old buildings, such as roof truss, floors, shingles, ecc. These elements, with few and inexpensive maquillages were given as new and with behaviour performances fitting the always new requirements. Moreover, the use of traditional and local materials could also contribute to reclaim and exploitation of the natural environment as also it has been in the past : it allows a low energetic cost, a low environmental cost thanks to low level of dangerous emissions during the production of the building components, low or no transportation costs, low waste during the production process, environmental costs distributed on a long life cycle, high recycling percent of materials and components, even weakened (even the burnt wood could in most of the cases be reused, thanks to the oversize dimensions employed). The use of wood as building materials has always satisfied some conditions which can nowadays be considered basic for the sustainability of a building. Thanks to traditional and new executive modalities, as dry assembling technic for reduced section components the are easy to mount, to replace, to dismantle, to get in the original form and dimension after each use, to be employed in different building sub-system and to recycle after the last use.

The reappraisal of traditional material and technics can also contribute to the safeguarding of the natural landscape : this is the case of the historical forest, which supply material with scheduled growing and cutting, and which development has been guided from long time by the consciousness and the skill of carpenters and builders.

4 Conclusion

Some of the above mentioned proposal, and especially those related to the reclamation of traditional buildings in existing settlements, have been tested in case studies (5) and other are still working out, in connection with some scheduled co-operation programs with local authorities responsible for maintenance and preservation of traditional cultural heritage. From the experiences carried out some remarks can be stressed, the main of which can be summarised as following.

Three are the problems related to a successful application of these intervention proposals : the firs is the lack of a clear legislation for the preservation and the maintenance of this kind of heritage, and at the same time a close plot of authorities dealing with it which can hardly manage the transforming process of the built stock. Moreover, there is often a great difficulty to place again existing buildings with peculiar constructive features within the developing plans for urban areas.

Then, a lack of knowledge of traditional methods and techniques, as modern ones have usurped the role of local builders and carpenters able to produce sustainable buildings.

At last the even high costs for the employment and the revaluation of traditional way of building, if compared to the benefits they can produce.

To all these questions it would be an attempt to give an answer by getting the result of some pilot project which are under development in the area interested by the previous analysis.

Abstract
The concept of sustainable development of human activities has highlighted the environmental impacts of buildings, particularly the use of energy for construction and operation and the resulting contributions to carbon dioxide (CO_2) in the atmosphere from the burning of fossil fuels for energy generation. A system to estimate energy used in creating buildings, and the resultant CO_2 emissions, direct from 3D CAD drawings has been developed to calculate embodied energy, CO_2 emissions and mass for all materials in a building, and to provide graphing and tabulation functions which call upon CAD information to provide a wide variety of breakdowns of energy and CO_2 by element category, material category, and individual materials. The significance of initial embodied energy so estimated is compared with the operational energy over the whole life of a building calculated using other standard models based on heating and cooling loads. This paper discusses this example of integration of evaluation methods from CAD information as well as the operation, uses, limitations, benefits and future role for this type of analysis in designing and managing for sustainability of construction.
Keywords: Embodied energy, life cycle energy, sustainable construction, 3D CAD

1 Introduction

The concept of sustainable development of human activities has highlighted the environmental impacts of buildings, particularly the use of energy for construction and operation and the resulting contributions to carbon dioxide (CO_2) in the atmosphere from the use of fossil fuels for energy generation. A system to evaluate energy used in creating buildings, known as embodied energy, and the resultant CO_2 emissions is needed to complement the models for estimating operating energy of buildings.

To estimate the amount of energy embodied in a building; and the resultant greenhouse gas emissions generated through energy consumed in these processes, prototype software was developed for the CAD package APDesign to calculate the material quantities, embodied energy and greenhouse gas emissions directly from a 3D CAD model [1]. This model provides quantitative values to assist in determining the environmental impact of alternative designs and building materials at the design stage of a building. The ultimate aim of the software is to integrate it with an existing operating energy model to create a procedure which design professionals would use to assess alternative designs in terms of the amount of energy required to construct and operate a building and the resultant CO_2 emissions from that energy generation.

This paper discusses this example of integration of evaluation methods from CAD information as well as the operation, uses, limitations, benefits and future role for this type of analysis in designing and managing for sustainability of construction.

2 Embodied energy

Embodied energy is defined as the quantity of energy required by all of the activities associated with a production process, including the relative proportions consumed in all activities upstream to the acquisition of natural resources and the share of energy used in making equipment and in supporting functions. Buildings have a significant impact on the environment due to the energy embodied in construction materials.

To be able to quantify the energy embodied in the construction of a building, the quantities of materials must first be estimated through a process of disaggregation to a level of detail which allows for the separation of components into their principal materials. Energy intensities of each material can then be multiplied by the quantities of individual materials and the products aggregated to obtain the total for each material, element or whole building.

Embodied energy intensities were derived from input-output tables and other national and international studies. To obtain an accurate and reliable database of embodied energy and CO_2 intensities for all materials used in buildings is an enormous task in itself and is a necessity for detailed comparisons of materials. The main requirement of embodied energy calculations at the design stage is obtaining accurate and useable material quantities and then combining them with currently available embodied energy and CO_2 values.

Previous investigations have calculated the total embodied energy from individual houses (e.g. [2],[3],[4]) and Pullen [5] has formalised the process in a spreadsheet which links to a series of databases for embodied energy calculations for houses. The energy used in the construction process is not of a magnitude sufficient to effect the alternative choices but should be included in the total [6].

3 3D CAD model

The chosen approach to fast and practical estimates of embodied energy, CO_2 emissions and mass values directly from 3D CAD drawings at the design stage requires both 3D CAD and accurate quantity functions to calculate embodied energy values from a database of embodied energy intensities. To avoid duplicating the techniques for estimating quantities from first principles, an existing computer program which provided many of the required functions was selected and then extended. The chosen software was a program called APDesign, a CAD package developed and used extensively in Australia, Europe, Canada and the USA.

APDesign is an AutoCAD based system, tailored to creating 3D models of building designs using a large inventory of standard and custom building items. All building items are entered into the drawing from an object database. Unlike the AutoCAD basis of the system, each line, or group of lines, on the drawing is a known building item, i.e. an identifiable object, with attached functions and associated attributes which relate to the drawing object. A typical detailed drawing is shown in Figure 1.

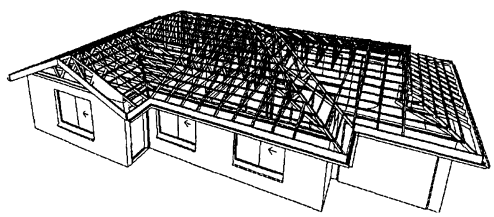

Figure 1 Example of 3D CAD drawing

It was necessary to extend the capabilities of APDesign to further levels of detail beyond the bills of quantities approach which was successfully implemented in the original software. Every item needed to be further disaggregated into its component materials and a generic approach developed to achieve such extra detail with minimal effort. The resulting software makes it a very simple and straightforward procedure for users to access and utilise the embodied energy analysis techniques.

The **embodied energy module** is a specialist tool created to allow embodied energy values, CO_2 emission values and building mass to be calculated automatically from the 3D CAD drawing. The embodied energy, CO_2 and mass intensity values are stored in a material database which is linked back to the building item database of APDesign while the relationships (known as formula sets) are separate databases.

The **building item database** as found in APDesign consists of items used by the construction industry as 3D objects. The database comprises only the critical design information (mainly dimensional parameters) needed to create each item (walls, doors, windows, footings, etc).

The **formulas** are a crucial part of the process to calculate embodied energy. They are used to calculate the quantities of specific materials associated with each building item by using dimensional parameters from the detail of the items and the primary graphic, as held in the building item database. Each building item is made up of one or more materials, each of which has a separate embodied energy, CO_2 and mass value. Therefore, it is necessary to split each building item into a group of materials by associating with that building item a group of formulas, known as a formula set, from which the amount of each material can be calculated. The formula sets are generic, i.e. they can be used interchangeably for similar building items, thus reducing the number of formula sets needed.

The **material database** contains the materials and the embodied energy, CO_2 and mass data associated with them. At present, the materials database contains around 500 materials. These are divided into 20 material categories such as steel, aluminium, timber, plaster, and so on.

The prototype software is the first system which has attempted to design a framework for fast and useable estimations of embodied energy, CO_2 emissions and mass values directly from 3D CAD drawings at the design stage and the future possibility of simulating various design options for comparative purposes.

3.1 Results

The detailed calculated values, totals and percentages of the embodied energy, CO_2 and mass are tabulated and sorted in four ways: by *description* - the same fixed order as used for the element and material categories; by *embodied energy* - in descending order of estimated embodied energy values; by *CO_2 emissions* - in descending order of estimated CO_2 emissions values; and by *mass* - in descending order of mass values. The mass values are displayed because they are calculated as an essential step in the conversion from 3D CAD volumes to the units of mass in which embodied energy are normally expressed.

Graphs enable users to quickly see the relativities of different building items and materials with regard to their embodied energy, CO_2 and mass values and also enable comparisons of different construction techniques and materials, e.g. Figure 2 shows the CO_2 emissions due to embodied energy by material category. The values shown are for a hypothetical project.

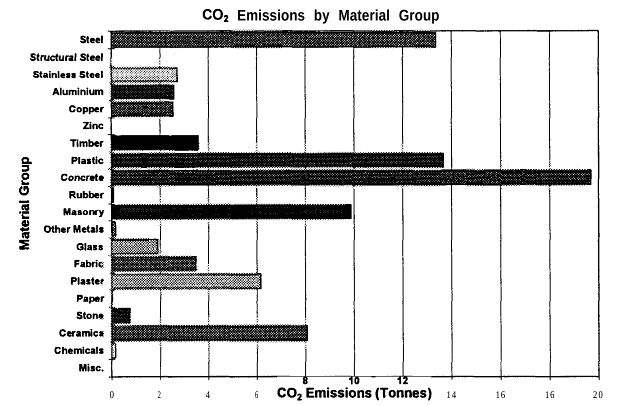

Figure 2 CO_2 emissions by material category

4 Operating energy

While the principles of energy efficient house designs have been known for some time, only a small proportion of new houses are energy efficient in Australia. Typical annual energy usage in Australian houses is shown in Table 1 [Table B.1 NS W/ACT Residential Sector Energy Use. 7, 8]. The annual heating and cooling loads are the most significant contributor and dependent upon the design of the dwelling.

Usage	*Annual energy consumption (GJ)*
Heating and cooling	64.44
Water heating	34.53
Cookina	15.42
Refriaeration	15.45
Appliances	7.67
Lighting	6.53
Other	13.26
Total	**157.30**

Table 1 Typical annual housing energy consumption

4.1 Nationwide House Energy Rating Scheme (NatHERS)

The Nationwide House Energy Rating Scheme rates the heating and cooling energy efficiency of a dwelling with a value from zero to five stars [9]. In at least one State of Australia, a four star rating is now mandatory, superseding the minimum insulation levels for walls, floors and ceiling. The dwelling rating takes into account the appropriate local climatic conditions, of which there are 27 zones in Australia. The NatHERS simulation software package predicts the temperature inside a dwelling 24 hours a day, 365 days a year, calculates the amount of energy needed to maintain temperatures within the desired comfort range and assigns a star rating.

5 Life cycle energy

The embodied energy of different types of dwelling construction and energy efficiency in the Australian Capital Territory have been compared to the annual operational energy as calculated by the Nationwide House Energy Rating Scheme. The basic dwelling was that of a single family house with changes made only to accommodate the differences between timber cladding, standard brick veneer and cavity brick construction and the specific requirements necessary to meet zero to five star ratings as defined by the NatHERS software. Many elements remained constant throughout the options; e.g. roof, windows, wall, floor and ceiling finishes, sanitary fixtures and plumbing, water supply, space heating, electric light and power. The ratings were increased largely by insulative measures (Table 2).

Starrating	*Timber*	*Brick veneer*	*Cavity brick*
0	No insulation	No insulation	No insulation
1	PLUS RI .O insulation to underside of floor, R2.0 entire ceiling	PLUS R1.0 insulation to entire ceiling	PLUS R1.0 insulation to entire ceiling
2	PLUS RI .5 to external walls	PLUS R0.5 to external walls	CHANGE ceiling to R2.5
3	CHANGE underfloor to RI .5, ceiling to R2.0, external wall to R2.5, PLUS external blinds, seal 85% of windows	CHANGE ceiling to RI .5, external wall to RI .5	PLUS RI .O to external walls
4	CHANGE underfloor to R3.0, external walls to R3.0. and ceiling to R3.5	CHANGE external walls to R2.0, ceiling to R2.5, ADD RI .O to around slab	CHANGE external walls to R2.0, ADD RI .O to ground slab
5	CHANGE to double glazing all windows, re-orient dwelling to north, seal downlights	CHANGE to double glazing all windows, ceiling to R3.0	CHANGE to double glazing all windows, ceiling to R3.5, ADD external blinds

Table 2 Insulative measures to achieve star ratings in a single family dwelling

5.1 Comparison of embodied and operating energies

Initial results show that

- it is not necessary to have heavy construction to achieve increases in operational energy efficiency for a dwelling (Figure 3, Figure 4),
- the timber dwelling required the greatest increase in embodied energy to achieve a 5 star rating (42% increase) from a 0 star rating (Figure 3),

- the largest incremental increases in embodied energy occurred when stepping up from a 4 star rating to a 5 star rating (Figure 3),
- conversely, very little additional embodied energy is required to raise the star rating from 0 or 1 to the next highest rating (Figure 3),
- the ratio of embodied energy to annual operating energy increased dramatically as the star rating increased mainly because of the rapid decline in operating energy (Figure 4), and
- the importance of embodied energy in a life cycle model of energy becomes significant (equal to 20 years of operating energy and 20% of life cycle energy for a dwelling life of 80 years) for 4 star rating and above (Figure 4).

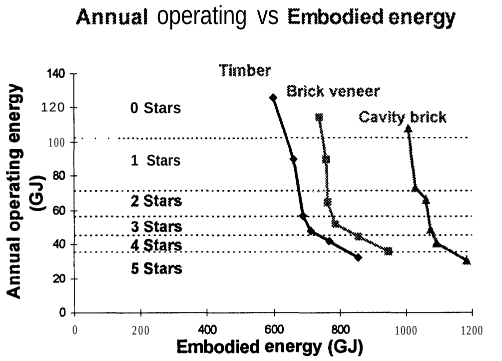

Figure 3 Annual operating energy as a function of embodied energy

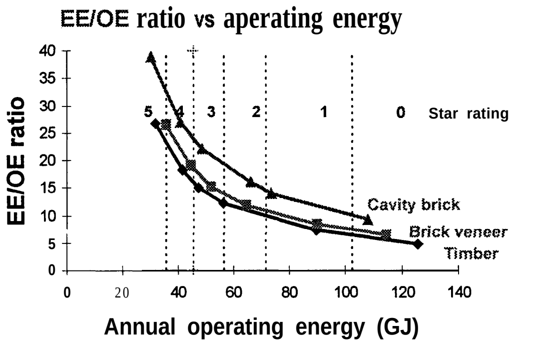

Figure 4 Embodied energy to annual operating ratio as a function of annual operating energy

6 **Uses**

The embodied energy model has been developed as an evaluative tool for assessing the comparative embodied energy impacts of alternative materials to assist in determining the overall environmental impact (as measured by embodied energy or CO_2 emissions due to energy use) of alternative design and building materials at the design stage of a building. It provides a designer with a measure of the total environmental impact of a building or component from a perspective never before undertaken.

Designers and quantity surveyors are familiar with the elemental cost planning approach to building de-composition and, as it is an accepted analytical approach to building design, the same approach facilitates comparisons between embodied energy impacts and building costs of elements of building, not individual materials. The effect of "trade-offs" should become apparent. For example, a particular insulating material may incur high embodied energy impacts in terms of product manufacture, but require little energy to install and maintain and it may enable greater energy savings to be achieved in the operation of air cooling or heating systems.

Embodied energy impacts are best studied at an early stage in the design process of buildings and should focus on the combinations of the main contributors to the totals for the building. The effect of using alternative materials on the total embodied energy and annual operating energy of a building, can most readily be investigated at this design stage, preferably before any major design decisions are taken.

The ability to perform any analysis work direct from CAD drawings is a relatively new concept and one that will probably be utilised more as systems are developed with more analysis and detailed studies. Likewise, the concept of embodied energy is relatively new and this program is one of the first to attempt to provide a simple and effective methodology for performing embodied energy calculations. The program is the first, as far as is known, to attempt to calculate quantities of every material in a building (rather than items which can be costed) and thus the first to estimate embodied energy direct from a 3D CAD drawing.

7 Benefits

The provision of fast environmental evaluations of embodied and operating energies and CO_2 of whole buildings is a major benefit in evaluation of alternative designs. It requires little additional effort by designers, architects and quantity surveyors to perform embodied energy and CO_2 calculations. The 3D CAD model also allows users to compare the embodied energy and CO_2 for parts of a building, if required.

This approach identifies the main contributors of embodied energy and CO_2, by element and material categories so that designers can concentrate on the areas where gains are likely to be most easily achieved and provides detailed material breakdown of building elements for other environmental assessment procedures. The various multi-level analysis options provide users with a highly flexible method for obtaining the data required for analysis and decisions.

The embodied energy total provides an energy value for the whole building on the same basis as operating energy for life cycle energy assessments and provides a method of assessing trade-offs between more energy intensive materials and less energy requirements for heating and cooling over the life of a dwelling.

There are a number of steps to be undertaken before a practical life cycle energy model can be made available to industry practitioners, and these steps include:

- development of the prototype embodied energy and CO_2 emission module to a commercial version, as has been done with the NatHERS software.
- expansion of the embodied energy and CO_2 database to cover construction energy and most materials and items commonly found in buildings.
- linking of the embodied energy module to the operational energy model in order to represent a total life-cycle (or ‘cradle to grave’) view of the energy impacts of dwellings.

8 Integration of evaluation methods

The embodied energy module in 3D CAD is an example of integration of a new analysis need (embodied energy) with an existing need (quantities of materials) based on an object oriented approach to specification of building items. Additional databases were created and additional analytical tools were developed to complete the integration. The effort required by users to apply such models is then only minimal. This is but a first step to implementing a life cycle energy model (and other applications) which includes the existing operating energy models.

9 Conclusion

Embodied and operating energy and CO_2 emissions are becoming important factors in the built environment and with the possibility of legislative requirements and standards, the ability to perform accurate calculations is essential. The prototype embodied energy software is the first example of a simple, yet effective CAD based tool to perform these calculations directly from quantities of individual components of a building. The complementary NatHERS operating energy model is an excellent example of a practical tool for analysis of an environmental impact of a dwelling. The two models both allow designers to undertake a sophisticated analysis on their designs and to compare alternative design solutions, quickly and effectively. There is an enormous potential for using 3D CAD based tools for analysis work, not only for embodied and operating energy, but for a range of environmental areas as well.

10 Acknowledgments

The prototype embodied energy software would not have been possible without the participation and guidance from a dedicated team of developers and researchers from the CSIRO Division of Building, Construction and Engineering in partnership with Cedar Enterprises, RMIT University and Wilde and Woollard and with financial support from the Energy Research and Development Corporation (ERDC).

the TWIN-model, an environmental calculation method as performance concept

Michael Haas, director of the Dutch Institute for Building Biology and Ecology (NIBE), Bussum, The Netherlands

Abstract
(Interests, Interactions and Implementations of Sustainable Design and Constructions in The Netherlands)
GreenCalc is a computer programme, which yields insights into the environmental impact created by the construction and exploitation of a building. This gives the initial impetus to the development of environmental performance standards. GreenCalc currently consists of four modules, namely:

- Materials usage during construction and maintenance
- Energy consumption during exploitation period
- Water consumption during exploitation period
- Liquid assets produced during exploitation period.

A module to calculate used volume of space by buildings is being developed.
The environmental impact created is expressed in environmental costs, which means it can be transferred between modules. Thus, a less environmentally favourable choice of materials can be compensated for by an exploitation method, which is more energy efficient.

The materials module is based on the TWIN model, a method which overcomes the limitations of current life-cycle analysis studies (LCA studies). The TWIN model is based on a 'double-layer' system. The first layer is an incomplete quantitative layer which uses all LCA results which are available (naturally just the quantitative data). However, the first layer is incomplete and contains 'gaps'. For example, the regional impact cannot be expressed in quantitative terms, although a fairly large amount of information is already known about it. The second layer was developed to take care of this; it consists of a completely qualitative system. Together, the two layers give the most accurate result which can currently be obtained.
In addition, the TWIN model can give an environmental assessment and a separate assessment of the health aspects. Since health is becoming a more and more important item, it makes sense to make it easy to gain insights into it here.
This contribution dovetails with the contribution by George Ang regarding Performance Concepts and with the contribution by Marcel Dewever regarding Environmental Costs.

Environmental impact, LCA, quantitative-qualitative, performance standards, environmental costs, health, computer programme.

Introduction

The publication in 1989 of the Dutch *National Environmental Policy Plan,* based on *Our Common* Future, made it clear for the public that the building industry ranks among the worst polluters. The *State of the World* 1995 shows that approx. 50% of all the world's dust-pollution flows are directly or indirectly linked to building activities. The Dutch report Care for *Tomorrow* reveals that the quality of the in-door environment is hardly healthy enough for living. In principle this has two causes; on one hand the ever enduring increase of chemicals in building, hereby enabling a greater efficiency in building, and on the other hand the increasing in-sulation of buildings with poorer ventilation performance resulting in an undesir-able build-up of moisture and toxics in interior spaces. Also *see Toxics in Buildings* by the author.

By opting building materials with a lower environmental impact and health hazard than those currently in use opt, an essential contribution can be made towards a sustainable development.

Need to gain insights at an early stage in the process

In the development process for a building, it is important that insights into the envi-ronmental impact of the building be obtained at as early a stage as possible, pref-erably when the very first sketches are made. The environmental impact of a building is primarily determined by materials usage. High-quality data about con-structions' environmental impacts can only be obtained from LCA studies, which require very detailed data.

There is a contradiction inherent between gaining insight at as early a stage as possible and having access to as detailed data as possible. This problem can only be solved by the development of a computer programme. This is why GreenCalc was developed, which can be used from the beginning of the design process up to and including the last working details, which makes it a good steering tool. Cur-rently, GreenCalc consists of four modules, namely: a materials module, an en-ergy module, a water module, and a liquid assets module. A module on usage of space is being developed.

Henceforth, the emphasis will be on the intrinsic background to the materials module, based on the TWIN model, which I recently obtained my doctorate with a thesis on.

LCA-method

In both reports *Environmental-orientated life-cycle-analyses of prociucfs, Manual and Backgrounds* in October 1992 an unambiguous assessment-method is de-scribed. It mentions the steps in order to achieve an environmental-consci-ous life-cycle analysis (LCA). In this method first all the interventions are stated, then the effects on the environment and our health. The actual assessment is based on the effects on the environment. These reports proposed a methodological ap-proach that has eventually become an international standard.

Due to the fact that the LCA-method has not fully matured yet, there are as still "gaps" or shortcomings in the method, especially considering the development of data. In this method health aspects are not fully acknowledged, the section on environmental impact is not worked out in sufficient detail, and a method of weighing data in order to reach a final assessment is lacking.

In practice only quantitative (measurable) effects are used in LCA-studies, thereby ignoring other valuable data in the final assessment. Therefore it is actually not possible to draw comparative conclusions for LCA-studies, while the agents in building are greatly in need of more reliable data considering environmental aspects than the well-known “selection-lists”.

Purpose of the TWIN-model

The purpose of the TWIN-model, my doctoral research, was to develop a method which, although based on the currently available data, extends beyond the existing intuitive or argued methods in order to compensate the lacking quantitative data based on measurements. Use can be made of data available from research and literature, including previously conducted life-cycle analyses. In the absence of reliable data, in order to obtain a balanced full life cycle view, the method allows for additional estimates, which provide insight and can be applied recurrently. Due to this open character, adaptation and adjustment will be possible at all times, hereby complying with ever changing process circumstances.

In addition, this presents the possibility of reversing the onus of proof. It will not be the task of the researchers to prove that a material, product, or building component impacts the environment or affects health, but rather the task of the manufacturer to show that this is not the case, or at least to a lesser extent than assessed (worst-case-analysis). The method can process both quantitative and qualitative data.

The classification model that is developed is capable of predicting environmental impact and health risks within certain defined performance levels.

Subgoal in the TWIN-model was to resolve a number of problems in the present LCA-studies, enabling clear comparisons between building constructions and eventually whole buildings.

assessment also based on health

In the present LCA-method the aspect of health is far from being sufficiently appreciated. In order to have this aspect fully acknowledged the LCA-method has been extended by incorporating health criteria. The extension is developed in the form of a separate module so as not to deviate too much from the standard LCA-method.

elaboration of impact in LCA-method

The section on impact has not been elaborated on in the present LCA-method and is therefore mostly not considered as an assessment criterion. Assessments can very well turn out differently if the factor impact is incorporated.

> In a recent LCA-study turned out that the winning of new sand more favourable was than using recycled sand. In this study the impact on the landscape was not incorporated. Therefore the winning of new sand had less environmental impact on the landscape in the case of the winning of new sand had been incorporated, then the final assessment might have turned out differently!

determination of weight-factors

In order to achieve a final assessment it is necessary to apply weight-factors for the step of defining classification. A set of weight-factors has been developed; this ‘step is indicated in the LCA-method, but has not been worked out in more detail. Heijungs states on this point in *Environment-orientated* life-cycle-analyses of *products*: “In the case of a quantitative environmental-criteria-analysis the various environmental effects are summed up after multiplying each effect with the corresponding weight-factor. The question who judges the environmental effects or who even should determine the weight-factors is not a problem of methodology, but of practical political nature."

As indicated in The tco-indicator 95: "A LCA must lead to a definite unambiguous result and not to a number of contradicting effect-scores, that cannot be interpreted by a designer (and many environmental experts)."

It is therefore important to determine the relationship between the various environmental aspects. In order to achieve this, weight-factors have been developed within the TWIN-model, thereby making it acceptable to relate the various environmental aspects to each other.

Speaking in terms of a metaphor we are talking about a method to compare the various fruit in a basket.

incorporating quantitative and qualitative data

Because it will take years yet before the necessary data will be available in the quantitative sense, it is necessary in the interest of a complete LCA-profile that data that are not quantitative be expressed in a qualitative sense. Again the LCA-method provides in this as Heijungs states: "In a number of processes not-quantifiable aspects are of importance. These should also be mentioned: the format explicitly provides for this kind of data". Nevertheless in practice not-quantifiable aspect are left out in the present LCA-studies, leaving a distorted impression. The TWIN-model explicitly provides in the possibility of relating quantitative and qualitative data in one model.

Description of the TWIN-model

The model consists of two parts, namely a quantitative part and a qualitative part. This last part consists of two matrices, one for an environmental assessment and one for a health assessment. Due to the fact that these pairs are to be considered as twins, the whole is called the TWIN-model.

shifting between layers of systems

A complete qualitative system has been developed that can be substituted by a quantitative system for each criterion; a system that closely links to and even covers to a high degree the LCA-method of the CML. Hereby two complete systems have come into being, of which the quantitative system represents the highest degree of accuracy and the qualitative system covers the area where no quantitative system data exist as yet. Only the combination of the two systems together reveal the full spectrum of environmental and health impacts.

The whole model can be considered as a layered system, in which the quantitative and the qualitative layers can be exchanged. When more knowledge is eventually developed in the quantitative sense, then there will be a shift towards the quantitative system. In the beginning there will be more knowledge in the qualitative system.

performance scale of qualitative data

The possibility of making an objective assessment of the environmental qualities of a building material, building product or building component is very limited. Much quantitative data is still lacking, so assessment can only be based on quality for the time being. In order to ease the subjective aspect, being typical for the qualitative system, the environmental and health criteria have been divided into sub-criteria. For each sub-criterion a performance description has been made in various levels (see supplement performance scales.) Certain environmental impact

the health-criteria of the TWIN-model as a matrix

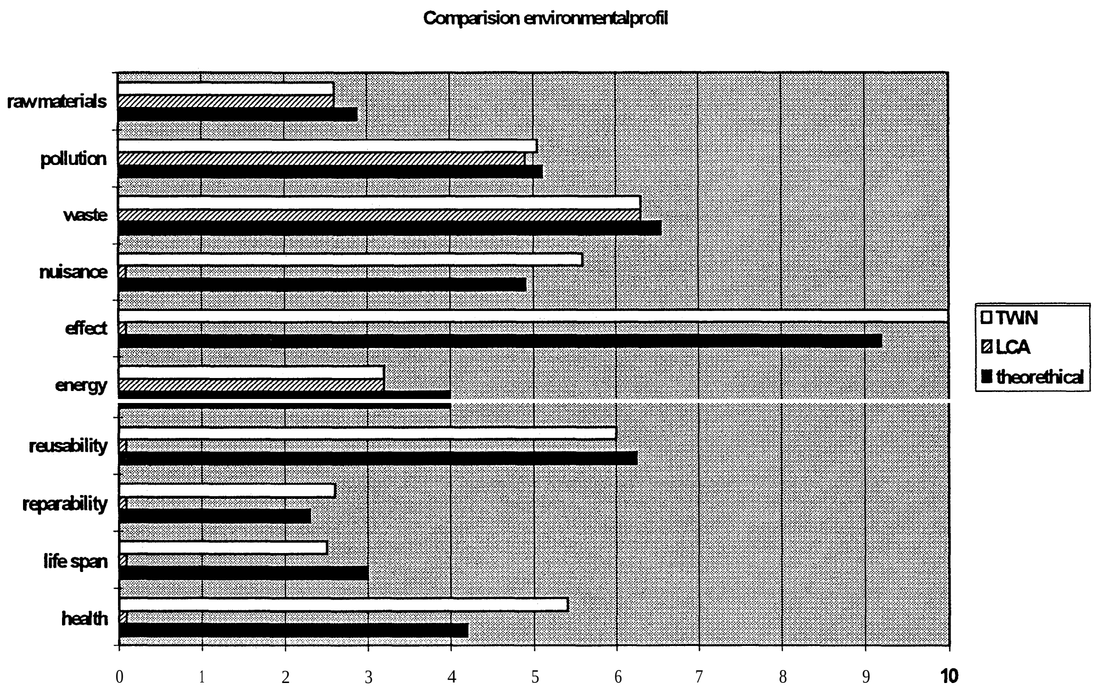
A major advantage of the TWIN-model is the possibility of not only comparing building materials, but also components and even whole buildings. Other methods cannot as yet offer this possibility. In addition it is possible to achieve integral assessments based on the best available data from other research sources (quantitative and qualitative data).

GreenCalc, an environmental calculation method for buildings

A computer programme has been developed in collaboration with market players, based on the TWIN model presented here. This programme is now available and contains an extensive database, which includes all the common types of building/construction, assessed according to the TWIN-model method, which is now covered by a patent.

In contrast to the method used in the TWIN-model, the results arrived at using the GreenCalc programme are expressed in environmental costs. This method dovetails better with the management decision-making culture: managers always think in terms of money and in particular are responsible for their own budget. The budget 'hole' or shortfall is much closer to home than the hole in the ozone layer. This is why our GreenCalc programme has turned the hole in the ozone layer into a hole in the budget. The link to environmental costs is arrived at by taking the available quantitative data as kg-equivalent CO_2 pollution and multiplying it by the costs of preventive and/or corrective measures for one kg of CO_2. These costs can be quantified very accurately within certain limits. In the case of qualitative data, comparisons are used. In order to be able to determine the regional impact,

corrective measures carried out are assessed and used to determine what the environmental costs for the correction of the environmental impact are.
Using this method means that weightings are no longer needed, as this function is taken care of by the expressing of all factors in money terms. This also means that the individual GreenCalc modules can be weighed up against each other. For instance, working with natural ventilation reduces energy consumption, but leads to the building having a greater bulk. Does the environmental benefit of the energy saving compensate for the negative environmental impact of the additional usage of materials? It is also possible to compare the retaining of the existing building against the construction of a new building and to work out the size of the environmental gain.
Finally, GreenCalc now makes it possible to translate the list of requirements for the building into environmental costs. These environmental costs then become the construction budget, which data can periodically be compared with. This means that environmental performance requirements can be formulated in advance and continually tested during the construction process to see whether they are being achieved.
I hope that Mother Earth will benefit from it.



in this diagram possibilities of the TWIN-model are shown, the lower line is the theoretical possible environmental impact caused by the product (this environmental impact might be know first in 50 years), the second line shows the results of a LCA-study, with a limited number of environmental aspect cautiously approached, the upper line shows the possibilities of the TWIN-model, LCA-results are included and the not available dates are added caused the worst-case-analysis; looking at the total, the picture becomes more c/ear than when working with only the LCA-results

SUSTAINABLE DEVELOPMENT BUILDING DESIGN AND CONSTRUCTION - TWENTY-FOUR CRITERIA FACING THE FACTS

Robert Angioletti
ADEME, France
Christophe Gobin
Dumez Construction, France
Marc Weckstein
CSTB, France

Abstract

The paper reports on the use of a set of twenty-four criteria established in 1996 covering the whole life cycle of a building. Four types of building (house, apartment block, off6ice block, supermarket) of either concrete or lightweight construction, in a rural, suburban or inner city setting, have been analysed.

Each of these alternatives was broken down into 'functional' components (site suitability, structure, exterior walls, indoor walls, equipment (HVAC, specific electrical circuits) and finishing, each using the most common relevant technologies.

Each alternative was screened through the twenty-four criteria, with a matrix approach to handle the large quantity of data. The results are tabulated in three matrices covering the object (building, technology and architecture), process (design, construction, operation and end-of-life), and interactions (environmental impact of building, relationship with townscape and socio-economic dimension).

The first lessons learnt from this work are presented.

Keywords: Sustainable development, research and development

1 Introduction

While sustainable development contains all sorts of ambiguities and sources of confusion, the general concept it embodies is nevertheless vital for the future of the planet, our society, and, lower down the scale, the building profession.

Greater importance must be given to long term prospects in the daily decisions involved in new building and to the whole life cycle of the finished structure, including what will happen to the site when it is eventually demolished.

The forward planner must identify the major challenges that will confront the building. This idea was the starting point for the working group formed by the Club BatiVille, made up of CSTB, ADEME and Dumez with assistance from Cabinet Space, to undertake a methodological approach to consider the building from the standpoint of sustainable development.

This purposely general and systemic approach looked at socio-economic development, the environment, resource use, and the waste generated.

The methodology comprises four mains steps:

- Analysis of mutual issues concerning both the building industry and sustainable development.
- Theoretical input to conceptualise sustainable development as applied to the building industry, leading to a set of characterising criteria.
- Instrumentation, specifying indicators of whether the criteria have been met, and, where applicable, suggestions for initial research and development vectors.
- Evaluation and validation by practitioners to stabilise the concept and propose concerted research agendas.

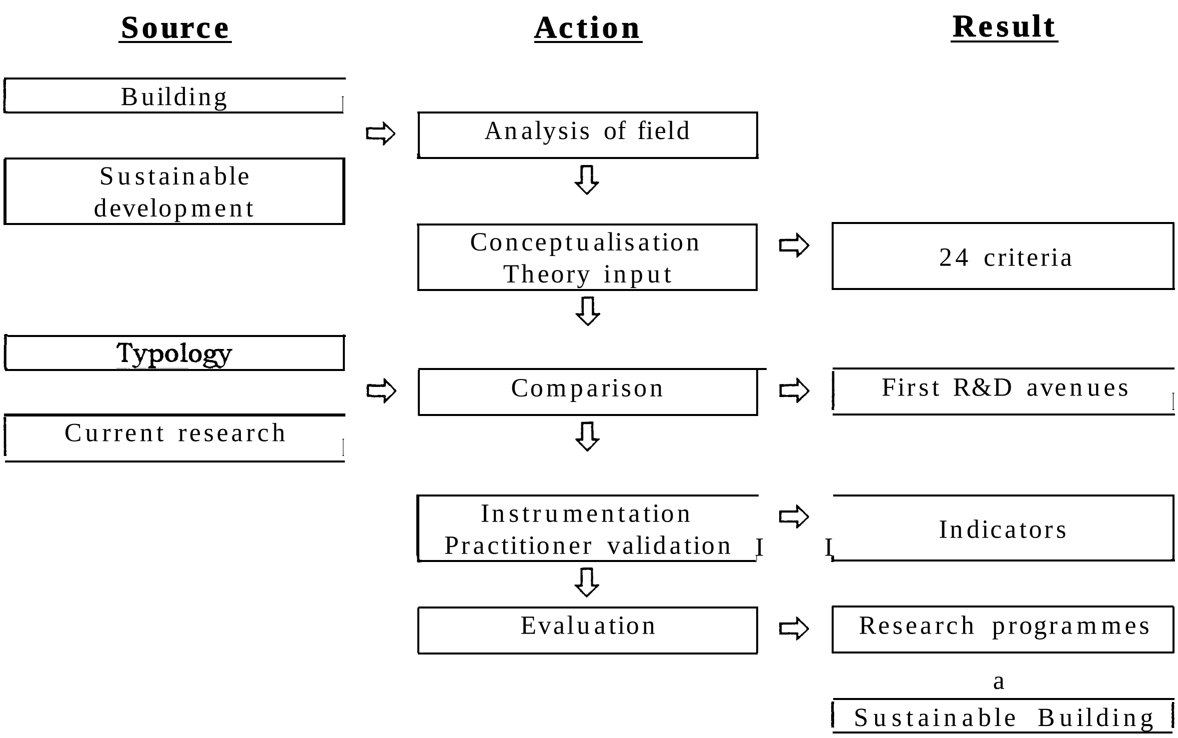


Table 1: Sustainable Building Methodology

The first step produced a set of twenty-four criteria (see below). A further step was taken in recent months to make progress in instrumenting these criteria and find those for which for which workable indicators already exist, those for which substantial on-going work promises tangible results within the foreseeable future (sometimes at the cost of broadening and refocusing goals) and those for which lack of currently available or pending knowledge (at least on the part of the members of the group) makes further research necessary to evaluate or invent pertinent indicators.

This paper describes this analytical work and resulting proposals for action. It is also hoped it will incite the scientific community and professional stakeholders to debate the initial results of our confronting the twenty-four criteria with concrete tools for their application.

2 Analytical Review of Criteria

The following list shows the main opportunities for improvements as indicated by looking at available technologies for each alternative examined, in the light of these criteria.

1 - Capability of fulfilling required function
- Generalise planning and design performance approach by specifying referents
- Improve home safety
- Evaluate health impact of building goods and materials and eliminate those known too be toxic or dangerous
- Improve indoor air quality and develop filter and purification equipment for buildings exposed to outside sources of pollution at urban sites
- Improve external noise mitigation

2 - Capital impact
- Promote whole life cost concept: eventually presupposes combining capital costs and time-dependent costs, including demolition, by broadening the approach to cover financial costs and internalisation of external (environmental, urban, etc.) costs
- Analyse the value of each of these items in order to optimise them

3 - Implementation logistics
- Include construction constraints and potential services offered by builders at the earliest project planning and design stages
- Encourage new products making construction easier (assembly connector design, etc.)

4 - Working conditions
- Stress clean jobsite approach
- Develop handling and lifting gear to reduce manual labour and improve safety at work

5 - Impact on personal pride
- Encourage quality assurance approaches to give workmen a sense of personal responsibility and make work more rewarding
- Improve circulation of information by tapping potential of new communications technologies

6 - Disturbance from construction sites
- Improve control of incoming supplies to jobsite and outgoing waste (packagings, waste sorting and re-use)

- Reduce waste at source: simplify product ranges, encourage re-use and returned packagings, reduce unnecessary packaging
- Reduce noise, dust, waste water and other nuisances to residents

7 - Raw materials resource use

- Develop methods of aggregating product life cycle analyses to have a better insight into use of raw materials resources in the building industry
- Encourage recycling

8 - Energy resource use

- Optimise energy efficiency of products, processes and buildings, and recover free inputs
- Make optimum use of locally-available renewable resources
- Develop and instrument product and construction process life cycle analyses.

9 - Lifespan and strength

- Build data banks on lifespans to integrate them into whole life cost approach
- Correlate natural ageing and accelerated ageing

10 - Optimised maintenance

Devise a description of the completed building designed around operating and maintenance requirements

Develop performance sensors (ageing and loss of performance)

Develop comprehensive, accessible preventive maintenance methods

11 - Consumption and waste

Improve knowledge of consumption and waste trends (water, municipal solid waste, garden waste, etc.)

Expand R&D on clean, low-consumption technologies (solid waste, air conditioning and other uses) to reduce running costs, resource use and pollution

12 - Costs of access to communal services

Develop tools by which urban project development methodologies can include for constraints and opportunities offered by business location

Develop methods of optimising capital cost of utilities

Investigate utilities cost structure in order to optimise pricing

13 - Control of movements

Adapt simulations to optimise movements in terms of safety and convenience

Improve quality of way in which circulation are dealt with

14 - Immaterial movements (control signals, information, communications)

Develop information transmission technologies in-building and between buildings and surroundings (power systems, low current systems, remote control, etc.)

Imagine new uses

15 - Inter-modal transport

Develop tools for optimising parking capacities to suit means of transport available near buildings

Investigate opportunities offered by virtual offices and teleworking

Investigate relationship between workplace and mobility (home-work-shops-leisure) and derive optimisation tools

16 - Capability for incorporating neighbourhood services

- Review expectations of occupants, their needs, and types of neighbourhood services that can be incorporated in buildings
- Examine construction techniques that really integrate such functions

17 - Avoided social costs

- Investigate social needs and means of providing for special needs: the old, handicapped, children, ethnic groups, etc.
- Investigate social issues and relationships as affecting design of buildings and/or urban districts

18 - Impact on heritage

Investigate spatial segregation and its social and economic consequences

Improve architectural and landscape representations of buildings and open spaces (townscapes, etc.)

Determine acceptable levels of nuisance to residents with reference to changes in community expectations: noise, sunlight, proximity, etc.

19 - Impact of building on environment

Development platforms for integrating tools for simulating and evaluating impact of building on its environment

20 - Capacity for change

Develop connection systems for indoor pipe and cable that facilitate replacement of obsolete technical equipment and ability to accommodate new products

Develop modular components

Encourage integration of basic functions in indoor and/or external walls (analysis of value, functionality, ergonomics, etc.)

Develop loadbearing structures suitable for convenient, inexpensive changes in indoor arrangements (removable and movable partitions, etc.)

21 - Capacity for new final use

Develop connection systems for indoor pipe and cable that facilitate change of use of premises

Develop, where possible, modular structural components designed for easy assembly/disassembly to permit convenient, inexpensive changes of use of indoor premises

Develop integration of basic functions in indoor and/or external walls (analysis of value, functionality, ergonomics, etc.)

22 - Opportunities for improving performance

- Simplify component ranges and standardise connection systems
- Improve installation/removal ergonomics and accessibility of installations, systems and components
- Develop renovation and maintenance systems that do not inconvenience occupants (insulation from outdoors, central boiler, distributions to communal facilities, etc.)
- Develop products and components of high environmental quality specifically suited to building improvement and renovating

23 - Ease of demolition

- Develop materials suitable for easy sorting
- Develop methods for making pre-demolition audits and organising the work

24 - Removal

- Develop construction systems that are easily dismantled (dry assemblies, lightweight materials, modularity, etc.)
- Develop quick methods (saving time)
- Design intermediate storage systems suitable for demolition sites (mobile waste disposal units, etc.)

- Develop systems of marking products for easy recognition during demolition

3 Conclusion

Three remarks are called for at the conclusion of this manifestly operational exercise.

1. The construction industry must make a significant effort if it is to arrive at its sustainable development goals. Expressed differently, our lifestyle offers great potential for progress towards balanced, effective development.
2. It is suggested there should be an international observatory of construction technologies in the light of these twenty-four eminently practical criteria, since they provide a convenient framework that can be shared by all professionals.
3. Apart from this analysis of potential improvements, and looking at processes and products in the light of this framework, it appears that there will quickly emerge two inevitable trends, (i) concurrent engineering will become essential to improve liaison between the various parties involved, and (ii) there will necessarily appear the concept of the autonomous 'self-contained' building, i.e. one which minimises energy exchanges with its environment.

Strategies for change - understanding sustainable development from a construction industry perspective

©A. Gilham MCIOB,
Centre for Sustainable Construction, BRE, Watford, United Kingdom.

Abstract

The construction industry, along with all other industries is being challenged to become sustainable. The industry is currently searching for a definition of sustainability which it can apply to its activities. However, sustainability is multi-faceted and infinitely variable in its interpretation. This paper, without making a definitive statement on sustainability, sustainable development or sustainable construction, considers the factors which will shape and influence the construction industry in the future. The paper:

- explores the developing framework for sustainable development
- considers some of the likely impacts on the industry
- sets out four strategies for change and development that the construction industry could adopt

The paper asserts that sustainable development means change and that the construction industry should search for solutions which help create an industry-wide "Strategy for Sustainablility". Whilst for many construction businesses such a strategy may well appear to be impracticable and too far from their current trading reality, there is evidence from the UK construction industry that commercial practices such as Partnering and Value Management are providing a platform for the development of sustainability strategies.

Further evidence from current CIB research projects suggests that the industry will have to adapt to new construction markets with environmental dimensions which will be driven by a mixture of political and market forces, requiring products which respond to genuine need and concerns.

The findings presented in the paper are drawn from work carried out by the author for: CIB Working Commission W82; the UK Government's Office of Science and Technology (OST) and Department of Environment, Transport and the Regions (DETR) and the Environment Committee of the UK's Chartered Institute of Building (CIOB) which addresses the needs of construction management professionals.

Keywords: Sustainable development, strategies, components and drivers of change

1.0 Introduction

The construction industry has a substantial impact on our society. It shapes our townscapes and provides us with shelter, work environments and leisure facilities. The industry and the resulting built environment impacts upon the natural environment over a long period of time and sometimes with devastating effects on local habitats and ecological systems. The construction industry, along with all other industries is being challenged to become sustainable. The industry is currently searching for a definition of sustainability which it can apply to its activities. Sustainability is, however, multi-faceted and infinitely variable in its interpretation. This paper, without making a definitive statement on sustainability, sustainable development or sustainable construction, sets out some of the key factors which will help shape and create a sustainable society and explores the options and likely impacts for construction.

Sustainable development means change and that the construction industry needs, in response, to search for solutions which move towards an industry wide "Strategy for Sustainablility".

The impact of this change, upon organisations and institutions, is currently difficult to define. For example, how can a company reconcile its responsibilities towards shareholders with issues such as community employment and welfare? How can that same company justify the inclusion of third-party interest groups in it's decision making process? However, based on current international research carried out by the CIB Working Commission W82 (Construction Futures), it is expected that industry will be required to address exactly these issues, giving corporate responses which go beyond their organisations' normal boundaries of activity and often beyond their normal areas of expertise.

2.0 The challenge for the construction industry

In the UK, the Latham report [1] has highlighted the need for change and improvement in the construction industry. The demand for construction which is "sustainable" places further pressure on the industry. The challenge for the industry is to identify new and innovative practices, technologies and ways of working which satisfy the need for a modern, competitive, efficient, responsive and socially responsible industry.

How can the industry transform the demand for change into an opportunity, to create and access new markets, find innovative responses which satisfy traditional industry demands and the new societal demands for sustainable development?

Unfortunately, the industry has to overcome many barriers to achieve this state. It is risk-averse, as are the majority of its clients, it is highly regulated, competitive, fragmented and dominated by contracts which regulate the involvement of the client in the construction process. These same contracts assign liability for failure onto the suppliers and providers in the industry over a long timespan.

3.0 Developing understanding - the framework for sustainable development

This paper does not attempt to define sustainable development; there are many definitions produced by others. Whilst not exhaustive, those definitions listed below indicate the range of expectations which various sectors of society have for sustainable development and what the expectation is for businesses. For example:

"........... to meet the needs of the present without compromising the ability of future generations to meet their own needs."

The World Commission on Environment and Development (The Brundtland Commission), Our Common Future. Oxford: Oxford University Press, 1987, p43

"Our vision is of a life-sustaining Earth. We are committed to the achievement of a dignified, peaceful, and equitable existence. A sustainable United States will have a growing economy that provides equitable opportunities for satisfying livelihoods and a safe, healthy, high quality of life for current and future generations. Our nation will protect its environment, its natural resource base, and the functions and viability of natural systems on which all life depends. "

The President's Council on Sustainable Development, Feb 1996.

"The central purpose of a sustainable enterprise should be to promote "sustainable livelihoods" through the creation of jobs and resulting purchasing power, and the production of products and goods and services that are needed to better the lives of people"

Arun Kumar, Development Alternatives, Network Conference, Boston 1993

"Business should cooperate with government and society to identify problems, articulate the goals, search for solutions, and implement measures. Business should be both profitable and environmentally sound"

Robert Campbell, CEO Sun Company, Boston 1993

Evidence of the breadth of issues to be considered can be gained from many sources including statements of intent regarding sustainable development from around the world. For example: The US Presidents' Council on Sustainable Development [2] makes 16 statements of belief which cover broad ranging issues such as:

- Economic growth - jobs, productivity, wages,
- Protection of the environment - monitoring, legislation,
- Individual, institutional and corporate responsibility, commitment and stewardship.

Furthermore, statement 16 in this US publication is a good illustration of how other issues such as education, public participation and social responsibility will be integrated into all aspects of business and governance. It says "Citizens must have access to high-quality and lifelong formal and informal education that enables them to understand the interdependence of economic prosperity, environmental quality, and social equity - and prepares them to take actions that support all three."

An indication of policy in the UK can be found in a report "Indicators of Sustainable Development,"[3] published in 1996, by the UK Government's (then) Department of

Environment. This presents two basic aspirations of society: to achieve economic development to secure rising standards of living both now and for future generations; and to protect and enhance the environment now and for the future. Four main aims were proposed in this document:

- to maintain a healthy economy, promoting quality of life and protecting human health and the environment in which all pay the environmental costs of their decisions
- the optimal use of non-renewable resources
- the sustainable use of renewable resources
- minimising damage to the carrying capacity of the environment and the risk to human health and biodiversity from the effects of human activity.

Following recent Governmental changes in the UK, wider social issues are also being included in this strategy. The remit of the former DOE has been broadened. The new Department of Environment, Transport and the Regions (DETR) has issued a consultation paper on the UK sustainable development strategy reflecting a more coordinated and integrated response to the major components of sustainable development.

Agenda **21,** stemming from the Rio conference in 1992 is placing the emphasis on local, community action on sustainable development. It aims, at community level, to:

a integrate consideration of social, economic, and environmental conditions
a increase public participation and partnership, and
a implement long term strategies for continuous improvements in the community

Whilst these aims have been slow to come to fruition with so far little, if any, impact on business, it would appear that measures are being introduced which will overcome many of the institutional barriers which have impeded progress so far. In a review of Agenda **21,** Dodds [4], lists actions which are explicit about the involvement of businesses, such as:

- setting up a representative, multi-sectoral planning body or "stakeholder forum" as the co-ordinating and policy group for developing and monitoring a long-term sustainable development action plan
- implementing a consultation programme with community groups, NGOs, businesses, churches, professional groups and unions to identify proposals and priorities for action
- setting up monitoring and reporting procedures which hold the local authority, business and households accountable to the action plan.

4.0 Likely impact on the industry

This broadening of societal values and interests challenges the motives and values which have previously driven growth and development and which have previously defined industrial success. Dodds [4] proposes that an industrial perspective of sustainable development is built upon three pillars:

- economic growth
- ecological balance, and
- social progress

He proposes that industry's contribution to sustainable development comes through "eco-efficient" leadership, which can be more, or less, effective depending on the trading framework in which each industry operates.

It is clear that construction businesses will be expected to integrate into, and consider more fully, the issues valued by others at national, regional and community level. The W82 research project: "Future studies in sustainable construction", looking at the construction industry in the year 2010 suggests that the industry will need to respond to the "genuine needs and concerns" society and environmental concerns such as toxic substances, energy and water conservation, water and air pollution; and the integration of environmental actions into community and economic benefits. The study also suggests that changes in regulation, planning legislation and the demand for a life-cycle approach to design will impact on working practices.

5.0 Strategies for change

For many in the construction industry the components of sustainable development pose unfamiliar challenges. Many of the issues, often conflicting in themselves, are not considered in the current decision making process. Typical future concerns for the industry to address will be:

- who are the stakeholders in any decision making process - are they partners or detractors?
- what are the areas of risk and security?
- which construction activities contribute to sustainable development and which are in conflict?
- what are the market potentials and competitive threats?

For its part, the industry needs to adopt a strategy for change to work towards achieving development which is sustainable. The Greening of Industry report [5] lists four strategies for change which industry can take and which appear to be applicable to construction businesses. They are:

1 The defensive strategy - complying with regulation

This is a typical response from organisations in the construction industry where quality is governed by regulations. Typically, the cost of the environmental component in an industrial activity is counted as a cost of compliance with regulation and minimum standards. Often, the cost of non-compliance is the primary motivator to make improvements and so to reduce the environmental impact of industrial operations. For some the solution might be to find an environmentally less sensitive site or to conceal the impacts altogether. Typically, in organisations which follow this strategy, there will be low levels of environmental awareness and understanding.

2 The offensive strategy (beyond compliance) - development of environmentally friendly products, or going beyond compliance for competitive advantage.

In the service sector particularly, the environmental component of a product or service can be portrayed as a market benefit, adding value to its clients and customers. BREEAM [6] is an example of an environmental quality standard which has proved to add value and to provide market benefits for its users. The quality standards required to achieve high BREEAM ratings are above those required by law and the users (customers) of BREEAM-rated buildings identify many benefits beyond the normally accepted financial criteria. BREEAM is also valuable in illustrating the benefit of partnership, recognising and incorporating the needs and concerns of a wide range of users and stakeholders in the project under consideration.

Improved quality and customer focus can be identified as key components required to move from a "defensive" strategy to an "offensive" strategy. Quality and customer focus are also common components for the cultural change which is being sought in construction in the UK as a result of the Latham review. [1] There is thus a close relationship between the requirements on industry to deliver improved environmental and commercial objectives.

3 Eco-efficiency strategy - tries to identify win-win solutions by reducing environmental impacts and costs; includes concepts such as total quality environmental management and industrial ecology

This strategy goes one step beyond the offensive strategy and builds in a win-win outcome for supplier and client. There are examples of this response where supplier and customer collaborate to provide mutual benefit over and above the normally accepted contractual provision. " An important aspect of eco-efficiency strategy is its service provision." " Value enhancement must be sought through focusing on providing the service connected to their products to customers instead of selling as much product as possible." [5]

To succeed this strategy requires understanding on both the supply and demand side. Examples of partnering in the UK construction industry typify the approach required with examples of success and failure depending on the "attitudes" of all parties.

Dodds [4] identifies three components of this strategy:

- eco-efficiency, and
- leadership - which he describes as having vision, being proactive, transforming organisations and people.
- effective and innovative use of technology

Once again, these are issues common to the developments taking place in the UK construction industry as a result of the Latham review.

An example quoted recently [W82 Conference, Hungary, October 97] was a carpet manufacturer in the USA who contracted to provide a "carpeted area" throughout a building for an agreed period of time and to take back the carpet at the end of its useful life, when it would be recycled. The key step towards environmental improvement in this case was the provision of a service; rather than sale of product. Benefits included:

- for the client - quality products appropriate to location, elimination of waste materials, maintenance free provision, free replacement in heavily trafficked areas leading to consistent image and condition;
- for the supplier - long term contract, reduced waste, reduced manufacturing costs using recovered carpet material, improved environmental management performance.

Key components required to move from the offensive to the eco-efficient strategy include: the valuing and costing of environmental impacts; and identifying and valuing the full cost of development, over time, for all stakeholders.

4 Sustainability strategy - focusing on new and emerging partnerships between business and other stakeholders

Finally, we have the most advanced strategy, requiring an understanding and tolerance of complexity. It is likely that this strategic response will be achieved through decision makers adopting new values which reflect the aims, objectives and aspirations of sustainable development. For businesses used to short time horizons with defined, discreet client groups and markets, the risk of including and responding to the range of stakeholders and potential "clients" may be too high. What shape might the sustainable business take? From a range of policy research projects, there are indications that sustainable business will be more holistic, systemic and integrated [7]. Core values are likely to include [5]:

- "Wholeness" - understanding and accepting the system relationships between industry behaviour and its impact (usually known as the externalities in economic theory). This means taking responsibility for the impact of the business, so recognising that businesses do not operate in isolation to their surrounding environment. This approach leads to a shared responsibility and unity between the business and its community.
- "Care for future generations" - where a "future generation" representative may be included in the boardrooms of industry to challenge their time horizon for decision making, requiring more emphasis on whole life costing and long term impacts. The business takes responsibility for the impacts of its process but extends this over time
- "Smallness" - utilising small work teams, defining responsibility at the lowest level possible, requiring an ability to attend to detail "at the coal face", with increased ability to respond flexibly and innovatively.

The change from eco-efficient to sustainability strategy perhaps poses the greatest challenge to construction businesses. However, there is evidence (partnering, etc) to suggest that changes in working practice are taking place in the construction industry to bring about partnerships, shared ownership, shared risks and benefits.

6.0 Conclusions

Sustainable development from a construction industry perspective undoubtedly means change. For an industry which is inherently defensive the prospect of, and opportunity for, positive change is not always apparent, particularly in the context of the complexities of sustainability. This paper has explored the requirements of a sustainable society and the likely components of sustainable development. There is recognition that many of the issues are new to business. They are often referred to, by business and researchers alike, as "fuzzy" issues [8]; they extend the boundaries of normal business considerations. The paper has set out four strategies for change which industry can adopt, asserting that change should be away from "defensive" strategies progressively towards, "offensive", "eco-efficient" and "sustainable" strategies.

Whilst for many construction businesses these strategies may well appear to be impracticable and too far from their current trading reality there is evidence from the UK construction industry that practices such as Partnering and Value Management are providing a platform for the development of eco-efficient and sustainability strategies. Mutual objectives; continuous improvement; and problem resolution are the three essential components of partnering [9] which provides a framework to bring about the collaboration, value sharing and long term risk and benefit sharing necessary to achieve sustainable developments.

7.0 Acknowledgements

This paper has been compiled from work carried out on a range of UK national and international projects including: CIB Working Commission W82; UK Government, Office of Science and Technology (OST) and Department of Environment, Transport and the Regions (DETR)work on sustainable indicators for construction; DETR funded Construction Productivity Network and Construction Industry Environmental Forum; Chartered Institute of Building (CIOB), environment committee work in the UK.

The Need for the Implementation of Quality Management Systems in South African Construction

J. J. Smallwood
Department of Construction Management, University of Port Elizabeth, Port Elizabeth, South Africa

P.D. Rwelamila
Department of Construction Economics and Management, University of Cape Town, Cape Town, South Africa

Abstract

People are not similar in terms of personality traits, personal goals, philosophy and culture and consequently require a system, or systems to enable them to be consistent and achieve goals first time every time.

Consistency only results from a documented Quality Management System (QMS) which effectively integrates Quality Assurance (QA), Quality Control (QC) and Quality Improvement (QI).

QMS's also facilitate the synergy between occupational health and safety, productivity and quality, as they ensure the use of, inter alia, documented procedures and instructions which when followed prevent defects, accidents, rework, waste, and ultimately complement the sustainability of the environment.

Clients and users seek assurance: that the construction process will not result in fatalities, injuries and disease, damage to the environment, and that buildings and structures will be free from defects, costly maintenance and will not compromise the environment or adversely affect the inhabitants.

To this end, findings of descriptive surveys conducted in South Africa among general contractors will be presented which include inter alia: most contractors do not have a documented QMS; competitive advantage, improved productivity and reduced cost predominated among reasons for implementing a documented QMS; cost, client satisfaction, productivity and future work predominated among factors negatively affected by non-achievement of quality, and unqualified artisans, shortened project periods, inadequate details and inadequate specifications predominated among factors which negatively affect quality.

Keywords: Quality Management Systems, synergy, sustainability, environment, client satisfaction

1 Introduction

Quality means conformance to requirements, nothing more, nothing less [1]. Construction of various structures, as general activities, needs to conform to requirements [2]. When we know the requirements there is no opportunity for varying interpretations of what is required. The requirements are contained in, inter alia, contract clauses, specifications, standards, schedules, drawings and details. If there is a possibility of relativity then the requirements should be mutually agreed and confirmed [3]. The degree to which these requirements are met will determine the level of customer satisfaction upon or after completion of a construction project and hence contribution to the sustainability of the built and general environment [4].

However, as with most products or services, customers want to be assured prior to commencement and after completion of a project or service that they will be provided with a 'quality' product or service [4]. According to Landin [5] the demand for quality assurance in construction is increasing.

Assurance does not mean guarantee, it means confidence. Confidence in turn results from consistency. As people are not similar in terms of personality traits, personal goals, philosophy and culture, they require a system, or systems to enable them to be consistent and achieve goals first time every time. Consistency will only result from a documented quality management system (QMS) which effectively integrates quality assurance (QA), quality control (QC) and quality improvement (QI) [3].

2 Quality as a holistic requirement

Occupational fatalities, injuries and disease and damage to the environment constitute defects as they are not project requirements. Completing an activity or project without incurring any of the aforementioned defects constitutes successful completion [6].

2 The cost of non-conformance (CONC)

According to Crosby [1], the CONC is all the expense involved in doing things wrong, inter alia, rework.

Research conducted in the United States of America by the Associated General Contractors (AGC) [7] of nine industrial projects determined the average cost of rework to be 12,4% and normal work to be 87,6% of project costs. The distribution of the 12,4% is scheduled in Table 1.

Distribution of rework	Response (%)
Owner changes	3,3
Design errors	3,3
Construction Errors	2,8
Other	3,0
Total	12,4

Table 1: Distribution of rework on nine American industrial projects [7].

Research conducted among South African general contractors determined the average cost of rework to be 13% of project value.

Based on the 32 203 million (at current prices) of construction completed in South Africa in 1996 and an average of 13%, the cost of rework could have been R4 186,4 million [8].

3 Need for QMS's

Kerzner [9] cites oral communication, which is preferred by most people in the construction industry, as a major source of communication breakdown. Oosthuizen [10] maintains that this problem can be circumvented by finalising the process of communication and recommends the use of checklists and the implementation of a QMS.

Problems related to health and safety, productivity and quality can frequently be traced to substandard, inconsistently applied or non-existent operating procedures and practices [11]. Standard operating practices and procedures are the core component of quality management and health and safety management systems as they guarantee uniformity of operation throughout an organisation. They effectively ensure that each time a task is performed it is done consistently, correctly and safely [11].

The implementation of a QMS on a project will ensure that construction conforms to specified requirements in all respects as it identifies the procedures, checklists, resources, activities and responsibilities [8].

QMS's also facilitate the synergy between occupational health and safety, productivity, quality and the environment as the use of, inter alia, documented procedures and instructions prevent defects, accidents, rework, waste and damage to the environment [4].

5 Cost and benefits of a QMS

The implementation of a quality management system based on IS0 9000 should realise the following benefits: common language for communicating QA; increase in client confidence; avoidance of client assessment; increased competition for 'quality' products and services; increased client satisfaction; reduced quality and corrective costs; increased client base, and competitive edge for certified contractors [12].

Mahoney [13] says a paper presented at the Public Works Department of New South Wales' seminar: 'Quality Assurance in Public Works Projects' noted overseas reports of a 5% saving in construction costs from a 1% expenditure to implement a quality system. A study by the Public Works Department of seven Australian projects ranging in value from A$8m to A$250m indicated direct failure costs in excess of 10% of construction value and proactive expenditure between 1 and 2% of construction cost on 'prevention' i.e. a quality system, together with another 1% for 'appraisal' can keep the direct failure costs below 2% of construction value.

6 Designers

A study carried out by the Building Research Establishment (BRE) in the United Kingdom on building defects concluded that 50% of the defects were attributable to design. A further examination of these 'design' defects (more than 1000 defects identified in the study) revealed that most of them were the result of either poor technical detailing or the oversight of specific requirements. Faults defected at the site require investigations, additional drawings and rectification. The process consumes valuable time at the expense of other work, and because of this, the total cost of the defect, investigation and rectification can be up to 5 times higher than if the fault is detected at the drawing board. The objective of design control is to have a thorough understanding of the requirements and thereby reduce the number of faults by detecting them at the drawing board [14].

Although there is an increasing move towards design-and-build and also the use of construction management in some countries, by and large, the traditional mode of procurement remains. It is therefore essential for both designers and contractors to practise IS0 9000. This will facilitate better understanding of the customer-supplier concept, which will lead to a better quality end product [14].

7 Construction waste

According to Bossink & Brouwers [15] 13 to 30% of all solid waste deposited in landfills in various countries consists of construction and demolition (C&D) waste. Figures from Germany and Western Europe indicate the ratio between the weight of C&D waste to be 1:2. Based on a yearly amount of 12 800 000 ton C&D waste and this ratio, the absolute yearly amount of construction waste in the Netherlands will be approximately 4 224 000 ton [15]. Data from Brazilian and Dutch construction sites indicate that construction waste ratios on site are as high as 20-30% and 9% of the weight of total purchased materials respectively [15].

According to Graham & Smithers [16] potential construction waste is caused by inefficiencies in design, procurement, materials handling, operation or residual on-site waste such as packaging. Research also indicates that clients can be a source of waste through careless inspection procedures, variation orders, or during part possession.

Waste minimisation strategies include inter alia, design focus and waste management [16]. Design focus includes: modular design, and adequate documentation and detailing to minimise construction waste as a result of construction errors attributable to design and variation orders. Waste management activities such as: project analysis; increased control of subcontractor procurement and supervision; improved documentation, and quality control contribute to the minimisation of waste.

QMS's can clearly complement design and waste management activities directed towards reducing construction waste and by doing so, complement the sustainability of the environment.

8 Integration of systems

The ConQuest Research Group [17] advocates the inclusion of environmental, and health and safety issues as quality criteria. According to Renfrew[17] the introduction of QUENSH, a single system covering environmental, health and safety and quality aspects will be more efficient than separate systems. The reasons cited include: a single activity plan; consolidated paper work, and a single project file.

9 Research

153 general contractors who were either members of the Building Industries Federation of South Africa (BIFSA) or the South African Federation of Civil Engineering Contractors (SAFCEC) responded to a national postal survey. This consitituted a 12,9% response rate.

Table 2 indicates the majority of contractors seem to support Cornick's [18] argument regarding the problem of defining quality. 'Conformance to requirements' and 'Excellence' were selected more frequently than other defmitions of quality. Excellence is one of those definitions which are not easy to manage and hence ensure, it is relative, and consequently it leaves much for interpretation.

Definition	Response (%)
Best practice	9,2
Conformance to customer requirements	18,3
Conformance to requirements	26,8
Customer satisfaction	13,4
Durability	4,1
Excellence	26,1
Other	2,1
Total	100,0

Table 2: Contractor selected definitions of quality

88,2% of contractors had a quality policy, not necessarily written. A quality policy embraces the overall quality intentions and directions of a project as regards quality. A policy, especially written also indicates commitment.

60,5% of respondents did not have a documented Quality Management System (QMS). This situation suggests that there is lack of coherence and fundamental thinking in quality management to the majority of respondents. A documented QMS is fundamental to the effective operations of a quality management system. It provides the framework for quality assurance and the basis for quality improvement. It is through a documented QMS that the contractor will be able to deal with the main areas of concern in a quality management system, which are: control and maintenance of the quality system; control functions to eradicate quality deficiencies; feedback to ensure effective operation of both controls is being achieved, and a review of the declared quality system to ensure that it reflects policy.

Of the 60 contractors who had a documented QMS, one contractor had IS0 9002 certification. Various specialist entities of four contracting groups (representing 3.3%

of respondents) had IS0 9000 series certification, their activities including inter alia, piling, pre-cast concrete work, steelfixing, electrical and process engineering.

Standard work procedures, verbal or written, followed by pre-activity discussions predominated among actions to achieve quality (Table 3). The percentage response indicates that no particular action was used by the majority of contractors.

Agency	Response (%)
Pre-activity discussions	43,8
Standard work procedures	49,0
Visual checks	10,3
Tests	28,8
Samples / References	15,0
Designer interactions	7,2

Table 3: Actions to achieve quality

Those contractors who had a QMS cited 'Competitive advantage' most frequently as the reason for implementing a QMS. Rightly, other respondents cited the reasons behind implementation of a documented QMS as 'Improve productivity', and 'Reduce cost' (Table 4).

Reason	Response (%)
Improve productivity	17,6
Quality problems	7,2
Reduce cost	14,4
Client pressure	7,8
Competitive advantage	24,8
Other	3,3

Table 4: Reasons for implementing a documented QMS

Table 5 indicates the frequency at which project parameters and other aspects are negatively affected by the non-achievement of quality. 'Cost', 'Client satisfaction', 'Productivity' and 'Future work' were identified most frequently. Non-achievement of quality has far reaching consequences for clients, designers, contractors, and immediate users of a constructed facility or occupants.

Project parameter/Aspect	Response (%)
cost	75,8
Productivity	62,7
Schedule	41,8
Client satisfaction	71,2
Environment	13,1
Rapport with designers	33,3
Future work	62,7

Table 5 : Project parameters/aspects negatively affected by non-achievement of quality

Table 6 schedules the factors negatively affecting quality. 'Shortened project periods', 'Unqualified artisans', 'Inadequate details' and 'Inadequate specifications' predominated.

Factors	Response (%)
Competitive tendering	37,3
Shortened project periods	66,0
Lack of quality pre-qualification	22,2
Lack of contractor registration	16,3
Adversarial relationships	22,2
Inadequate specifications	51,0
Inadequate details	53,6
Design	20,3
Unqualified artisans	67.3
Increased subcontracting.	20.9
Variations	19,0
Inadequate health and safety	20,3
Inclement weather	14.4
Cvclical industrv	26.1

Table 6: Factors negatively affecting quality

According to Rwelamila [19], project procurement systems provide quality management frameworks. Therefore it is important to address the question of suitability of procurement system when addressing quality management issues. Contractors were asked to rate the basic procurement systems listed in Table 7 according to their suitability for achieving quality. Although generally between 30 and 40% of contractors stated that all procurement systems were suitable in addressing quality problems 62,4% of contractors stated that 'Design and build' procurement system is considered to be `Suitable'/`Very suitable'. 'Package deal and turnkey contracts' systems were cited as `Suitable'/`Very suitable' procurement systems for achieving quality by 58,6% of the respondents.

Procurement system	Response (%)						
	Very unsuitable	Unsuitable	Neutral	Suitable	Very suitable	Don't know	Total
Construction management for a fee	5,1	13,9	23,4	35,0	12,4	10,2	100,0
Design and build	5,8	65,	21,0	42,8	19,6	4,3	100,0
Management contracting	37,	82,	29,2	34,3	14,2	10,4	100,0
Package deal & turnkey contracts	5,0	57,	25,7	35,0	23,6	5,0	100,0
Project management	2,2	95,	21,2	40,1	21,2	5,8	100,0
Traditional	5,2	7,4	23,7	40,7	17,1	5,9	100,0

Table 7: Suitability of procurement systems for achieving quality

Education influences commitment to 'do it right first time'. Current thinking in practising total quality management (TQM) [20] demands the involvement of all stakeholders in a quality management system, hence education is needed across all levels of people involved in a project. Table 8 provides an indication of the extent of education in quality. The percentage of employees who had received education in quality increased commensurately with their organisational responsibility. These quality increased commensurately with their organisational responsibility. These results do not support the requirements of TQM, because a significant number of employees do not receive education in quality.

Occupation	Percentage educated in quality (%)						
	0%	>0 ≤25%	>25 ≤50%	>50 ≤75%	>75 ≤99%	100%	Total
Top management	27,0	3,9	7,9	5,9	5,9	49,4	100,0
Middle management	29,8	6,4	15,6	11,3	12,1	24,8	100,0
Site agents/managers	34,5	6,5	13,7	8,6	15,8	20,9	100,0
Foremen	34,2	8,2	14,4	7,5	15,8	19,9	100,0
Junior foremen	41,5	9,6	14,1	10,4	11,9	12,5	100,0
Artisans	40,1	15,6	17,0	11,6	8,8	6,8	100,0
General workers	99,3	0,0	0,0	0,7	0,0	0,0	100,0

Table 8: Extent of education in quality

'Training", "Education', 'Focus' and 'Publicity' predominated among quality related aspects requiring attention (Table 9).

Aspect	Percentage educated in quality (%)				
	More	Adequate	Less	Don't know	Total
Client intervention	14,0	49,3	34,0	2,7	100,0
Designer intervention	30,2	59,1	9,4	1,3	100,0
Education	88,1	9,9	0,7	1,3	100,0
Focus	73,6	21,3	0,7	4,4	100,0
Legislation	18,7	49,3	27,1	4,9	100,0
Publicity	57,2	38,6	1,4	2,8	100,0
Training	92,5	6,8	0,0	0,7	100,0

Table 9: Degree of attention required

10 Conclusions

Clients need assurance that requirements will be conformed to.

The non-achievement of quality has a substantial negative effect on: cost, health and safety, productivity, schedule, the environment, client satisfaction and the ability to obtain future work. However, the effect of the non-achievement of quality on the environment is not appreciated by South African contractors.

There are factors within and outside the control of contractors which affect quality; the South African contractors identified: shortened project periods; inadequate specifications and details, and unqualified artisans most frequently. Procurement systems also influence the achievement of quality, the Design-Build form being identified most frequently.

QMS's complement conformance to requirements as they identify the procedures, checklists, resources, activities and responsibilities. Generally, South African contractors have not implemented QMS's and rely on informal actions to achieve quality.

Education and training in quality is essential to empower management and workers to contribute to quality management. However, South African contractors have generally not undertaken education and training in quality and in fact identify both as the aspects relative to quality requirement the most attention.

Although South African contractors realise the importance of quality they have not implemented appropriate practices and systems, and ultimately QMS's, to assure conformance to requirements and sustainability of the built and general environment.

The need for the implementation of QMS's in South African construction is amplified by the CONC.

11 Recommendations

Contractors should calculate the CONC for all their projects in an endeavour to raise the level of awareness of the impact of non-conformance to requirements.

Clients should deliberate the suitability of procurement systems in general, but certainly relative to their suitability in terms of enhancing the achievement of quality.

Contractors should implement or plan to implement QMS's as a requirement for pre-qualification on projects in excess of a certain value.

Contractors should educate and train all levels of management and workers in quality to facilitate conformance to requirements and the implementation of QMS's.

12 Acknowledgements

The author wishes to acknowledge Danie Venter, Director, Institute for Statistical Consultancy and Methodology, University of Port Elizabeth for the statistical processing of data and the General Contractors who responded to the various surveys.

Management of Construction & Demolition Waste Streams

Mats Torring
Dep. of Geology and Mineral Resources Engineering, NTNU, Trondheim, Norway
Demex Consulting Engineers A/S, Copenhagen, Denmark

Abstract
Utilisation of construction & demolition waste (C&D waste) by recycling can provide opportunities for saving energy, time, resources, and money. Furthermore, recycling and controlled management of C&D waste streams will save use of land and create better opportunities for handling other kinds of waste.

Recycling of C&D waste has been carried out since the start of human building activities. However, systematic recycling in the frame of professional building and construction industry is rather new. The prospect of the use of C&D waste depend on a range of factors related to the building and construction industry, and consumption of energy and resources, where the main three factors are population density, occurrence of and access to natural materials, and level of industrialisation.

To optimise the use of natural resources and C&D waste, to fulfil the requirements for materials for construction, and an appropriate operation of recycling plants there is a need for long term action plans concerning use of materials and co-ordination between different interests among authorities and companies within the building and construction industry.

The major constituents of an economic model for management of C&D waste streams, on which the author is working, is presented in this paper. The purpose of the model is to facilitate decision makers to achieve the goals of economic efficiency and environmental protection simultaneously with the aim of creating a stable market for recycled materials. An analyse of prospects of successful recycling of C&D waste in various parts of the World is presented, and aspects of implementation of waste management plans are discussed.

Keywords: Construction, Cost-Benefit, Demolition, Management, Recycling, Waste

1 The need for C&D waste management

In me European Union with a population of approximately 350 million, it is estimated that the annual generation of C&D waste is between 175 and 370 million tons or equal to ½ - 1 ton per capita per year [1]. This makes between 25 % to 50% of all municipal waste. The figure is probably representative for most of the industrialised world. A global C&D waste production of 2-3 billion tons per year may be a best wild guess.

In many countries, industrial as well as developing, C&D waste is considered as harmless, inert waste which does not give rise to problems. However, C&D waste consists of huge masses of materials which are often deposited without any consideration, often inviting illegal deposit of other kinds of waste. Moreover mixed C&D waste also often contains hazardous substances that percolate into the ground, due to paint and other surface treatment substances. Utilisation of the waste by recycling can provide opportunities for saving energy, time, resources, and money. Furthermore, recycling and controlled management of C&D waste streams will save use of land and create better opportunities for handling other kinds of waste.

Another great challenge is to reduce the impact of disasters, natural-, technical- or human made disasters, especially wars. It is evident that there is a great need for C&D waste management after such events.

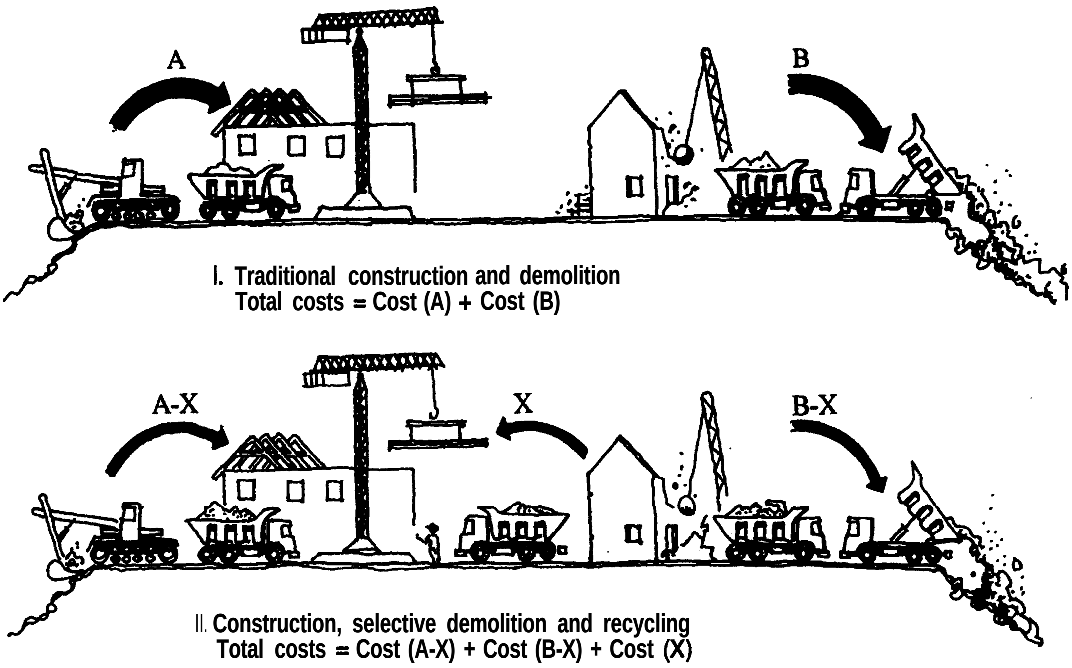

Figure 1:
Model of total costs of traditional and selective demolition. The top figure shows traditional construction and demolition where all natural resources are new and all demolition wastes are tipped. The figure below shows construction, selective demolition and recycling, where a part of the natural resources is substituted by recycled materials. This option often saves costs of transport, supply of natural materials and disposal of demolition waste.

2 Model for management of C&D waste streams

The decision of how to treat C&D waste normally has both political and financial aspects, with long or short time durability. Problems to take into consideration can be; whether a specific waste product should be sorted and recycled, where a permanent recycling plant for a specific region should be established, and at what capacity, or if materials shall be processed on-site or off-site for a specific project. Other problems can be to analyse the effects of different regulations and fees.

An economic model for management of C&D waste streams can facilitate decision makers to achieve economic efficiency and environmental protection simultaneously. This decision is often referred to as «Best Available Technique Not Entailing Excessive Costs» (BATNEEC). Such a model can be achieved by optimising the total costs and benefits of a C&D waste management system affected by the following items:

- Optimising the use of natural resources (by substitution with recycled products)
- Minimising energy- and water consumption (processing, dust suppression etc.)
- Minimising production of residual products (load on landfill, pollution)
- Minimising the transport load
- Minimising the risks in working environment (cost to keep a certain level)
- Minimising impact from dust-, vibrations-, CO_2-, noise emissions
- Minimising capital costs (investments in recycling plants etc.)
- Minimising of operational expenditures (salaries and maintenance etc.)
- Maximising the value of recycled products (material, energy)

Table 1: Items affecting C&D waste management

Input in the model should preferably be a monetary value for as many of the items as possible. Public preferences are often expressed by taxes (landfill, transport, water and energy). Moreover monetary values should be placed on pollution, as well as dust-, vibration- and noise emissions. The impact from these items will vary widely from place to place, and definition of monetary values will require considerable efforts. Many items can alternatively be represented by a non monetary value (level of impact), when different alternatives are evaluated, by using the model mainly to structure a problem.

During optimisation, it is important to consider all levels involved in the process, from the micro economy at the building site, to the global economy, in order to obtain a fair distribution of responsibilities and costs. When the economical inputs have been stipulated the cost-benefit should be analysed at the following levels:

C - for a contractor (e.g. demolition, transport, disposal, value of material)
L - for a local level (e.g. pollution, road maintenance, costs for landfills)
R - for a region (e.g. pollution, use of resources and land)
N - nationally (e.g. road maintenance, fees or subsidies)
G - globally (e.g. CO_2-emissions, use of resources)

Whether or not the goal at a certain level is maximum profit, or cost minimisation, a general economical goal to minimise the total cost (T) can be presented as follows:

T-cost = C-cost + L-cost +R-cost +N-cost + G-cost, T-cost $\rightarrow 0_{min}$

Optimisation of the items mentioned in Table 1 are often in conflict. As an example it can be mentioned that the best solution in a transport perspective may be to have many small recycling plants at different sites, though the most feasible alternative for an operator would be to have one big centrally located plant. These issues are of extra importance concerning the marginal waste. fractions such as plastic, plate glass, gypsum etc. Many producers of building products are gradually accepting the idea of taking back waste from their own products for reprocessing, but this often requires transit stations for a sound transport economy.

In order to establish goals for a recycling effort in a region, it is desirable to assess, the existing situation. Qualitative and quantitative evaluations must be made of the productions and streams of C&D wastes in all phases of the life cycle of buildings and structures. Attempts must also be made to forecast the probable development within a foreseeable future exemplified with different scenarios. The quantities and streams of C&D waste are often difficult to determine. Large quantities of waste produced never appear in official waste treatment systems, and are therefore not registered.

The inventories should include assessment of existing treatment facilities for C&D waste and the existing market for products that are to be substituted. Studies should also be made of the possibilities to co-ordinate recycling of C&D waste with waste products from other industries, for instance power plants and domestic refuse incineration plants. The objective for many countries has so far been the recycling of a certain percentage of the total amount of C&D waste. Targets should preferably instead be set for the best qualitative use of materials.

There are often discussions about avoiding «downcycling» of materials and to produce «high quality>. products. «High quality>> reuse of C&D waste does not always correspond to production of the product with the highest value, but rather the most feasible product in a specific project or region. It is important to consider that resources are also used to produce recycled products. As an example it can be mentioned that crushing of concrete into concrete aggregates will use more energy, than if the material was used as a coarse filling material, and water used to reduce dust from crushing will create a residual product. Moreover the concrete made from concrete aggregates often require use of more cement.

An early prototype of the model has been used for C&D waste management in Denmark's capital Copenhagen incl. suburbs (1. mill. inh.). For treatment of the rubble fraction (concrete, masonry, asphalt), the optimal solution was found to be a recycling plant with a capacity of 500.000 tons pr. year, which now is established 4 km from the centre of town.

It is important that the model used to analyse the options for handling of C&D waste streams is presented in a form, that all parties involved in, and depending on, a decision, can easily understand. A detailed mathematical equation might not be useful if the decisions based on the result are difficult to implement.

3 Prospects of recycling in different places in the World

The three main factors affecting the prospects of recycling of C&D waste are; population size and density, occurrence of-, and access to natural raw materials, and level of industrialisation. In Table 2, the prospects of systematic recycling of C&D rubble in different parts of the World have been analysed according to these factors.

Area code	Population density	Natural raw materials and deposits	Level of industria-lisation	Example	Prospects of successful recycling
I	High	Adequate	High	Many cities in EU, USA and the Far East, e.g. Hong Kong, Copenhagen, (Denmark)	+ + +
II	High	Adequate	Low	Many megacities in the Third World: Mexico City, (Mexico) Jakarta, (Indonesia)	+ + +
III	High	Scarce	High	Amsterdam, (The Netherlands)	+ + + +
IV	High	Scarce	Low	Dacca, (Bangladesh) Shanghai, (China)	+ + + +
V	LOW	Adequate	High	Rural Scandinavia	++
VI	LOW	Adequate	LOW	Rain forests and mountain regions in developing countries	+
VII	Low	Scarce	High	Kuwait, Abadan, (Iran)	+++
VIII	Low	Scarce	Low	Steppelands, Sandy deserts or tundra's in developing countries	+

Table 2:
Table summarising the main factors affecting the prospects for successful recycling of C&D waste. Rating from "+" (doubtful) to "+ + + +" (profitable)

From Table 2 three examples are highlighted below:

Amsterdam, in the Netherlands, is the first example. The city is densely populated. Natural raw materials are scarce and the level of industrialisation is high. It is not surprising that the highest possible value recycling of C&D waste is practised in the Netherlands. The idea of deliberately mixing wastes which can be separated does not appeal to the Dutch.

Copenhagen, in Denmark, is the second example. The city is densely populated and the level of industrialisation is high. However, because there is ample supply of natural raw materials, economy and common sense dictate lower value recycling than in Amsterdam. Production of pure fractions of C&D rubble has proved uneconomical and the commercial market has shown preference for blended rubble. This is so in spite of the fact that public authorities for environmental reasons have discouraged the use of mixed materials.

Dacca, in Bangladesh, is the third example. The city is densely populated. Access to natural raw materials is difficult, and like other Third World cities Dacca struggles with the problem of reducing huge quantities of municipal solid waste that daily adds to already immense and unsanitary landfills. It would appear that the use of C&D rubble as road construction materials could substantially assist in solving both a waste disposal problem and a raw materials supply problem. This is true also for other large cities in the Third World which, contrary to Dacca, are located close to abundant raw materials deposits, but where permanently congested traffic conditions make access to the deposits difficult. Mexico City is an example in point.

4 Implementation

In order to reach the goals of C&D waste management, it is necessary that all barriers and obstacles are detected and considered. A long-term action plan has to be made, combined with adequate development and research. Implementation of the necessary economical-, technical- and administrative instruments require that initiatives, involving legislation's and regulations, are taken.

4.1 Economy

In a market economy, the choice between recycled and natural materials depends upon price and quality. The quality of concrete with recycled aggregates can be the same as that of concrete with natural aggregates, but recycled concrete aggregates are regarded with suspicion.

Hence, recycled concrete materials will be preferred only when the price of such aggregates is considerably lower than that of the natural materials, even when the recycled aggregates meet given specifications. The economic barriers can be overcome by introducing economic instruments which encourage recycling and use of recycled materials. As an example, taxes demonstrating the true cost to society for waste accumulation, and fees in favour of recycling should be mentioned.

4.2 Policies & Strategies

C&D waste must be considered as a specific individual type of waste associated with the building and construction industry. It is important that the management and handling of waste is carried out by the industry itself. Generally, the building and construction industry is relatively conservative, and changes in normal procedures often take time and need long-term policies and strategies.

One of the most important barriers is the many different interests in C&D waste. It is usually the politicians, departments and public offices concerned with environmental issues who prepare the policies concerning waste recycling and reduction, whereas the building and construction industry is controlled by politicians, departments and offices concerned with housing, construction and public works. To co-ordinate the interests of all parties, especially concerning implementation of cleaner technologies in the industry, it is necessary that long-term policies and strategies, with respect to achieving goals for recycling of C&D waste should be adopted. These goals should then be continuously revised in accordance with the political and environmental situation, and followed up by adequate legislation and regulation at all levels, national, regional and local.

4.3 Certification of recycled materials

Even when recycled materials fulfil current standards for natural material, and the prices are competitive with prices of natural materials, certain obstacles still exist. Due to traditions and psychological barriers, the general attitude towards recycling in the building and construction industry is largely inhibitive to the utilisation of recycled materials Therefore; it is of great importance that recycled materials are officially certified so they can be accepted by all parts in the building and construction industry.

It is recommended that considerable emphasis is placed on specifying the areas of utilisation and quality standards for recycled materials. These must be in accordance with the local demand in order to improve confidence in the recycled materials and solve problems regarding the responsibility of using recycled materials.

4.4 Planning demolition projects

Demolition has until recently been regarded as a low technological process. Rapid demolition and disposal of structures were the main aims of the contractor. Special measures to separate the different types of materials were not possible due to the time factor, nor were they desired.

A necessary condition for the recycling of building waste is carefully sorting of the waste. Waste materials from new constructions and rehabilitation, such as surplus, over ordered materials, packaging etc., are sorted at site or at a suitable treatment site according to the organisation of the work site. This separation into materials categories is rather simple. The sorting of waste from demolition is, however, a more complicated process.

Optimal handling and recycling of C&D waste depends on the materials being sorted in-situ and in co-ordination with the demolition process. It is therefore necessary to alter the traditional methods of demolition and introduce <<selective demolition>.. This requires that before and during the demolition process an effective sorting of the different material categories is carried out, thereby preventing any mix of materials leading to pollution of, for instance, recyclable concrete/masonry rubble with wood, paper, cardboard and plastics etc.

It is recommended that demolition projects should be planned and controlled in detail, in the same way as all other building and construction projects to ensure selective demolition and correct handling of the demolition waste.

4.5 Education and information

The improvement of cleaner technology and achievement of goals for reuse and waste minimisation is inextricably tied to an understanding of the different problems in integrated building waste management and recycling of building and construction waste materials. Therefore, education and information within all parts of industry on all levels are needed.

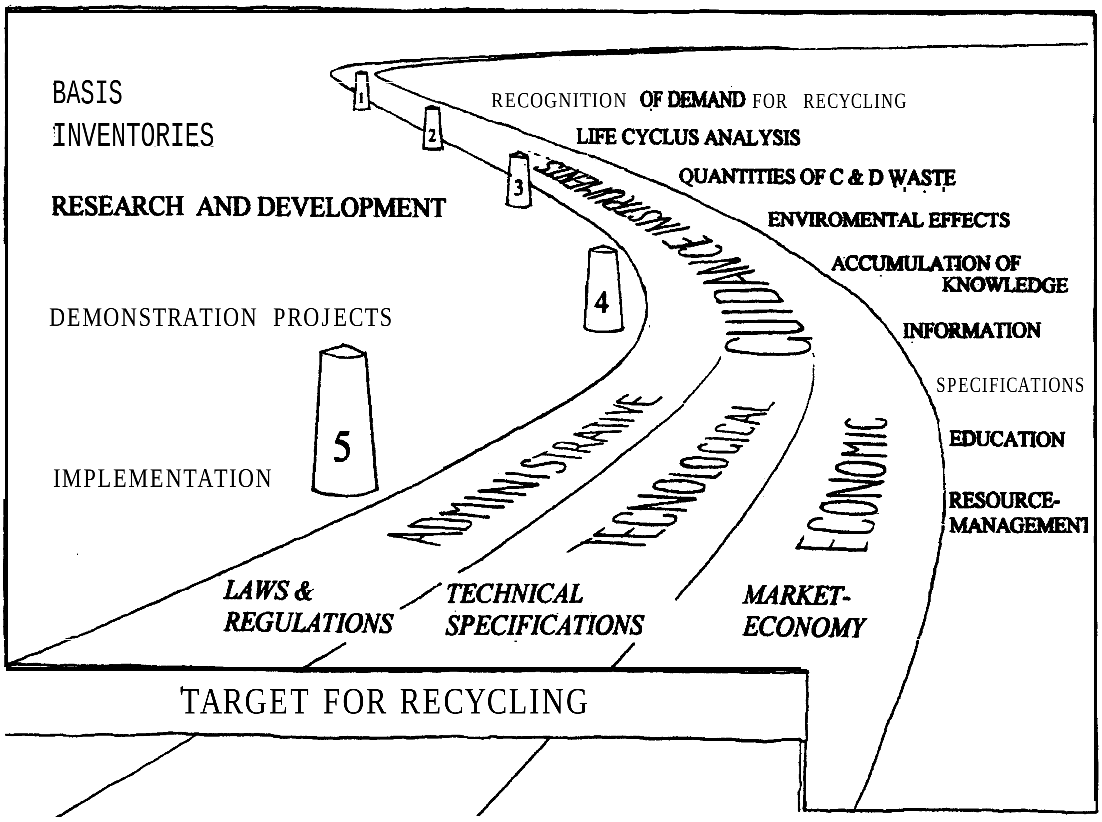

Figure 2:
The way to the target for C&D waste management relies on economical--, technical- and administrative guidance instruments jointly with a long-term commitment.

5 Conclusions

Recycling of C&D waste is more feasible in some places in the World than others. With a well defined analyse where all items affecting the choice of C&D waste treatment facilities are considered, it will be possible to find the optimal solution for each type of waste product in various situations. Many barriers have to be considered during the implementation of a C&D waste management plan, which requires long term action plans involving economical-, technical- and administrative guidance instruments jointly.

Sustainable Development and the Future of Construction, a CIB W82 Project

L. Bourdeau
Centre Scientifique et Technique du Batiment, Sophia Antipolis, France
P. Huovila
VTT Building Technology, Espoo, Finland
R. Lanting
TNO Bouw, Delft, Netherlands

Abstract

This international CIB Project aimed at answering the following question *: "What will be the consequences of sustainable development on the construction industry by the year 2010 ?"*.

This future study was focused on investigating the relationship and clearly defining the links between the principles of sustainable development and the construction sector. The followed methodology allowed to present and to take account of the specificity and orientations of more than ten countries, and to display a clear vision of what the construction sector could be in fifteen/twenty years in the framework of a sustainable development and how this goal could be reached.

The study was made of two main steps: a first step was dedicated to national efforts in order to get results at national level; a second step was dedicated to an international synthesis and the validation and dissemination of the results.

The study precisely led to :

- the identification of the issues, constraints and currently followed policies in the field of sustainable construction;
- the identification of the foreseen changes and mutations in the sector through answers given by experts on five questions dealing with : i) the kind of buildings which will be build in 2010 and how existing buildings will be adapted, ii) the ways of designing and constructing, iii) the kind of materials, services and components, iv) the kind of skills and standards which will be required, v) the kind of cities and settlements which will be developed;
- the analyses of the consequences for the phases of the construction process;
- the definition of recommendations to the main driving actors of the sector;
- an illustration of best practices through some case studies, design methods, buildings or building products.

Keywords: building, environment, sustainable development, future studies.

1. Introduction

This international CIB Project was launched in the W82 Amsterdam meeting (Spring 1995). In accordance with the scope of this Commission dealing with "Future Studies in Construction" - to supply, analyze and interpret the external (exogenous) factors affecting the development and future of the construction field, and, to produce, formulate and evaluate its future alternative - the Project aimed at answering the following question:

" *What will be the consequences of sustainable development on the construction industry by the year 2010 ? "*.

"Sustainable development is a development that meets the needs of the present without compromising the ability of future generations to meet their own needs". According to this definition from the World Commission on Environment and Development (1987), it is clear that the various activities of the construction sector have to be regarded and analyzed when considering sustainable development. As a matter of fact, on one side, the build environment constitutes one of the main support (infrastructures, buildings,...) of the economic development, and, on the other side, its construction has significant impacts on resources (land, materials, energy, water, human/social capital) and on the living and working environment. Hence the construction industry has a lot of direct and indirect links with the various aspects of sustainable development. It is still an unsteadily concept, but it surely concerns the construction sector.

The First International Conference on Sustainable Construction held in Tampa in 1994 [1] introduced the following definition of sustainable construction "the creation and responsible maintenance of a healthy built environment based on resource efficient and ecological principles" (Kibert and alii).

This very broad definition must be seen only a starting point to build a more concrete definition of the concept of sustainable construction and to precise the stakes and issues of sustainable development with regards to the construction sector. More research is required to investigate the relationship between sustainable development and the future of construction (Figure 1).

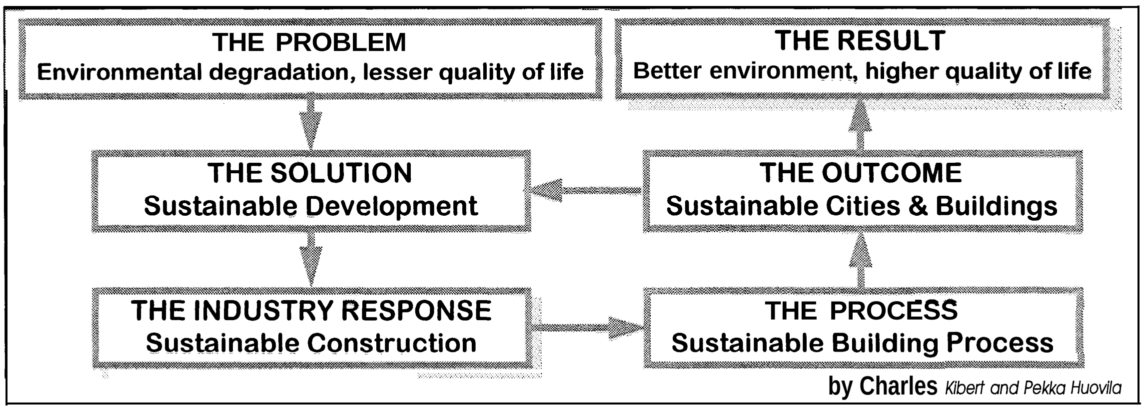

Figure 1: Sustainable Construction Road Map

2. Methodology

The study [2, 3] was focused on the clear definition of the links between the construction sector and the principles of sustainable development. It followed a methodology which had several main characteristics: i) it was an international study allowing to present and to take account of the specificity and orientations of various countries; ii) it was a future study aiming at defining a clear vision of what the construction sector could be in fifteen/twenty years in the framework of a sustainable development and how this goal could be reached; iii) it was carrying out by experts coming from organizations deeply involved in the topic at national levels.

The Project was divided in several tasks (Figure 2) grouped in four phases.

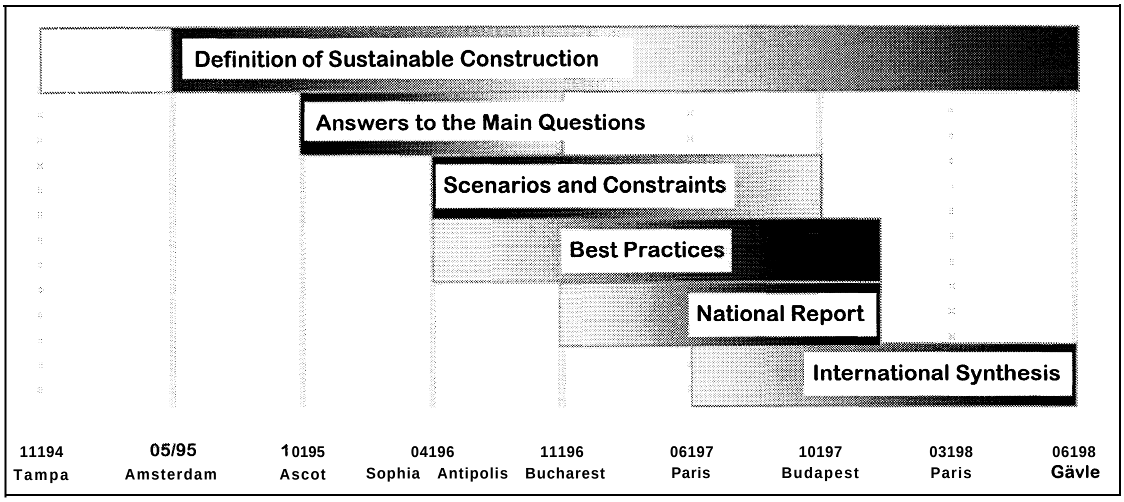

Figure 2: Main Tasks of the Project

Three different coordinators were nominated for the first three phases of the project: Sandy Halliday, for BSRIA, accepted to lead phase 1, Pekka Huovila, from VTT, led phase 2, and Caspar Richter, from sbr, led phase 3.

About fifteen countries were involved in some or all of these phases and eleven were able to produce a final National Report (Figure 3).

United States	GaTech	G. Augenbroe & Saeid Sadri

Figure 3: Main Members Involved in the Project

3. Phase 1: Definition of the concept of Sustainable Construction

Phase 1 of the Project sought to identify what each participating country or region understands by “Sustainable Development” and “Sustainable Construction”.

It is why it was asked to the 10/95 Meeting participants to present papers which gather national initiatives on Sustainable Construction and to try to discuss about a definition of sustainable construction [4, 5]. It was proposed to start from the definition provided by Kibert and alii.

The intention of the Meeting was to generate an interactive debate consistent with the holistic nature of the subject. In total thirteen papers from ten countries (Canada, Finland, France, Hungary, Netherlands, New Zealand, Palestine, Rumania, UK and USA) were received and discussed on a wide range of topics.

The meeting consisted of a series of informal interactive sessions to identify common themes and concerns. The papers were extremely diverse but common threads identified.

Several definitions of Sustainable Construction were offered which reflected the regional diversity and differing priorities in the participating countries. They included a more precise but still concise definition of "Sustainable Construction" derived from Kibert's one, to more general and detailed views such as the French one which introduces 24 criteria [6].

4. Phase 2: Answers to 5 main questions

The questions to be answered in Phase 2 were the following:

- *What kind of buildings will be build in 2010, and how will we adapt existing buildings?*
- *How will we design and construct them?*
- *What kind of materials, services and components will be used there?*
- *What kind of skills and standards will be required?*
- *What kind of cities and settlements will we have then?*

There was no common methodology given to participants on how to find answers to these questions. That was left open to be freely defined in each country: e.g. scenario for sustainable construction, analysis and documentation of expert interviews and brainstorming sessions. National studies consisting of answers to the five questions together with a more precise (i.e. more concrete) definition of sustainable construction from participating countries were asked to be presented in the 4/96 Meeting [7].

It was also decided that the precise content of the coming Phase 3 would be described in this meeting. The ideas of i) integrating the activities of other relevant CIB Working commissions and Task Groups and ii) including the presentation of some success stories were already risen.

Phase 2 was started with Belgium, Finland, France and the Netherlands. The number of participating countries increased soon to twelve after Australia, Canada, Hungary, Italy, Japan, Rumania, United Kingdom and United States decided to join the project.

It was not easy to agree on one common definition for Sustainable Construction. Therefore each country was given the liberty of using the Kibert definition or its own definition for Sustainable Construction to develop answers to the 5 main questions.

Answers differed between nations, and within nations. A complete map of answers from a country (Finland) is presented in Figure 4.

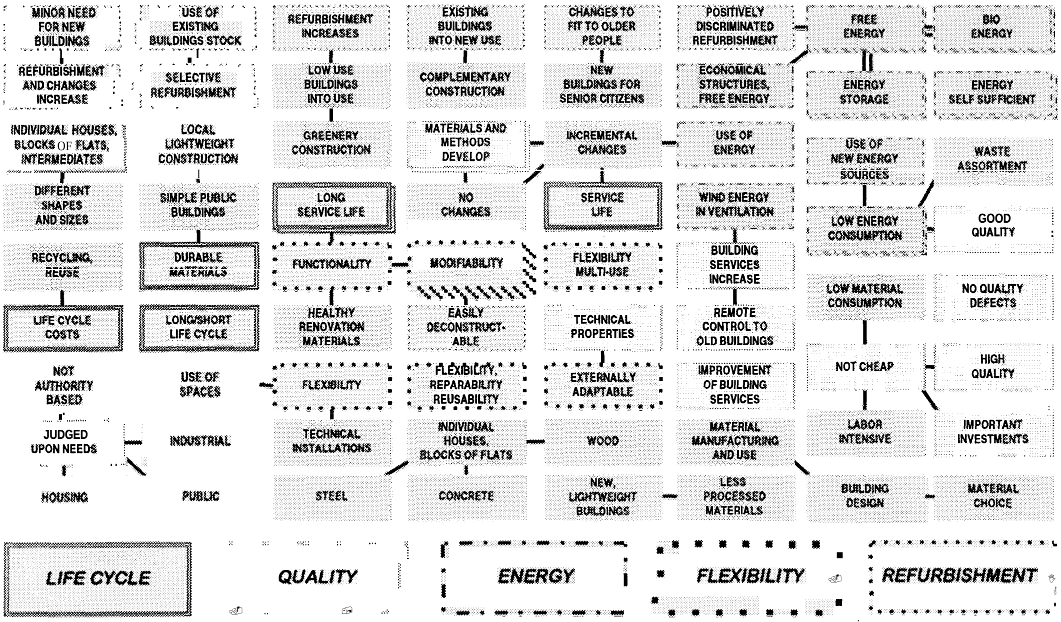

Figure 4: Main Themes of Sustainable Buildings in Finland in 2010

5. Phase 3: National Reports

First results of Phase 2 of the project rose a need for a common methodology to be applied in Phase 3 enabling later international synthesis based on national studies.

It is why a methodology to be followed was proposed in mid-96, which is based on a multi-dimension analysis of the problem (Figure 5). Three dimensions are introduced:

- Ecological principles (six principles are defined in the construction field in order to meet the three basic goals of a Sustainable Development: to eliminate resource depletion, to eliminate environmental degradation, and to create a healthy interior and exterior environment).
- Resources (four resources are concerned: land, energy, water and materials).
- Life-cycle phases of the construction process (five phases are defined: develop and plan, design, manufacture and construct, operate, deconstruct).

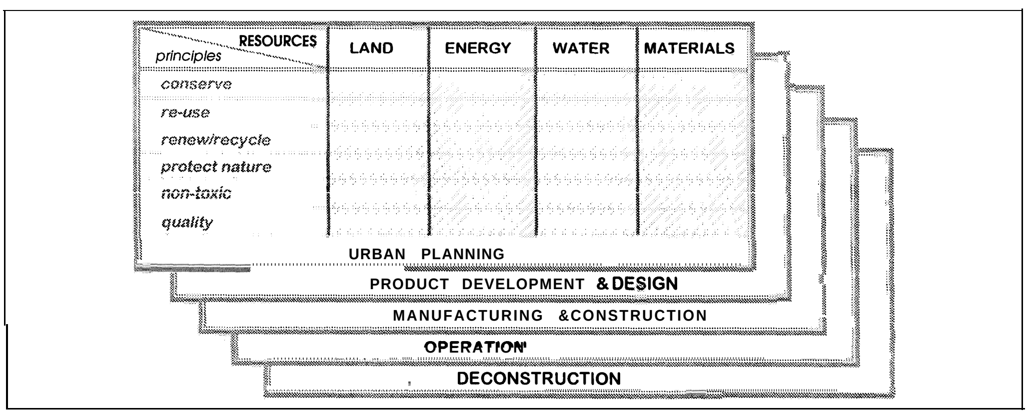

Figure 5: Proposed Format for National Reports

The idea was that for each point of this three-dimension space, it is possible to think about the consequences for the construction industry and therefore to give elements of answer to the five questions defined earlier.

A general important remark which came from several participating members was that the definition of Sustainable Development and therefore the definition of the ecological goals and principles which were proposed did not fit necessarily the concept in all the countries. As a matter of fact, it appeared from the Ascot and Sophia Antipolis papers that the concept from some countries can be much broader than the "ecological" concept proposed here [8, 9,10].

But on the other hand, this methodological approach offers an interesting support for thinking about consequences to the construction industry. It enables to grasp the overall idea and to debate over the appropriateness of activities meant to contribute to a Sustainable Development. It also provides a good instrument to make a synthesis of national reports.

It is why it was agreed to use this methodological approach for Phase 3 of the Project. To solve the problem linked to the general important remark mentioned above, it was agreed to give the possibility to every country to add to each dimension as many topics as needed.

At last it was also agreed that the project participants would present in their National Report best practices of Sustainable Construction from their countries.

6. Phase 4: International Synthesis

The last Phase of the Project was an international synthesis of the results (Figure **6).** That work, which started in Summer 97, was based on National Reports.

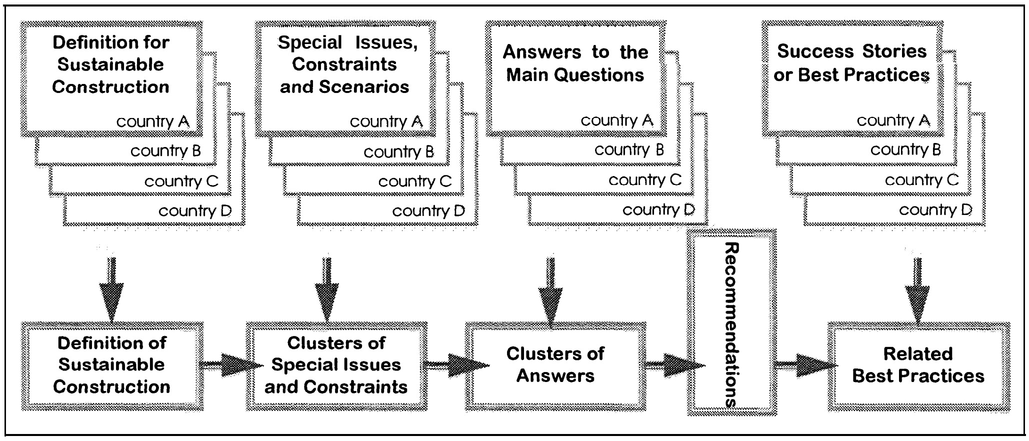

Figure 6: Methodology for the International Synthesis

The final results of the project give an international view of long term contribution by Sustainable Construction in Sustainable Development. Clusters of national differences, due to special issues and national constraints give more specific views on different levels and approaches by clusters of countries. Best practices of sustainable design are gathered. Recommendations for government, management of construction and machine industry and for research and development are also provided.

An example of synthesis of the answers given to the 5 main questions in the various national reports is reported on Figure 7.

Resources	Main issues	Consequences for cities and city planners
Land	Efficient use of land	Restricted suburbanisation
		Adaptation and regeneration of the existing built environment taking account of future needs
		Remediation of brownfield sites
		New soil cleaning technologies
		Land reclamation for industrial use
		More low density building
	Intensive use of land	High density building, underground building; double use of land
		Underground drilling techniques
		Building in nuisance zones
	Conservation of open space and green areas	Combined transport corridors (roads, rail, cables, ducts)
		Creating new space by underground construction
		No fragmentation, no ribbon building

Resources	Main issues	Consequences for buildings and designers
Land	Efficient use of land	Multi-functional buildings
		Temporary or transportable buildings
	Intensive use of land	Double use of land (above and underground)
		Flat roofs for recreational purposes
	Longevity of buildings	Design for flexibility/adaptability
		Support/infill modularity
		Design for life cycle performance
		Introduce standards for longevity in building codes
		High quality building
		Life cycle costing tools
		Understand needs and requirements of future users
	Greater use of existing buildings	Redestination of non-functioning buildings
		More refurbishment and retrofit activities
		Refurbishment techniques (vertical/horizontal extensions; lightweight constructions)
		Performance standards for regenerating existing building stock
		Better condition assessment methods
		Decision support tools demolition/ renewal

Figure 7: Example of Main Issues for the Resource "Land" and Consequences for City Planners and Designers

7. Conclusion

Sustainable construction should be an important component of creating a sustainable development. However, no clear consensus on the exact meaning of such a sentence seems to be agreed today. This W82 Project aimed at contributing to reaching such an agreed clear vision of the future of construction within a sustainable development assumption.

At the moment, the project led to a set of ten or so National Reports and an International Synthesis, most probably gathered in a CIB Publication, which contain:

- the identification of the issues, constraints and currently followed policies in the field of sustainable construction;

- the identification of the foreseen changes and mutations in the sector through answers given by experts on five main questions;
- the analyses of the consequences of sustainable development for the phases of the construction process;
- the definition of recommendations to the main driving actors of the sector;
- an illustration of best practices through some case studies, design methods, buildings or building products.

The main goal of the present international synthesis was to extract main issues from the national reports, to detect the common ones and to stress the main differences (in scenarios, consequences, recommendations to actors,...). The next step should be to reach a more consensus vision through a global common model (with of course eventually items specific to regions or countries) and to set up indicators and policies to translate this vision into reality.

8. Acknowledgments

The authors of this paper would like to thank, on one side, all the authors of the national reports and, on another side, Sandy Halliday and Cas Richter who coordinated Phase 1 and Phase 3 of the Project respectively.

Open Building Implementation
Matching demand and supply for flexibility

R.P. Geraedts
Associate Professor of Project Management
Department of Project Management and Real Estate, Faculty of Architecture,
University of Technology, Delft, The Netherlands

Abstract
Open Building provides strategies for consumer oriented and sustainable buildings and neighbourhoods, based on specific principles and methods in programming, design, production planning, construction and facility management. Open Building inables built environments to adjust, meeting changing social, environmental and technical requirements.

Many office blocks are unoccupied because they no longer meet present requirements. Installations in particular often prove not to be sufficiently flexible to follow changes in their use without too many adaptations. It is expected that in this sector there will be an increasing lack of occupancy in the coming years. This tends to lead to demolition and new-construction projects and to considerable wastage. Such activities not only involve a destruction of capital, but they also have an adverse effect on the environment. What is needed to avoid vacancies is the possibility of adapting buildings to the rapidly changing demands of users. The technical installations are often found to be the key factor with respect to the possibilities of adapting buildings. However, the demand for greater flexibility in buildings, and hence in installations, does not arise from economic considerations only.

Developments in the building sector show a number of trends all of which point to the growing importance of flexibility in buildings and installations. In addition there is the trend towards durable building. Environmental problems and energy management are very much in the limelight. Recyclability and sustainable buildings will be major criteria in judging future buildings. Among the factors that play a role here are saving of base materials, minimizing waste production, ease of dismantling, adaptability and deposit money arrangements. Clearly, flexible buildings that are readily adaptable to changing conditions respond to this trend.

Conclusions
A method called Flexis has now been developed whereby a detailed picture is obtained of the flexibility demanded and offered. Flexis enables the parties involved in the realization of a building to communicate about the flexibility of that building and its installations in relation to each other. The Flexis method can be used to judge the various flexibility aspects of existing buildings and their installations, but also to formulate the requirements with respect to flexibility when new buildings are to be realized. Thus, Flexis forms a means of communication on both the supply and the demand side of the building market.
Keywords: Open building, sustainability, flexibility profile; installations, partitionable, adaptable, extendible, multifunctional.

1 Introduction

The design of flexible installations in commercial and industrial building is very much an optimization problem, in which the building and the installations are inextricably bound up with each other. For a ready adaptation to market fluctuations it would be desirable to impose the condition that the building, along with its installations -in various combinations- should be suitable for several uses. And this should be borne in mind already during the development phase.

The development of a vision with respect to the flexibility of a building, or of a flexible-building concept, should therefore go hand in hand with the development of an associated flexible-installation concept. In fact, it is recommended to integrate the design of a building and that of the installations at the earliest possible stage. of development.

1.1 Alter or move

Hundreds of millions of dollars are spent annually in Holland on the alteration of buildings, but these efforts often fail to generate optimum work situations. Alterations involve not only considerable expenditure but also nuisance, both direct nuisance caused by the reconstruction and indirect nuisance resulting from temporary inefficiency of the work situation. Owing to the flexibility of their accommodation being exhausted, or through the absence of flexibility, businesses tend to reach the limits of their growth much sooner than is permissible in the light of the depreciation schedule. Spatial and technical adaptations in buildings are unavoidable and structural.

This means that in the case of a change in task or in mode of oneration it must be possible to adapt the accommodation" to the new functional requirements. The following diagram roughly indicates the steps that can be taken when a building no longer meets the requirements imposed by its use (figure 1).

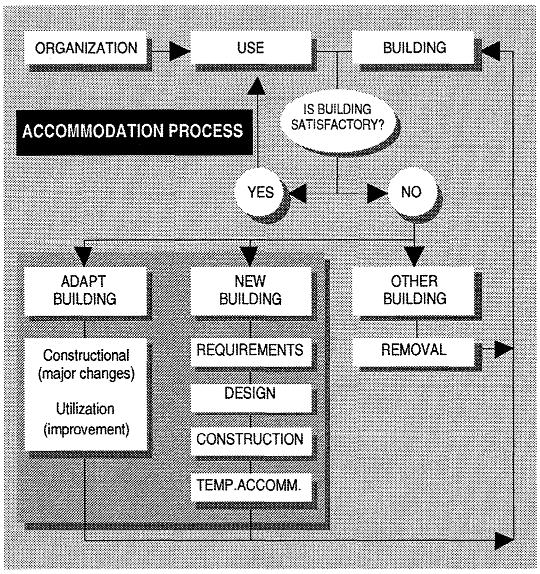

Figure1 Steps to be taken in the accommodation process when a building no longer meets the requirements; shaded area indicates the essence of Flexis

Three options are open to an organization: adapting the existing building, constructing a new one, or moving to another building [1]. Flexis is not concerned with the latter option. But adaptation of an existing building or erecting a new one are two possibilities that can be considered with Flexis.

2 Installation systematics

During the development of Flexis the need was felt of setting up a consistent system for the description and determination of technical installations in buildings. The methodical description of installations is based on the functions they can perform. This makes it possible to formulate project- and product-independent performance requirements and to compare project- and product-bound technical solutions with the performance requirements.

By a functional installation concept is meant the project- or product-independent formulation of the installation functions wanted in a building. It is a formulation of the demands to be met and it finds application mainly during the programming phase of projects. Installation systems are project- and product-independent technical solutions fitting an installation concept. For each installation concept (= demand or performance requirement) various technical solutions or installation systems can be formulated and offered (= supply). Installations are specific product and material configurations the components of which have been specified and which are the tangible form of the installation system previously formulated. An example is a mobile air conditioner of a certain make. At the level of the greatest detail each installation can be subdivided into various components. To meet the need for clustering and generalization the Flexis method distinguishes five kinds of components: user-interface facilities, measurement and control facilities, distribution facilities, production units, supply and removal facilities and constructional facilities.

2.1 Installation levels or modularity

Modularity refers to the various spatial levels at which the installation functions are in operation or are offered. Within the framework of Flexis two major levels are distinguished: the local and the central level (see figure 2). The central level is the set of all the levels higher than local. In a building these are a floor, a wing and the whole building. Examples of installation facilities at these levels are central supplies or central units and main distribution channels. In general it can be concluded that the flexibility of an installation is determined to a considerable extent by the (spatial) level at which that particular function is offered.

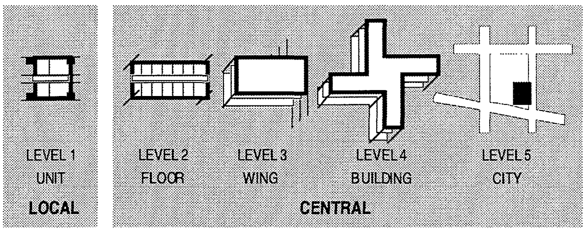

Figure 2 Various levels at which installation functions can be offered

3 Flexibility

Flexis distinguishes four aspects of the flexibility of installations in buildings: partitionability, adaptability, extendibility and multifunctionality.

Partitionability is the possibility of splitting up, rearranging or combining installation systems into different spatial units in a simple way. An important point in this connection is whether distribution, conversion, supply (transfer) and the measurement or control of installation functions take place locally or centrally. Another important aspect is a possible distinction between the collective (support) and the individual (infill) mode of offering functions and the zoning of distribution facilities.

The adaptability of an installation is the possibility of altering installation systems in a simple way to meet changes in the user's demands (the installation function required) resulting, for example, from a structural or functional rearrangement of the building, from changes in use, the coming of other (groups of) users, or technological renewals and modernizations considered necessary.

Extendibility is the possibility of adapting installation systems in a simple way to additional user demands, for instance by the addition of more or new installation components called for by structural or functional extensions, both inside and outside the existing building.

Multifunctionality is the possibility of using or deploying installation systems or components for several functions. This allows of a more efficient use of space and permits clustering and concentration of installation components. This concept is sometimes also called integration.

3.1 Assessment aspects of flexibility

In order to judge the flexibility of building installations or their components, each flexibility aspect is divided into a number of subaspects (see figure 3).

ASSESSMENT ASPECTS OF FLEXIBILITY	
PARTITIONABLE	1 DISTRIBUTION (+) supply 2 DISTRIBUTION (-) removal 3 CONVERSION (central unit) 4 TRANSFER (functions) 5 MEASUREMENT 6 CONTROL
ADAPTABLE	7 DISCONNECTIBLE 8 ACCESSIBLE 9 ADJUSTIBLE
EXTENDIBLE	10 CAPACITY (local) 11 CAPACITY (central) 12 DIMENSIONS (distribution) 13 LOCATION (shafts)
MULTIFUNCTIONAL	14 INTEGRATION (functions) 15 UNIVERSAL (components)

Figure 3 Aspects used in judging the flexibility of installations

4 Judging partitionability

Figure 4 shows what is meant by the assessment criteria for the flexibility aspect called partitionability. It comprises the subaspects of partitionability: distribution (supply and removal), conversion (central unit or supply facility), transfer (of installation functions), measurement (consumption) and control (use).

4.1 Partitionability criteria, weighting factors and score

In figure 4 three possible ratings (3=positive, 2=neutral, 3=negative) are given for each assessment aspect of partitionability. In addition, different weighting factors are introduced for the assessment aspects (5=very important, 4=important, 3=fairly important, 2=hardly important). The rating multiplied by the weighting factor gives the partitionability score.

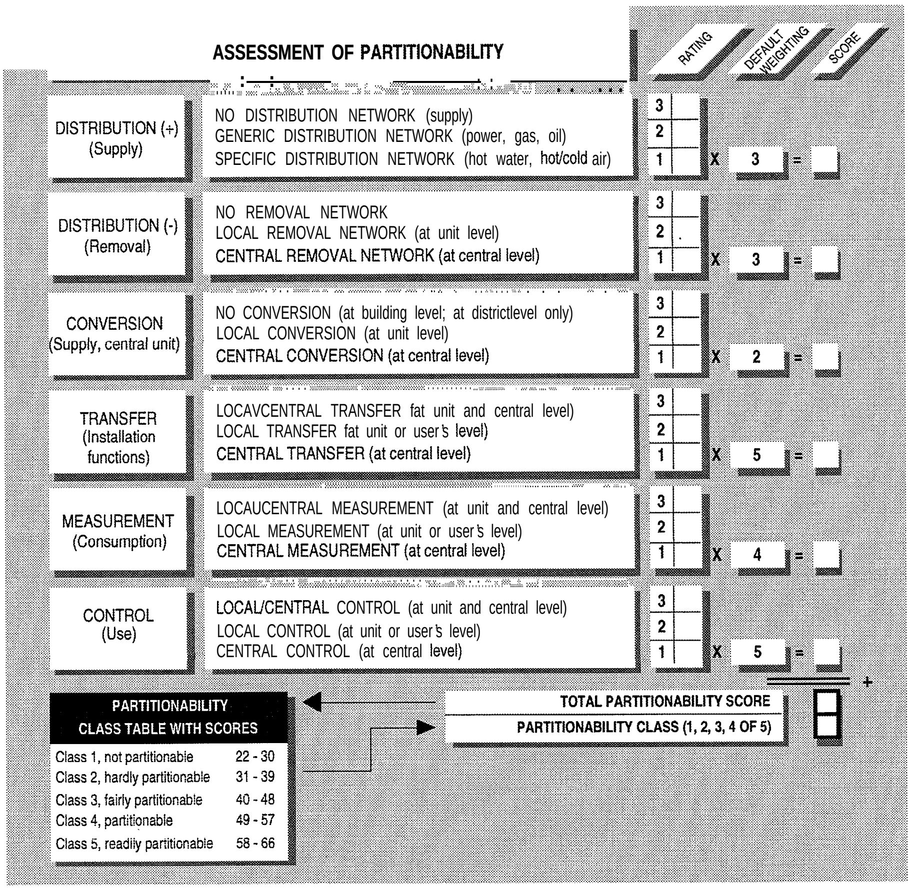

Figure 4 Criteria and weighting factors used in judging partitionability

4.2 Partitionability class

Thus a final judgement can be given as to the overall partitionability. It is the weighted partitionability score of the installation system concerned that comes within a certain score range. This score can be expressed as a partitionability class and can be found in the relevant table.

5 Judging adaptability

Figure 5 shows what is meant by the assessment criteria for the flexibility aspect called adaptability. For this purpose three subaspects of adaptability are used, disconnectibility (installation components), accessibility (also components) and adjustability (measurement and control).

5.1 Adaptability criteria, weighting factors and score

In figure 5 three possible ratings are given for each assessment aspect. In addition, different weighting factors are introduced for the assessment aspects. Ratings multiplied by weighting factors give the adaptability scores.

5.2 Adaptability class

Thus a final judgement can be given as to the overall adaptability. It is the weighted adaptability score of the installation system concerned that comes within a certain score range. This score can be expressed as an adaptability class and can be found in the relevant table.

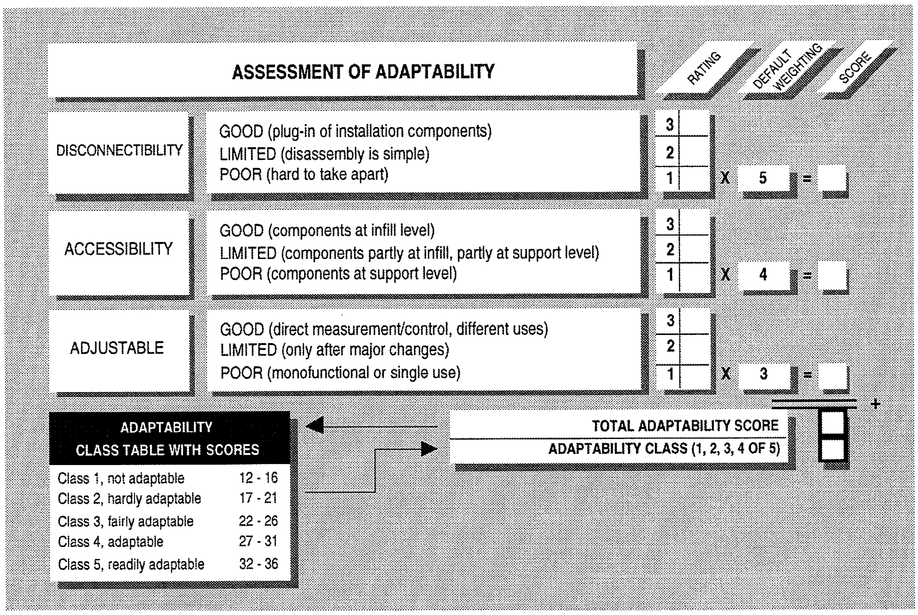

Figure 5 Criteria and weighting factors used in judging adaptability

6 Judging extendibility

The diagram below shows what is meant by the assessment criteria for the flexibility aspect called extendibility. For this purpose use is made of three subaspects of extendibility introduced earlier, capacity (of the supply facilities, both local and central), dimensions (distribution networks) and location (ducting shafts and zones).

6.1 Extendibility criteria, weighting factors and score

In figure 6 three possible ratings are given for each assessment aspect of extendibility. In addition, different weighting factors are introduced for the assessment aspects. The ratings multiplied by the weighting factors give the extendibility scores.

6.2 Extendibility class

Thus, a final judgement can be given as to the overall extendibility. It is the weighted extendibility score of the installation system concerned that comes within a certain score range. This score can be expressed as an extendibility class and can be found in the relevant table.

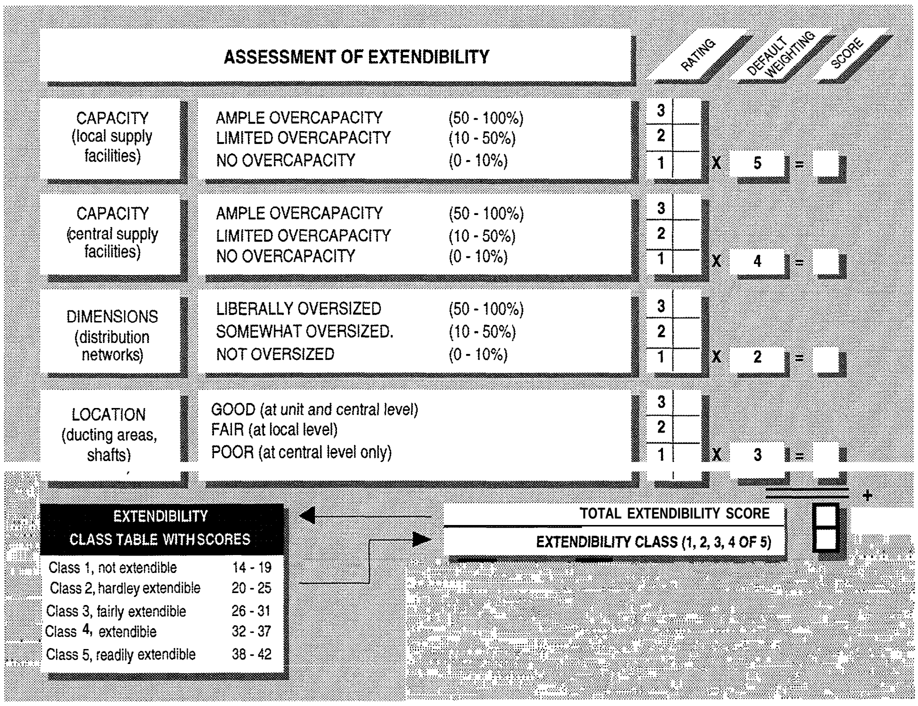

Figure 6 Criteria and weighting factors used in judging extendibility

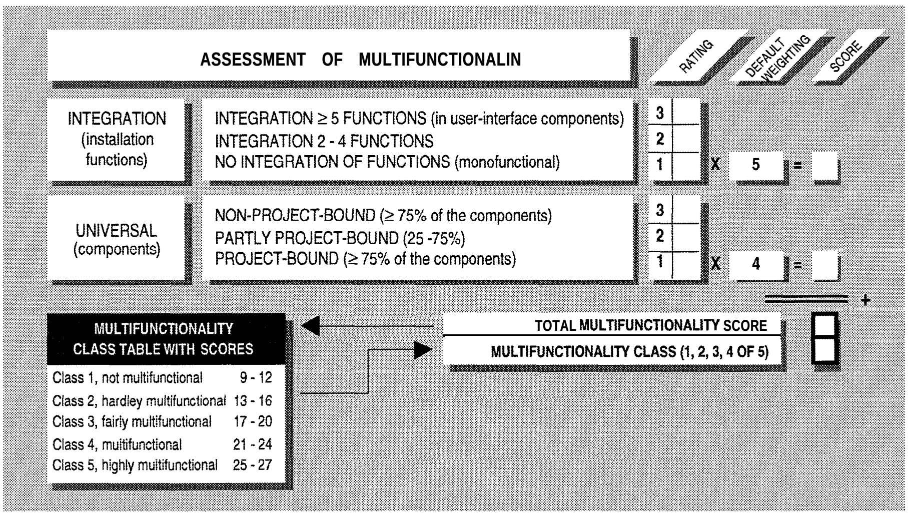

Figure 7 Criteria and weighting factors used in judging multifunctionality

7 Judging multifunctionality

The last aspect used in assessing the flexibility of installations is multifunctionality. A multifunctional installation or component can be used for several purposes. It permits a more efficient utilization of the available space and enlarges the ductless area through clustering and concentration. Another aspect that plays a role in the assessment of multifunctionality is the extent to which a system is universal.

In figure 7 three possible ratings are given for each assessment aspect of multifunctionality. In addition, different weighting factors are introduced for the assessment aspects. The ratings multiplied by the weighting factors give the multifunctionality scores. Thus, a final judgement can be given as to the overall multifunctionality. It is the weighted multifunctionality score of the installation system concerned that comes within a certain score range. This score can be expressed as a multifunctionality class and can be found in the relevant table.

8 Judgement of overall flexibility

In the foregoing we discussed in detail the criteria used in judging the various flexibility aspects: partitionability, adaptability, extendibility and multifunctionality. Similarly, at a higher level, the overall flexibility of an installation can be determined. Here, too, weighting factors, scores and flexibility classes have been developed. To record the outcome of the flexibility assessment of installation systems or their components, a special assessment form has been designed.

8.1 Flexibility profiles

For a direct comparison between different installation systems use c.an be made of the calculated flexibility classes. But this approach does not at once show which is the most important aspect of flexibility. With one system emphasis may be on partitionability, whereas with another it may be on the extendibility of the installation. To make this clear at a glance, we can draw what is called a flexibility profile.

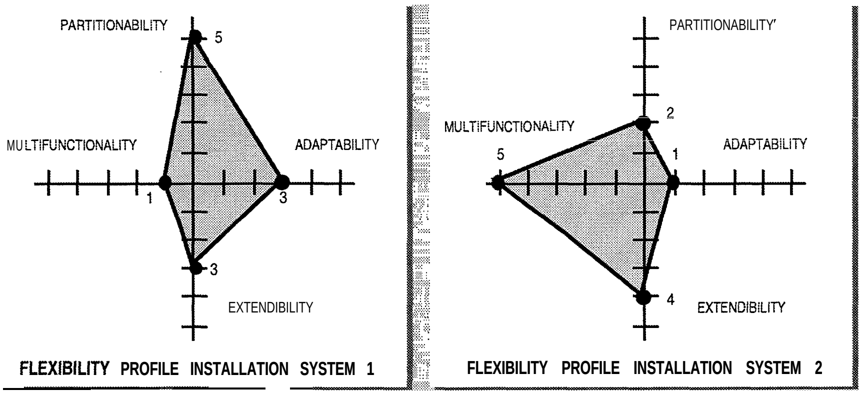

Figure 8 Two examples of flexibility profiles of installation systems

In the flexibility profile of installation system 1 (see figure 8) the partitionability score=5, the adaptability score=3, the extendibility score=3 and the multifunctionality score=l. Together they represent the total flexibility score (the shaded area). In this way different installation systems can be easily compared by graphic means.

Acknowledgements

The research project Flexis was commissioned jointly by the Dutch Building Research Foundation (SBR) and the Dutch Institute for the Study and Stimulation of Research in the field of building installations (ISSO).

A centre for sustainable housing technologies in Brazil

M. A. Sattler
Department of Civil Engineering, Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil

Abstract
This paper addresses the supporting ideas and main proposed activities governing the implementation of a sustainable low cost housing development to be built in the State of Rio Grande do Sul, (southmost State of) Brazil. The housing development is proposed to become an *Experimental Centre for Sustainable Housing Technologies,* with the aims of demonstration, research, and education, directed towards students, professionals, researchers, concerned public authorities and the public in general. A Brazilian institution (FINEP) will be funding the author to lead an interdisciplinary team in a research project, about to be started, to further develop the best ideas presented in an international design ideas competition, *Sustainable Housing* ***for*** *the Poor,* that was also organised by the Federal University of Rio Grande do Sul.

It is estimated that by the end of this millennium the Brazilian population will be around 180 million, and the lack of housing, between 5 and 12 million, according to different sources. No prospects are seen for a quick change in wealth distribution in such a wealthy country, with abundant natural resources. How far housing is concerned, the tendency is to keep providing poor people with the existing type of poor quality solutions, that are also related to poor environmental management.

The project proposal described in this paper illustrates the work the interdisciplinary design team associated to the project intends to develop in order to create healthy and comfortable housing solutions, at an affordable cost, with minimised environmental impact. In a first stage the funds to be allocated to the project will be devoted to fully develop the architectural and urban planning design of the Centre, that later will be implemented and then monitored (future stages of the whole research project).

The main issues, that will challenge the interdisciplinary design team, include: use of renewable energy sources; solid and liquid wastes management; use of building materials with low environmental impact; creation of productive landscape, for food production; and social and educational issues.
Keywords: demonstration centre, low cost housing, sustainability.

1 Introduction

At the start of a new millennium, some considerations are due regarding the environment we are building, and, in particular, the Brazilian situation. Estimates for the year 2000, tell that the Brazilian population will be around 180 million, 80% of which will be living in urban areas. The prospects point out to a worsening of the present problems, including that of a worsening of the income distribution among the population, where the present numbers show that 50% of the economically actives have a monthly income of less than US$ 200.

Unless there is a considerably shift in the present tendencies we hardly will see any modification in the following expectations:

- The increase of unemployed or badly paid people, living in favelas, under the bridges, in installations occupying the sidewalks of the cities or in dry litter collectors used during the day as a working tool and during the night as a place where to rest. These conditions, associated to a famished or badly nourished and unhealthy population, stimulate the development of a proper environment for the intensification of violence, crime, drugs dealing, etc., that characterise the daily routine of many Brazilian cities.
- The increase of all sorts of pollution, that include, in the big cities, the air and noise pollution determined by the traffic of vehicles; the solid and liquid waste disposals, generated in volumes much above the assimilation capacity of nature.
- The irrational energy consumption patterns, associated to the exhaustion of non-renewable energy sources.

The cities of the next millennium certainly will not need to be like this. They only will be so, if we continue to leave them grow in a disorganised manner or contribute towards their growth according to the present model, that is clearly not sustainable. To make them sustainable, we have to redesign them, including them in a global context of sustainability, extending this redesigning beyond the boundaries of the urban tissue, including the treatment given to rural areas and to society on its whole. Each detail of this whole, nevertheless, has to be carefully planned.

On this way, when we think about low cost housing schemes according to a sustainable model, including them in a larger context, we must consider not only the housing unit that will constitute the family's home, but the whole where this unit will be just a part, and, stepping through the several scales, the relationships established between this unit and the whole environment.

We will, then, also be dealing with matters like: the production and treatment of wastes generated by each of the housing units (as well as with the whole of the units) and the alternatives for obtaining water and energy for different uses. Within this larger context, one can not forget the issues related to the individuals' health, that is directly connected to his food, to the quality of this food, that, on its turn, depends on the way the same food is produced. The way people move must also be rationalised, in such a way to minimise the time wasted on transportation, as well as the associated pollution and energy consumption. This way, each person would be able to use their time and energy in a more clever way, either by increasing the time spent with the family and friends or by providing themselves more time for activities more closely related to their interests.

An interdisciplinary research project is being started, co-ordinated by the Department of Civil Engineering of the Federal University of Rio Grande do Sul, aiming at the implementation of an experimental housing settlement, to be built in accordance to sustainable principles. The whole project includes the development of a full architectural project, its implementation and a post occupancy assessment.

2 The Design Ideas Competition

The architectural project, to be started now, will follow the guidelines defined by the results of an international Design Ideas Competition Sustainable Housing for the Poor, organised by the Federal University of the State of Rio Grande do Sul and sponsored by ANTAC (Brazilian Association of Technology for the Built Environment) and PLEA (Passive and Low Energy Architecture).The main aim of this competition was of *stimulating the presentation of design alternatives on architecture and urban planning compatible with the Brazilian reality and the principles of Sustainable Development.*

The experimental housing settlement is to be built either in the city of Alvorada, with a large population of very poor people, or in Porto Alegre, the capital city of the southmost (30ºS; 51ºW) state of Brazil. Porto Alegre has a population of about 1.5 million inhabitants, although the Great Porto Alegre, where Alvorada is located, has about a million more.

Porto Alegre has the advantage of being one of the most ecologically conscious cities in the country (and this is mostly due to Jose Lutzemberger, an alternative Nobel prize winner for his fights and contributions to the environment preservation in the State and in Brazil, in general, since the early 70’s). Strict pollution control legislation are under way to try to recover the quality of the water of a large estuary that defines one of the borders of the city; there is a exemplar system of solid wastes collection and recycling now covering all areas of the city. Besides that, there is a growing demand for organically grown fruits and vegetables, in general. These are marketed in several shops, but mainly through a consumers’ and producers’ co-operative that also organises a very popular weekly street market and that strictly controls the quality of the marketed products.

The also called *production village* is envisaged to be organised in such a way to supply not only housing for the poor, but also job opportunities for people, primarily with an agricultural background. This background will be interesting not only for selecting people able to manage their vegetable gardens and from that to be able to achieve a minimum life sustainability, but also as a possibility for creating new jobs, once they are organised, as planned, as a producers’ co-operative, with the aim of producing organically grown fruits and vegetables for supplying the surrounding cities population demands.

2.1 Housing scheme

The housing settlement was devised to have twenty houses (a scale small enough to be easily manageable) and a social/educational centre, for diurnal education of the youngsters and nocturnal education of the adults, giving also options for other social activities for the whole community. Each house is expected to be surrounded by a sufficiently large domestic orchard to supply the food demands of each family (fruits, vegetables, poultry, etc.). This orchard will also give an opportunity for creating the desirable microclimatic conditions for the local built environment, that has to face hot weather in summer and fairly cold and windy weather in winter.

As far as possible, the design will present alternatives for diminishing the demands on externally supplied energy sources and for the recycling of the domestic and community wastes.

Also, the building site will be chosen in, such a way to make underground water available for domestic consumption and for vegetable production including also the provision for collection and reservation of rain water.

2.2 The housing units

The construction of the individual units will make use of locally and traditionally accepted building materials, including timber and bricks or blocks of several origins (like clay bricks, soil-agglomerant, etc.).

The houses will be designed in such a way to accommodate a family, with a minimum area of about 40 m^2 (new houses for low income people in Brazil have been built with an area of less than 25 m^2)and making allowance for future expansion. As a general guideline, a target budget of 150 to 200 US\$/m^2 for the construction of the houses (in addition to the labour of the futures users) is being taken as a reference.

The school/social centre is going to house a maximum of 100 children/adults in two classrooms, convertible into one large single room.

The construction plot will be chosen to be located within a radius of about 40 km from Porto Alegre's city centre and well supplied with potable underground water, with a total area of 10,000 m^2.

2.3 The results of the Design Ideas Competition

The above mentioned competition, that will lead to the development of the final project, was open to students of architecture and allied disciplines, as well as to architects, world wide. Team entries were encouraged.

The Organising Committee received 38 submissions, being awarded 6 prizes: 3 to professionals and 3 to students. From the 38 entries, 6 were submitted by professionals and 32 by students.

The prizes, totalling US$ 6,000.00, were announced on the 7th July 1995, at a ceremony held at the end of the Conference.

The results of the competition and respective prizes were as follows:

- *Professional track:* 1st prize (one sheet of the set submitted to the competition is shown in the next page) - Michael D. Morrisey, H20 Workshops, Australia - US$ 2.000,00;
- *Student track:* 1st prize - Nigel J. Craddock , The Martin Centre for Architectural and Urban Studies, University of Cambridge, UK - US$ 750,00.

3 The research project

The research project to be developed intends do create a Research Centre for new technologies related to social housing, incorporating, on the one hand, the principles of sustainable development, and on the other hand, the idea of housing as the habitat of man in the social context.

In this way, housing is **the** end, discarding such concepts that sees housing as a way of reaching an economical balance, promoting the civil construction industry as the main protagonist in solving the unemployment problems, the so-called low qualification of labour, the need for urban expansion, etc. On the above mentioned way, the laboratories for the study of housing technologies could ignore the user, limiting their scope to such subjects like the production of low cost and easy to use materials and, much probably, concentrating efforts on restricted areas or specific to product conception.

Thus, starting from the idea that the dwelling is the locus for the reproduction of labour, it is believed that the function of housing is beyond that of a simple protection, but incorporates all the processes of health, education, protection, enjoyment of life and relationship with the social and natural environment. Therefore, the conception of the laboratories, basically, assume the existence of a Research Centre where the urban way of life could be analysed as a performance assessment parameter of the presented proposals. The production and implementation of the projects could be followed by monitoring where the processes, products and recommended performances could be assessed in a larger context considering multidisciplinary interferences, including social, technical, environmental, cultural issues, among others.

The project as a whole will be developed in four stages:

- Modelling and projects development;
- Implementation and occupation
- Monitoring
- Product development

The modelling and projects development phase will include all the stages relative to the planning of the physical infrastructure and functional support to the activities to be developed locally. These include the land survey, the zoning project, the development of architectural projects for the houses and other buildings, including also water and energy supply, sanitation, communications, etc. On the way this work is being conceived, we also consider in this stage, agriculture projects, for local food production (permaculture, aquaculture, cornposting, etc.), alternative projects for solar and wind energy collection, rain or underground water collection, liquid and solid wastes management. Considering that in the general project there is the intention of keeping people as close as possible to the living area, among the proposed proposals alternatives for job and income generation should be assessed.

Once the modelling and projects development phase is concluded, the implementation and occupation of the site will start. As the built environment production process will be of self-building, some qualification and training courses should be conducted during this phase. The construction work management will provide the project team the feedback to adequate the adopted project technology to the reality defined by the local availability of materials and workmanship, as well as to the users' requests.

The next phase, the monitoring, that is expected to last for two years, will be followed by the technical team, starting by the occupation of the dwellings by their users, having the implemented proposals assessed. The main aim of this phase is to generate indicators for the assessment of the proposed technologies, considering the social-environmental impact they produce, besides allowing a comparison between the traditional solutions and the alternative proposals.

The final phase of the project of products development, where after the assessment and the check of the real possibilities for the developed products to be absorbed by the market, new projects could be developed to make these products available, using the infrastructure of the productive sector.

4. Discussion

Both the future implementation of the Centre, as its operation after completion, will require the participation of multidisciplinary teams from several institutions. Once concluded the project, the effort of the different contributors certainly will be rewarded by the opportunity, perhaps unique in the South American continent, of having aggregated in the same place, a whole series of environmental strategies that, usually, are only partly developed and applied in different places. Even more important is the attachment of the project to the Brazilian social reality, and the expected results to be obtained through the project, not only the technical results, as those of organisation and mobilisation of the involved target groups, that will enable the offer of alternatives to present critical situation.

The proposed Centre, if successful, will be a consultation reference for a wide public:

- To those interested in Sustainable Buildings, the houses and other buildings in the Centre, built basically with the use of local low cost materials e low embodied energy, besides having the participation of the future users, will offer a opportunity to verify the application of bioclimatic architecture to low cost housing, like the natural conditioning of buildings, and, if possible, the use of solar energy for water heating, as well as of the other sustainable construction techniques to be used;
- To those interested in Sustainable Agriculture, there will be the garden and orchard that will feed the residents, including a variety of plants cultivated according to sustainable management techniques;
- The liquid and solid wastes management systems, will identify new possibilities for wastes treatment with no environmental damage;
- In such an integrated and balanced system the domesticated animals also should integrate the site, accomplishing their recycling functions and providing proteins to the residents. Chickens, pigs, fishes, bees, ducks and goats, as well as other animals, might be introduced into the site, where useful information on sustainable ways of keeping these animals will be made available.

With its proposals of education, demonstration and research, the Centre, in the project development stage and, probably, through its normal operation in the implementation stage, will supply to the society a better understanding of subjects related to sustainable development, like:

- ENERGY: As far as possible, the Centre will try to provide their energy demand through the use of local resources. The buildings will use passive solar techniques. Biological systems will process the residues to produce methane gas. PV systems and wind turbines might be installed to produce electricity.
- BUILDINGS: The architectural shaping of the Centre will match the following aims: integration with the environment, use optimisation of the available energy and reinforcement of the social interactions.
- FOOD: Particular attention will be given to practices that: protect and enhance the soil characteristics; reduce energy consumption and the use of fertilisers and other chemical products; maximise the possibilities of multiple use and reduce water consumption;
- WATER: An integrated system of water flow will allow the research and demonstration of techniques like aquaculture, irrigation and the biological treatment of waste water;
- RESIDUES: Through a rational operation, the Centre will minimise energy and materials consumption, that will also minimise residues. From the unavoidable residues, the organic material might be reintroduced into the local ecosystem. The kitchen residues might be used for feeding animals, while other residues might be composted or receive a biological treatment for methane gas production.

3. Conclusion

Although the implementation of the winning scheme, as an *experimental centre* for demonstration, research, and education, is still a goal to be achieved, this is under way now, with its design stage to be started in the coming months. But while that does not start, the dissemination of principles for the design of sustainable communities has been made continuously, through exhibitions and talks regarding the competition's results.

Anyone looking at the existing housing sites in Brazil, realises that ***nature*** has not been taken into consideration when they were designed, and, what is even more worrying, little attention has been given to ***life,*** in general. It is hoped that the implementation of the Experimental Centre for Sustainable Housing Technologies will serve as reference to new housing developments in Brazil.

Design for Adaptability
- a hierarchical decision process for adaptability

S. H. Blakstad
Department of Building Technology, Norwegian University of Science and Technology, Trondheim, Norway.

Abstract
In both business and in the building process, we experience a development away from stable and linear processes, towards more change, shorter innovation cycles and constantly ongoing adaptations to changes in the environment. This demands a higher degree of adaptability in buildings and in the design- and construction process. At the same time as organisations change more rapidly, some corporations have started to consider how their offices support their business, and if the facilities allows the organisation to work efficiently.

This paper presents an approach for designing adaptable office buildings. The high rate of change makes it necessary to be able to start development without having defined the objectives and specifications at the most detailed levels. Decisions in the planning process are being pushed forward, so that the just-in-time concept applies for decision-making as well as production. The design team has to cope with changes at all times during the process. One way of coping with those changes is to develop a hierarchy of plans, each with its own time scale. This paper describes a hierarchical approach to design- and decision-making based on to the technical and functional life spans of the building. Adaptability and reuse of buildings can, ideally, save resources. This paper also deals with how adaptability influences the economy related to office buildings.

Our understanding has been developed during research projects, where in-depth case-studies have been used to address these issues. The paper will therefore use ***Dagbladet*'s** renovation project in Oslo as a case to present the hierarchical decision process which can be used to improve design for adaptability. ***Dagbladet*'s** primary goal was to continue to be located in Akersgata, which houses the largest newspapers in Norway. In order to do this they had to adapt the existing buildings, which were far from ideal for flexible, modern offices. In order to cope with this difficult situation, they implemented a flexible and strategic planning process, a layered decision process. The physical steps taken to solve this problems are based on traditional techniques like flexible partitions etc. What is interesting about the case is that to be able to adapt the existing buildings, they focused on the ***process of making,*** on strategic planning and decision process, and not only on the physical solutions.
Keywords: Design process, Adaptability, Life-cycle perspective

1. Introduction

Today's businesses face a rapidly changing environment, due to changes in the markets, in technology and international competition as well as a shift towards more knowledge- and information-based services. To survive in this changing environment, businesses themselves have to innovate, adapt and change.

As businesses change faster, so will their functional and spatial requirements. This leads to changes in office buildings, as well as to where and when people work. Buildings are solid, and more difficult to alter. Once erected, they are expected to last for decades, in some cases even centuries. This means that to meet the challenges posed by businesses, buildings must be adaptable.

Adaptable buildings are more than just «flexible». During the last 25 years the word «flexibility» has been used to characterise almost every office building. Some of them have proved themselves to be very successful, others not. For many clients, the extra cost of building in modular systems for flexible partitions and technical services has proven to be too high compared to the resulting flexibility in use. What is designed to be flexible, might prove to be inflexible in use. It is hard to predict where and how the changes will occur.

This paper will focus on adaptability of office buildings, because most of our cases are of that type. A Norwegian case study, the renovation of the newspaper ***Dagbladet***, will be used to illustrate one strategy that can be applied in order to design more adaptable buildings; a layered decision- and design-process, which we have called «the decision hierarchy)).

2. Design for Adaptability

In order to structure our discussion we have used the following definitions for «design» and <<adaptability>>: By «design» we not only mean architectural design, *but the whole process of developing a project, and the decisions taken during that process.* The actual «design», according to the more narrow definition, is developed by architects and consultants, while most of the decisions regarding needs, finance, use etc. are made by the client or his representatives. These are different in character, but in this paper we will not discuss these differences further. Our aim is to look at the whole process of project development.

We define <<adaptability>> as *the ability to change, responding to changes in the environment.* When we consider adaptable office buildings, these changes are initiated by changes in:

- demand for organisational change, related to use (= functional requirements)
- technological innovation
- changes in the financial and contractional environment (Real Estate Market)

Changes in the environment challenges the adaptability of buildings. At the same time the building itself goes throught a change process related to the building's deterioration and technical decline. The gap between the level of performance and the increased level of expected standard (building quality, user expectations and legislation) widens as the building ages (se Figure 1).

We will describe «Design for adaptability)) as a strategic process, which must be developed and refined throughout the project. In order to design more adaptable office buildings, there are a number of *strategies that can be applied.* Some of these are:

- Adaptability and flexibility in the building (like flexible, modular partitions etc.)
- A flexible portfolio of buildings (the user moves when his needs change)
- Responsive management of the building(s)
- More flexible ways to use the building (e.g. free address offices)
- Adaptability in the process of planning, designing and managing office buildings

In this paper we will focus on the latter strategy, which is fundamentally different from the others, because it moves our attention from the product, the building, to *the process of making* the product. This is the entire development cycle of the building, which include both the briefing process (user and client needs), design, construction and Facility Management, building management, use and demolition. In our work we have described the building process as cyclical. An example is shown in Figure 1.

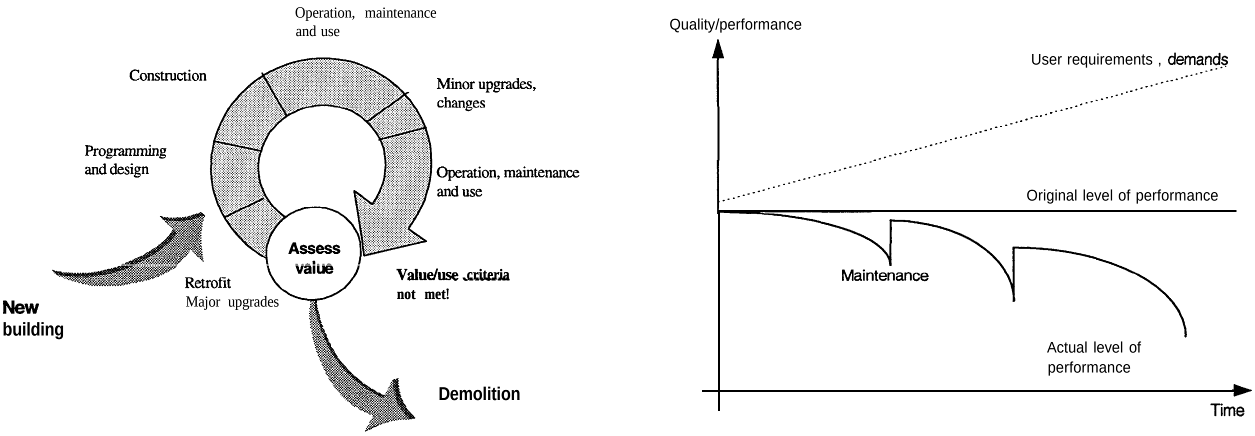

Figure I. The life cycle of an office building (left) and an illustration of the increase in demands in relation to an existing building's level of quality/performance (right).

2.1 The hierarchy

One way to deal with adaptability and changes in the planning process is to layer the decisions according to change rates and expected life span of each layer. This approach was used in the *Dagbladet* project, but before presenting their solution we will discuss this at a more general level.

When we divide the process into layers, each of these can be developed and worked out separately according to the development of the project. Long-term and strategic decision-layers can be decided upon early, and these will create a framework which the other layers have to be developed within. The detailed content of the different layers can differ and be project-specific, but some of the aspects that must be considered are shown in Figure 2.

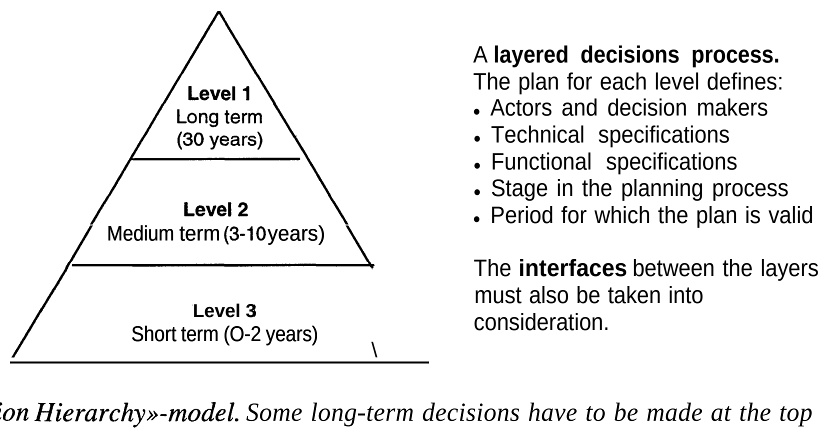

Figure 2. The «Decision Hierarchy»-model. Some long-term decisions have to be made at the top level. Within the limits of the long term plan, more rapid responses to changes can occur. At the bottom level, e.g. the floor plan, adaptations can be made from one day to the other.

In the following, we will look at some aspects of thelayered decision process, both in general and in the *Dagbladet* project. In part 3 we present the different stakeholders and a framework for implementing this in the design and planning process. We will also focus on the change process and on how the match between user needs and the buildings changes in time. Part 4 describes how the layers are defined according to service lives, considering both technical, functional and economical aspects. Part 5 shows the decision hierarchy for *Dagbladet* in more detail.

3. Changing user needs – adaptation as a two-way process

The organisation's needs change over time. In most cases, these changing requirements must be accommodated in a building. Organisations may choose to change location and move to another building, or the changes can take place inside the same building for a period of time. This is a two-way process, with adaptations in the way the organisation uses the space and with physical adaptations in the building.

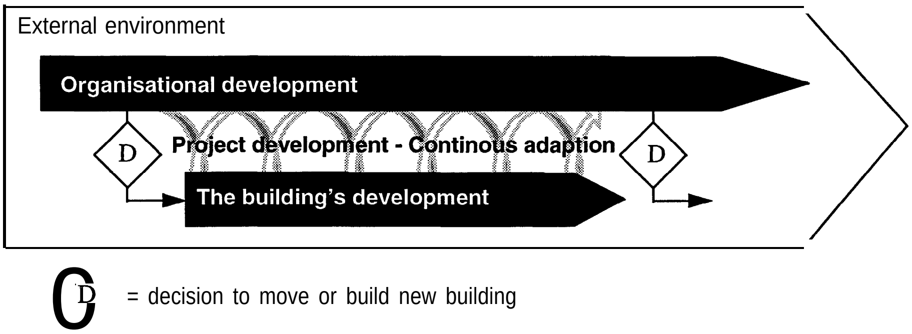

Figure 3. Both organisations and buildings develop over time. Between the building and the organisation there is a two-way process of continuous adaptation.

3.1 The match between organisational development and the building - Dagbladet

The newspaper *Dagbladet* has been located in Akersgata in Oslo since the 1950's. From the very beginning there has been more or less constant retrofitting and expansion of the buildings. We have mapped the retrofits and the changes in the buildings and in the organisation since they first moved to Akersgata. A schematic illustration of the development is shown in Figure 4. When we have investigated these changes, we find that they were instigated by new technology in the production of the newspaper and by new legal requirements regarding office work and work environments (Blakstad, Christiansen et al. 1997)

In the 1980's *Dagbladet* occupied three different buildings: the oldest from the 1890's, the others built during the 1950's, and they realised that more flexible and modern offices and larger areas were necessary.

After economic and environmental evaluations, *Dagbladet* decided to refurbish the buildings in 7 stages, with normal daily newspaper production going on simultaneously. The planning process started in 1993 and the first construction stage started in 1995. When the last construction stage was finalised in 1997, 7000 m² was retrofitted and 400 m² constructed as an extension to the *4.* - *6.* floor.

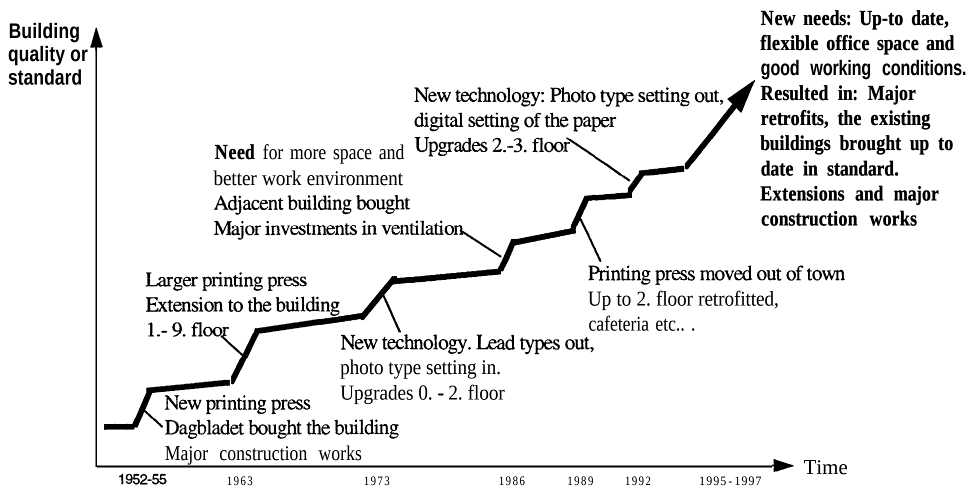

Figure 4. The development in Dagbladet's buildings in Akersgata.

The building's development and its suitability for the users are to some extent defined by its adaptability. In ***Dagbladet's*** case the different properties of the three different buildings became evident during the renovation. The building from the 1950's was designed to fit the demands of that time as efficiently as possible, and was very area-efficient when constructed. Its ability to fulfil today's demands were on the other hand much poorer than the ability of the building from 1890 (Blakstad, Christiansen et al. 1997). Low floor-to-ceiling heights and narrow modules between the windows were some of the problems that had to be solved by the designers. Even though this was given a lot of thought, and good solutions were implemented, you can still find many evidences of these problems in the new offices: too narrow offices, insufficient space for cabling and installations, and some floorplans suffering from fixed locations of meeting rooms and restrooms for smokers (these require more ventilation). These are examples of how physical constraints in the building limit the possibility for change.

3.2 Stakeholders and decisionmakers

In the decisions hierarchy, different stakeholders are involved in different layers of the decision process, trying to match the organisation's development and requirements with the building. The long-term decisions are the most strategic ones, and in *Dagbladet*'s case, the corporate, strategic management participated at this level assisted by the architect. The short term decisions are the ones that are most close to the end-users. It is at this level the need for adaptability and quick changes according to the work process is most needed. In the ***Dagbladet*** case, the decision makers at this level were department managers and end-users assisted by the interior architect.

4. Service life

The concept of hierarchy of decisions, which we have presented, is based on the layering of different parts of the building, according to their expected life-span. The different materials and components can be divided into groups according to their ***service life.*** Service life is defined as: «time during which an item remains serviceable)). The layers we will use for the hierarchy will be based on the expected service lives and the different layers' functions in the building. For this purpose we have used relatively broad categories. Our purpose is to develop a practical tool for planning, not a system to predict service lives of materials and components in the building. To develop this further into a generic approach we will have to consider both the logistics of the planning process and the service life of the layers.

4.1 The Physical Layers

In his work, Stewart Brand has defined 5 different layers (Brand 1994): Site, structure, skin, services, space plan and stuff. The example shown in part 5 does not follow this definition of technical layers. This is due to the fact that the grouping of decisions (on technical specifications) was both based on when in the planning and design process they were made, as well as on technical service lives.

4.2 The Functional Demands

In most cases, we find that it is the changes in functional demands that provokes change, not that the physical layer has reached the end of its technical service life. This is, of course, more true for the «internal layers» (services, space plan and stuff) which are closely related to use.

In many cases, the services layer is the most expensive to change. At the same time, this is the layer that constrains adaptability most. This means that in order to design adaptable solutions it is essential to co-ordinate design efforts and take into account both architecture, structural and technical aspects.

4.3 Cost implications and added economic value

Adaption and changes in buildings have cost effects as well as possible economical benefits. The economic service life of a building is the result of the balance between the building's and the component's technical life and the level of functional performance. When we study the cost effects of adaptability, we have to consider:

- Possible higher investment costs, due to more expensive, flexible solutions when constructing the building.
- Adaptable space plans are not always the most area-efficient (that effects both investment costs and costs-in-use)
- Renovation costs of adaptations and changes.

Adaptable buildings might also prove to be cost-efficient in the long run. This is due to:

- Reduced construction costs for future adaptations and reduced costs-in-use, compared to operating an unsuited building
- Possible gains in the efficiency of running the business and reduced risk of productivity loss due to renovation and adaptations (or at least for shorter periods).
- Reduced financial risk on investment

One example of this trade-off between construction costs and the costs of future adaptations are the calculations made for the *Dagbladet*-project. In order to obtain the desired level of flexibility, ***Dagbladet*** invested about 5000 NOK/m^2 in the retrofit. In the future, rearranging from cellular offices to landscapes will cost 200 NOK/m^2, and rearranging from landscapes to cellular offices will cost 500 NOK/m^2. The job can be finished in a night or a weekend. In order to make quick adaptations possible, they must not disturb the workprocesses in the newspaper. For ***Dagbladet, an*** uninterrupted production process is the most important of all economic considerations.

5. A Hierarchy of Decisions and Layers

For *Dagbladet*, one way of achieving the desired flexibility in their new offices was to accommodate a flexible design- and construction process. This fact became even more important because the renovation was carried out in 6-7 stages. While one part of the building was being renovated, other parts were still in the design phase. In order to do this, the two highest levels of the hierarchy were decided upon before the construction of the first parts started (Blakstad, Christiansen et al. 1997). The plans for the lowest level – the floor plans – were developed individually for each floor and department. This level can change very quickly, but the flexibility in this layer is dependent on the highest level decisions that are taken in level 1, the General plan, and level 2, the Master plan.

5.1 Level 1 - General plan

Contents	Functional specifications	Technical specifications	Participants, actors	Time frame
Strategic decisions Specification of demands	States the importance of flexibility Defines the vertical communication, location of stairs and lifts Defines a pattern for main horizontal communication paths Defines fire sectioning Defines and describes accessibility (for customers and for the disabled) Defines the location of specific functions such as main computerroom, filing, library etc.	Gives a record of loadbearing possibilities in the different buildings and floors Defines future shafts Specifications for acoustics and noise control Specifications for materials: floors, ceilings. Gives specifications for the modular partitioning system Specifications/descriptions of lighting, services and information technology & communication	Professional assistance: The Architect. Corporate top management CEO Project leader Steering committee	30 Years

5.2 Level 2 - Master plan

Contents	Functional specifications	Technical specifications	Participants, actors	Time frame
Locations within the building and functional demands	Location of departments in relation to each other to improve interaction and workflow Location of some special functions Demand specifications for some of the functions, area, number of people etc.	None	Professional assistance: The Architect. Department managers Union representatives Project leader	3 Years

5.3 Level 3 - floorplans

Contents	Functional specifications	Technical specifications	Participants, actors	Time frame
Floorplans with off ices and interiors	Floor layout Offices for each department and individual Final location of meeting- and smokers rooms (within the limits of the masterplan) Off ice furniture and equipment	Interior partitions Local technical services Materials, colours and finishes	Professional assistance: The Interior Designer End users Department managers Project leader	3 months

6. Conclusions

In a strategic process for adaptable design, an important issue is to shift the designer's and client's perspective from short term realisation and profit to longer term goals. It is also important to develop a knowledge of the entire life cycle of the office building and the users' possible, future demands. The understanding of the building as a static product of the construction process, not intended or designed to change, is perhaps the most important obstacle for the design of adaptable buildings.

In the past, design of adaptable building has been more or less synonymous with adding in physical flexibility, such as modular partitions etc. We might argue that there is a lot to gain by focusing on other types of adaptability in the building, e.g. multifunctionality, robustness and extendibility. This is, however, not the main focus of this paper. The main objective is to highlight the importance of <non-physical>> strategies for adaptability. We have presented an example of how a layered decision and design process has been successfully implemented in a Norwegian renovation project. The strategic approach is what makes this example valuable for others to study.

The Decision Hierarchy is one strategy to ensure strategic, long term decisions as well as possibilities for change on a day-to-day basis. As in all design and decision making, awareness of the process and its dynamics, the actors and the information flow is vital in order to design adaptable office buildings.

New classification system for easy identification of the content and use of standards by standards users

UNI, Milan, Italy

Abstract
Starting from the ICS classification created by ISO, UNI (the Italian National Standards Body) together with DISET - Politecnico di Milano has developed, in a research funded by CNR (the Italian National Research Council), a new classification system incorporating a better "hierachizated" structure, from the general to the detail, that fits very well the computerized search of the existing standards as well as the classification of new EN standards for the building sector.
The new classification system is meant to ease the identification of the contents and the use of the technical standards- by all the operators of the building process, from commissioning to dismantlement/recycling, and to improve sustainable building practices.
The paper presents the new classification system in the version developed and validated for the UNI DATA BASE and that has been proposed by UNI as a basis for the revision of both the allocation of descriptors in the construction field of CEN and the ICS in the building sector of ISO.
Keywords: information classification system, building standards' data bank, sustainable building practices

1 Introduction

The new classification system and the data bank are the results of a five years research programme titled: "Completion and implementation of the Classification of National and European Technical Standards according to new criteria and descriptors - Prototype of a Standards' Data Bank in the field of application of the Construction Products EC Directive", funded by the CNR (the Italian National Research Council) Goal Oriented Building Project and developed by UNI (the Italian National Standards Body) together with DISET - Politecnico di Milano.

The research team was composed by: Pierangelo Boltri, Bruno Daniotti, Angelo Lucchini, Carlo Marucci, Roberto Morandi, Giuseppe Turchini, Mario Sanvito.

The main goal of the research was to ease and to improve the use of technical standards from the various building operators (investors, contractors, designers, users, etc.). This required the definition of a list of operators and the consequent detailed analysis of their needs, usual terminology and habits very useful to structure the Standards' Data Bank on the real needs arising from their professional work.

In other words the leading idea was to structure the Standards' Data Bank more on the needs of its users' than on those of the standardmakers.

As direct consequence of such choice a new information classification system had to be defined.

2 The new information classification system

The new information classification system was defined to allow the easy and quick search in the Standards' Data Bank of the information that matches specific users' needs.

The classification system was then structured into more "fields" each one representing a possible way of approaching or selecting the standards' information and therefore of defining a specific path or tree of searching.

The structuring of the classification system in separate fields allows the comparison in Boolean way of the results gatherable by different paths, to obtain the selection of information that better fits the user needs.

The classification fields are organized in two main groups: one for those concerning the identification of the standard, and the other for those regarding its technical contents.

In detail the first group includes the following classification fields:

1. *Standard title*
2. *Standardisation body:* UNI, CEN, ISO, etc.
3. *Standard code: e.g.* UNI 8270, IS0 140, etc.
4. *Dates:* of publication and revision;
5. *Standard rank:* regional, national, european, international;
6. *Standard character:* compulsory or agreed; draft, operating or in revision standard;
7 *Field of application:* use destination/s (see Table 1) to whom the standard has relevance.

The second group comprises these other classification fields:

1. *Object:* it indicates the part/s of the building the standard refers to.
   This field is hierarchicly structured from the most general and complex items concerning the: indoor environment, indoor spaces, building parts as a whole, outdoor environment, construction tools and facilities (see table 2) to the various categories of building components and technical equipments, down to the products' families (see table 3).

Code	Field of application
1	all buildings
2	houses
3	intermittently occupied buildings/ hotels
4	leisure/sport buildings
5	urban infrastructures
6	schools and universities
7	office buildings
8	commercial/shop buildings
9	industrial/production buildings
10	stock buildings
11	hospitals/sanitary premises
12	community buildings

Table 1. Codes and classification of the “field of application” field

Code	Object: general and complex items
1	Building indoor environment
2	Indoor space distribution
3	Building technological system
4	Building outdoor environment
5	Construction tools and facilities

Table 2. Codes and classification of the first level of the “object” field

Code	Object: categories of building components and technical equipments
3.1	*Subsystems:*
3.1.1	Foundations
3.1.2	Elevation structures
3.1.3	Connecting structure for stairs, lifts, ramps, etc.
3.1.4	Vertical envelope: external walls, windows, etc.
3.1.5	Upper horizontal envelope: roofs, skylights, etc.
3.1.6	Lower horizontal envelope
3.1.7	Ground horizontal envelope
3.1.8	Internal vertical partitions: internal walls, doors, etc.
3.1.9	Internal horizontal partitions: floors
3.1.10	External vertical partitions: fences, gates, parapets, etc.
3.1.11	External horizontal partitions: balconies, external ramps and stairs
3.1.12	Heating, ventilation and air-conditioning systems
3.1.13	Water supply systems
3.1.14	Drainage systems
3.1.15	Discharge plants for aeriform substances
3.1.16	Movement systems for waste materials
3.1.17	Gas supply systems
3.1.18	Electric equipments
3.1.19	Phone and data transmission installations
3.1.20	Lifting and transportation systems
3.1.21	Fire alarm installations
3.1.22	Anti-gas installations
3.1.23	Protection installations against electric discharges
3.1.24	Antitheft installations
3.1.25	Indoor furnitures and appliances
3.1.26	Outdoor equipments

3.2	*Components and products:*
3.2.1	Materials, semi-manufactured and for general use components
3.2.2	Protective paintings
3.2.3	Adhesive and sealing products
3.2.4	Joint elements
3.25	Thermal and acoustic insulating products
3.2.6	Waterproofing and vapour barrier products

Table 3. Codes and classification of the "object" second and third level

2. *Prevailing building material:* when relevant, it allows the identification or exclusion of some materials or products, it can be mentioned for completing the description of the object or used independently (see table 4).

Code	Prevailing building material
1	Ferrous metals
2	Non-ferrous metals
3	Clay
4	Ceramic
5	Cement, concrete, gypsum, mortar, etc.
6	Wood and derived materials
7	Bituminous materials
8	Rubber products
9	Plastics products
10	Glass and derived materials
11	Natural stones and derived materials
12	Textiles
13	Other generic categories such as composites, etc.

Table 4. "prevailing building material" field's codes and classification

3. *Agents/Phenomena:* they allow the identification of eventual relevant agents, actions, solicitations and effects (e.g. for test methods) (see table 5).

Code	Agents and phenomena
1	Acoustic
2	Atmospheric and pneumatic
3	Biological
4	Chemical
5	Mechanical
6	Electrical and magnetic
7	Hydraulic
8	Optical-luminous
9	Igneous
10	Radioactive
11	Thermodynamic

Table 5. Codes and classification of the "agents and phenomena" field

4. *Requirements:* it indicates the requirements the standard eventually refers to. The essential requirements defined by the EC directive on construction and bulding products are listed first and separately from other economical, functional and technical requirements (see table 6).

Code	Requirements
1	*Essential requirements [i]*
1.1	Mechanical resistance and stability
1.2	Fire safety
1.3	Hygiene, health and environment
1.4	Safety in use
1.5	Sound insulation
1.6	Energy saving and heat insulation
2	*Other requirements*
2.1	Economy, durability and reliability
2.2	Dimensional fruibility/accessibility
2.3	Aestethics
2.4	Building and management safety
2.5	Information management

Table 6. Codes and classification of the "requirements" field

5. *Items:* it is always applicable., it indicates the informative content of the standard (see table 7).

Code	Items
1	Terminology, classification, symbols
2	Requirements
3	Specifications
4	Laboratory test methods
5	Field test methods
6	Calculation methods
7	Codes of practice
8	Contractual technical aspects, qualification procedures and similar

Table 7. Codes and classification of the "items" field

The information classification system was definitively set up in the version nere presented only after numberous tests performed on a small prototype of Standards' data bank in which only about 200 standards where inputted. The contents of these standards were well known to the research team members.

In this phase many searches were successfully tested using different accesses to the data bank with reference to various needs of information, thus simulating the typical necessities and behaviour of more categories of building operators.

Once the ICS was validated the problem became the classification of all the standards and laws that had to be stored in the data bank.

To this goal a handbook explaining in easy terms and with the help of many examples the new ICS application was edited and given, after a detailed presentation, to every member of the technical secretariat of UNI together with the task of cataloguing all the standards related to their specific field of competence. After a few samples of standards' cataloguing, meetings were held to check and discuss the practical aspects of the new ICS application and the handbook effectiveness. Some small integrations of the handbook were recognized necessary. Once the handbook was updated all the standards given to each member of the UNI technical secretariat were successfully catalogued.

This job was done quickly and really well. It allowed the creation of the "UNI CNR building standards' data bank" in which all the classified standards were inputted.

For the future, to facilitate the input of the standards' classification directly by the staff of the technical secretariat or by the technical committees of UNI, digital input masks were prepared corresponding exactly to the paper cards used to classify the standards in the research here presented.

The classification operations will be integrated in the editorial process every standard from the very beginning to help the precise identification of its scope and contents according the new ICS here described.

3 The "UNI CNR building standards' data bank"

Since the 80's UNI and DISET Politecnico di Milano had already created two prototype data bases for the building standards' with simpler technologies: one on paper cards and one on diskette, both were really useful only to those users who having enough knowledge of the existing standards were able to search and select them only on the basis of their title and/or number.

Nevertheless, on the basis of the informatic prototype UNI has developped at the beginning of the 90's a standards' data base called "UNI edil", were *edil* stands for *building,* that has got quite a good success among some Italian building operators, some Public and Private bodies, Universities, Technical High Schools, etc.

It was therefore considered more useful and-convenient to incorporate, with the help of the UNI data elaboration office, the new classification system into the "UNI-edil" data base.

The final prototype of the "UNI CNR building standards' data bank" (see Figure 1) is on a CD-ROM in which the old and the new data bases coexist to ease the standards' searching and to maintain the original output of the complete standard in digital format at the same time.

Any data base user can search the standards using both the new classification system and the old generic search fields; in particular the new classification system allow the parallel searching in all the new fields (see figure 2).

Every search leads to a list of standards, each one with its number and title. The abstract and/or the full text and figures can than be obtained on the video and printed as well.

Besides the user may perform Boolean operations among the standards' lists selected in parallel through different classification fields, this to obtain the group of standards that fits his needs.

To facilitate the use of the new building standard's data bank a User's guide and an Help-on-line, both explicating the meaning of the terms used for the standards' classification and how to perform the standards' search, were also prepared.

5 Conclusions

The new information classification defined by UNI and DISET Politecnico di Milano allows the easy and quick search in the "UNI - CNR Standards' Data Bank" of the information that matches the specific needs of the various operators of the building sector. It has been successfully validated.

At the moment, World Wide Networks gives their users a lot of information which is not easy to access, because of its scattering in differently organised databases.

With a classification system like the one here presented it would be much easier for the building operators to find the information that suits them.

The new information classification system has therefore been proposed by UNI as a basis for the revision of both the allocation of descriptors in the construction field of CEN and the ICS in the building sector of ISO.

Promoting BEQUEST: Building Environmental Quality Evaluation for Sustainability through Time.

A. Hamilton and S. Curwell
Research Centre for the Built & Human Environment, University of Salford, Salford, UK
I. Cooper
Eclipse Research Consultants, Cambridge, UK

Abstract

The broad aim of the BEQUEST Network is to create a forum for concerted pan-European research, training and practical action in assessing the quality of the urban environment in order to identify the basis for a common understanding and implementation of sustainable urban development. The network has been funded for three years under the European Union Environment and Climate RTD programme, and is due to start operation in April 1998. This paper gives an account of the key features of the network and its modus of operation. We are developing an internet supported system for working and communicating that will address the role and responsibilities of industrial, commercial, and all other societal actors involved in the development and use of the built environment across the scale from individual buildings to whole cities, in EU. member states.

At the core of the network are the 14 partners from research institutions across Europe who will drive the programme forward by a series of workshops at intervals of a few months, and continuous use of a dedicated intranet. The results of our work will be tested by the societal actors who are associates of BEQUEST, on an extranet of partners and associates. The extranet will allow for formative assessment of BEQUEST products with immediate feedback.

In the first year of the programme we will identify and analyse existing sustainability blueprints, and current approaches to implementation. Through this process, we will build up a common understanding, and recognition of cultural and environmental diversity. In the second year we will produce:

1. An analysis and classification of assessment methods
2. A protocol for sustainable development
3. A decision matrix to promote understanding of the protocol.
4. A directory of sustainability advisors to promote implementation of the protocol.

The remainder for the project will be concerned with testing and disseminating the protocol and its “tool kit” firstly with our associates and then with all other interested parties in Europe responsible for shaping the built environment. We will also set up Internet and other structures to promote continuity of this initiative.

Keywords: Built, City, Environment, Extranet, Internet, Intranet, Sustainability, Urban.

1 Introduction

The BEQUEST Network arose out of the conference, "Environmental Impact Evaluation of Buildings and Cities", held in Florence in September, 1995 [1]. The main objective of this group is to lay the foundations of a common EU. understanding of sustainable urban development through a multi-disciplinary network of representatives of all actors involved in the provision, use and maintenance of the built environment. An integrated approach to built environment quality assessment is to be developed which will help to reduce the environmental uncertainty facing decision makers in the development and infrastructure industries. For this major European project the network is to be expanded from the present size of fifty members in 10 countries to create a broad international, interactive community composed of a very wide range of disciplines from both the demand and supply sides of the development, infrastructure and construction industries, in order to assess the built environment at a range of scales, from building component design through to strategic city planning, across a range of cultures and regions. The context of research project is shown in Figure 1. The groups represented in this figure are derived from the work of ATEQUE [2]

2 Background

The difficulties in reconciling the demands of modern commerce and transport with the desire to provide a good quality environment have long been recognised. The associated congestion, pollution, noise, deterioration of streets, public places and architectural heritage and general loss of amenity experienced is seen as a very difficult collective problem requiring broad understanding and multi--disciplinary action. [3]

The problem is compounded by other factors:

* the increasing urbanisation of humankind - two thirds of Europeans now live in urban areas [4],
* the longevity of buildings and city infrastructure - 60 to 100 years is not unusual for individual buildings,
* the very large quantity of resources which existing cities contain and which are consumed annually to continuously develop, maintain and use them.(In the UK it has been estimated that the construction industry uses about 6 tonnes of building materials annually for every member of the population [5]).

If all these factors are considered together then the built environment sector presents one of the biggest challenges for society, both in terms of the development of a collective aspiration for better quality, more sustainable patterns of living and the time it will take put these ideas into effect [6].

A key issue is the scale of impact on a spectrum extending from the individual to the global level embracing buildings, urban districts and cities. It is clear that some definitions of sustainable urban environments seek a better environmental and economic balance between the city and its hinterland, whilst others look towards greater autonomy of urban communities. Increasing the density of urban areas as a means of intensifying land use and transportation efficiency is being examined, but this approach is also questioned in terms of the functionality of the cities and the quality of environment that might result [7, 8].

At the district/city scale local authorities have established various local objectives under Agenda 21 [9]. The usual response is to identify local "indicators" which will be used to benchmark the current environmental performance of a community and against which future improvements can be measured. A wide range of alternative indicators are being used by differing local authorities and these do not always coincide with those suggested nationally [10] which will mean differing objectives and standards, not just across national boundaries, but even between neighbouring local authorities. In this context it is important to note that Agenda 21 proposals constitute entirely voluntary action. In the meantime major city or infrastructure projects must continue to undergo environmental impact analysis in line with EU Directives [11]. These regulations are interpreted in national planning control guidelines which will, at best, ameliorate the negative environmental consequences of larger scale projects.

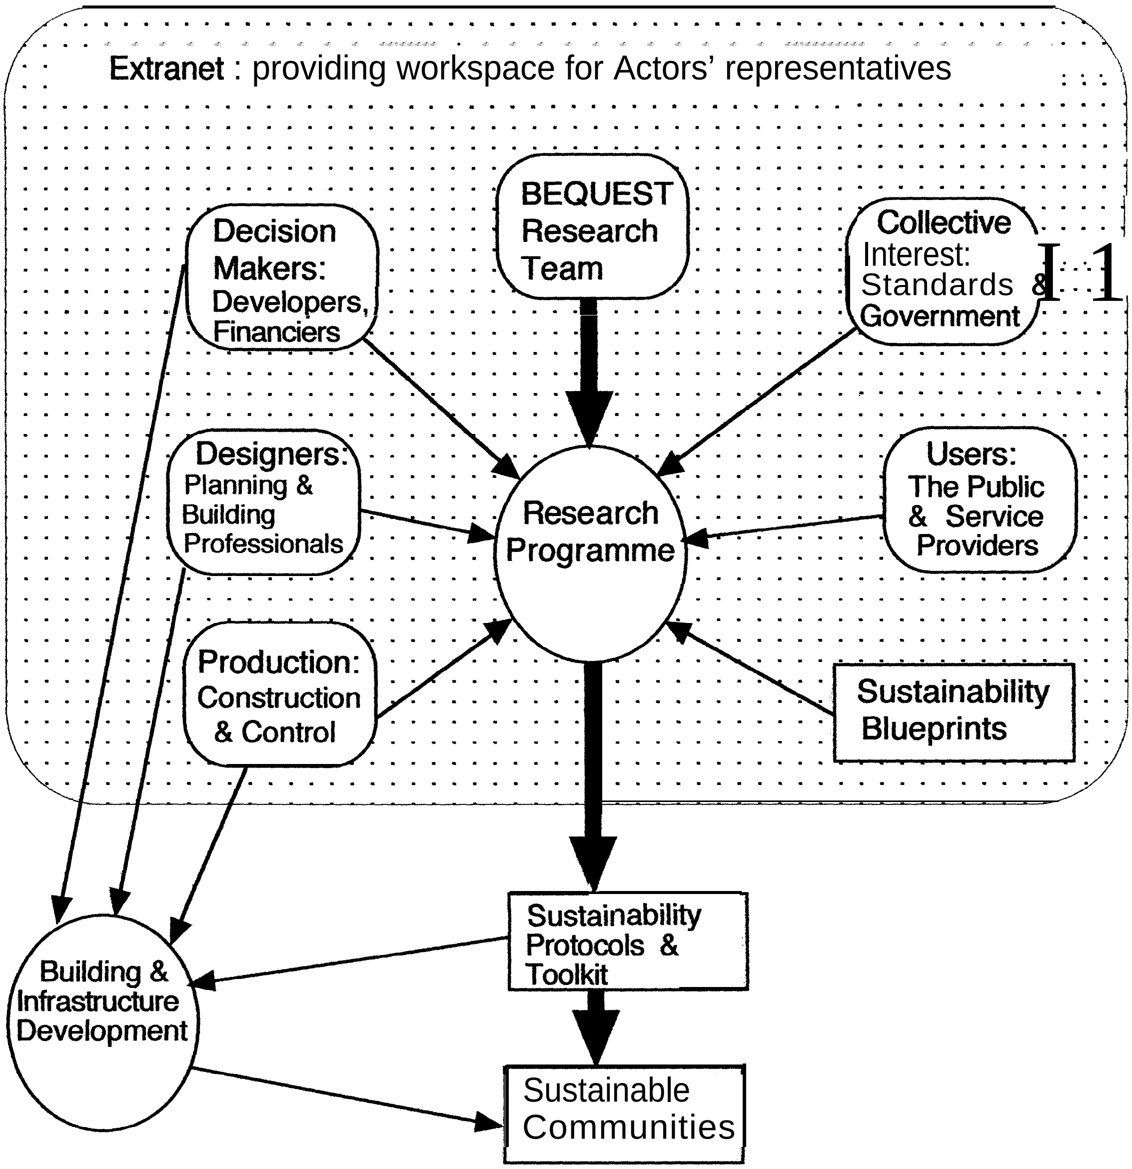

Figure 1 Context of the research showing influences and primary outcomes

At the building scale regulations in the majority of Northern European Countries are aimed at ensuring good standards of energy efficiency in new buildings. Increasing numbers of new buildings may undergo some form of broader environmental assessment at design stage, e.g. BREEAM [12] and BEPAC [13]. Other systems are under development in a number of countries, e.g. Sweden and Germany, and internationally through the Green Building Challenge [14]. However, as with Agenda 21, these systems or methods are not regulatory-requirements and so standards and application is very variable across building types and across different nations.

Many of these environmental assessment techniques were conceived with a view to reducing the environmental impact of building and urban development, rather than pursuing the broader goal of sustainable cities. At present each of these areas of assessment have developed and continue to operate discretely and as such it is far from clear that individual actions are actually contributing to real improvements in the sustainability of towns and cities. How then should the professionals within the construction and development industry recognise and respond to these features and criteria? What has emerged is a very clear need for greater dialogue between all societal actors at each level of the building-city spectrum, together with better sustainable development assessment "tools", in order to converge towards a more common understanding of what constitutes a good quality, sustainable urban environment. This is the reason for existence of the BEQUEST Network and its primary objective is to develop a taxonomy or "road map" through this difficult territory.

3 Research method

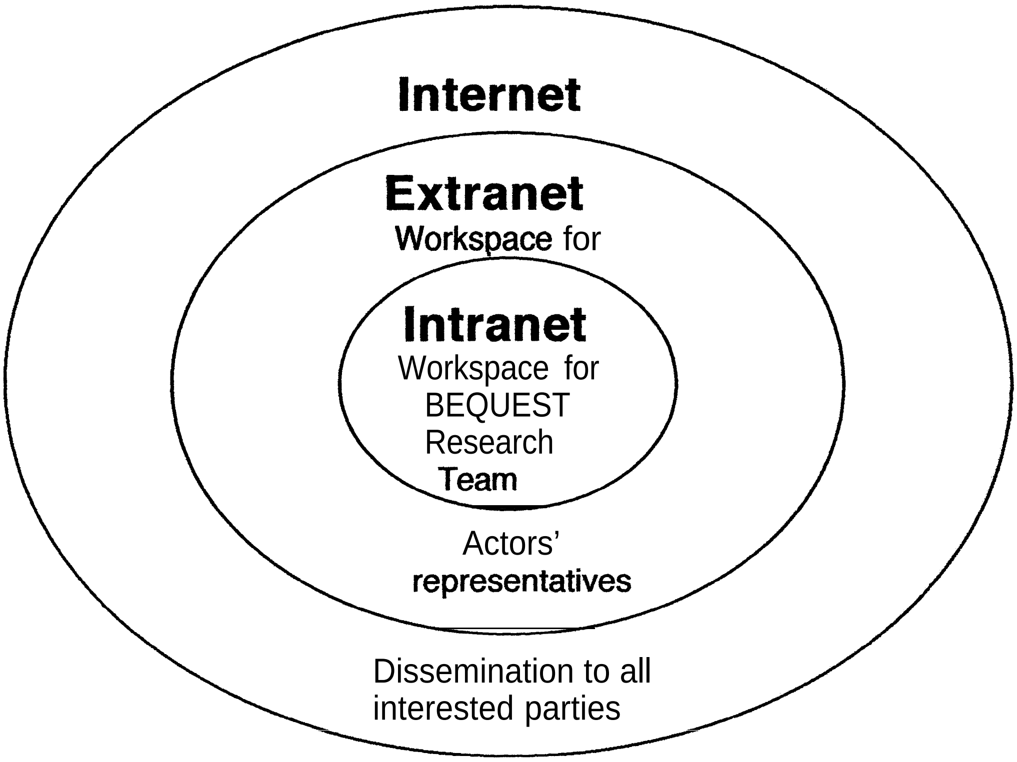
In EU parlance the BEQUEST project is a "Concerted Action", i.e. it attempts to bring together current research thinking and practice. Therefore throughout all three years of the project consultation and negotiation with a wide range of actors from both the demand and supply side of the property and infrastructure sectors across the EU will take place via a consultative network described as the BEQUEST Extranet, see Figure 2. This process will tap the highly diverse knowledge and expertise of a wide range of environmental researchers, professionals, infrastructure providers and managers in order to build a consensus definition - or, where this is not possible, to clearly recognise and understand where the differences lie between member states, levels of action, interest groups and professions. Mature deliberation, debate and evolution are key elements of the whole project and so an iterative learning cycle of workshops and report back to the Extranet members is planned. The members of the consortium, to be known as the Intranet, see Figure 2, will act as mentors and facilitators of this process. Interim findings are to be made available through an electronic news letter.

In the second and third years of the project finished documents will be inter linked, and logical pathways through the documents will be provided by a decision matrix. By the end of the project this will create a decision support tool-kit which will make use of, and be interlinked to, existing Internet sites concerned with all aspects of sustainability and sustainable development.

4 BEQUEST objectives

The members of the network have identified five main objectives which taken together provide a detailed Agenda for all professional actors to consider in the context of sustainable urban development:

* development of a common language & understanding of sustainability between all the parties engaged in the built environment.
* better understanding and the development of more appropriate environmental quality assessment methodologies for sustainability
* development of a common integrated framework for assessment
* identification of environmental quality standards and the dissemination of best practice.
* to implement these ideas in order to catalyse change.



Intranet. In the initial stages of the project an intranet will be set up to facilitate immediate communication between members of the research team. The intranet will be a discussion forum and will also hold documents in the process of production; it will thus be a means of collaborative working. Access will be limited to researchers, who will be able to air embryonic or partially formed ideas within a closed community.'

Extranet. The extranet will be a forum for Actors' representatives. They will also use the extranet to test the products of research in conjunction with the BEQUEST research team.

Internet. When the tool kit is fully developed and tested it will be published on the Internet.

Figure 2. Communications and workspaces

5. Assessment methods and models

An essential paradox of a sustainable society is the conflicting requirements of sustaining the local and global environment whilst at the same time providing for the flows of production and consumption needed to maintain a good quality of life for humankind and, simultaneously, taking account of issues such as social equity and bio-diversity. The project is examining a number of blueprints and concepts that have emerged which attempt to answer all or some part of this challenging agenda, such as "Natural Step", the "Service Economy", PICABUE, "Ecological Footprints" and Natural Capital.

In the pursuit of sustainable urban development, what tools and models do we need and how will we use them? In order to completely represent the complex interactions that represent the city are we faced with a problem akin to "modelling the universe" ? How can we, at the same time, remain modest? A wide range of environmental quality and performance assessment methods are available, such as EIA, BREEAM, BEPAC, Eco-Points, Multi-Criteria Analysis, etc. New techniques are emerging from current EU programmes such as SPARTACUS, ULYSSES, SUSTEE, etc. Can these techniques be integrated into an effective multi-modal framework that addresses all aspects of sustainability and how is this to be achieved?

We have defined the essential characteristics of this framework as developed from the working of CIB TG8 [15]:

* object orientated, i.e., capable of describing the city and its sub-elements
* functional, i.e., capable of assisting decision makers to make trade-offs
* transparent, i.e., capable of identifying data buried in an aggregated score (poor aggregation destroys information)
* value sensitive, i.e., capable of expressing values from a range of individual perspectives.
* integrative, i.e., capable of assisting professional co-ordination

To be able to handle complexity we need to identify, from the long list of parameters that can and should be considered in an assessment, those which are the primary effects. As identified earlier, the degree of difficulty of meeting different assessment requirements could be reduced or eliminated by transforming or amalgamating some parameters into fewer, more general indicators. Conventionally the main candidates for this are money and energy. Identification of reliable indicators is a problem in itself - there is a risk of false or incorrect understanding, like measuring the speed of the car by the tachometer. A process of gradual research and evolution will be necessary in order to increase our confidence in the selected indicators and provide better understanding of which indicators we can safely use in which circumstances and in which locations a process that will take longer than the lifetime of the BEQUEST project.

Central to the identification of indicators is the issue of the sphere of investigation - the spatial dimension. Different factors in assessment - energy flows, commuting travel distances, pollution, food production, building raw materials etc. - each have a separate area of influence with its own boundary, that can be traced from a particular community. In the affluent countries food is clearly sourced world wide. It &increasingly obvious that building materials are also glob& commodities, and this is becoming- common between both the affluent and less affluent countries. The selected domain has major implications. The problems of international agreement over these issues is a major stumbling block to the development of life cycle analysis tools for buildings and construction products. We need these agreements if we are to have effective cooperation from manufacturers, who argue that there must be a standard system - a level playing field so that, for example, manufacturing does not move to locations where there are lower pollution control requirements.

6 Facilitating change

A city is a living entity. The environmental impact is the sum of that resulting from all the individual actions of the population. Thus, to continue the motoring analogy, trying to facilitate change is akin to tying to mend the car whilst driving along. We have to carry all the citizens with us - they must wish to change their behaviour and aspirations if we are to have any hope of moving towards sustainable patterns of living and working. Thus it is crucial to developing effective means of public participation. The key issues are:

* How are unexpressed interests of stakeholders taken into account?
* How is access to information provided to all stakeholders?
* Are they able to participate, do they have the appropriate language and understanding?

Answers to these questions are vital if we are to empower individuals to change there own lifestyle.

In market economies, participative mechanisms are unlikely to create change unaided due to the strong influence of capital in directing and determining the nature of much urban development. BEQUEST's aim is to establish methods and procedures which individuals and groups (see Figure 1) can readily appreciate and use, both in terms of environmental quality assessment and in terms of participative procurement systems. The project is designed to involve a significant number of the “doers and shakers” and to use their comments and views to develop really workable environmental assessment and procurement tools.

7 Conclusions

The membership of BEQUEST represents a significant cross section of the professional actors involved in the urban development process and so the spread of views and lack of consensus on what constitutes sustainability is very worrying in terms of developing concerted, coherent action towards Sustainable Urban Development, SUD, in practice. Clearly this requires all actors to begin to address the broader problem, to "think about things they have not seen as part of the problem". Essentially designers and developers need to accept the need for wider participation in development decision making. Financiers and developers and their design teams should seek much greater resource efficiency in all aspects of building and infrastructure procurement. Policy-makers need to recognise the broad principles involved and begin to provide a clearer lead, a clearer vision of what SUD is and the types of life style that r-night accompany it. They also need to provide a better regulatory and fiscal background that will clearly facilitate appropriate change. All need techniques which will adequately value the quality of the built environment as well as the social, resource and natural capital contained in our existing communities.

A key conclusion to be drawn from the work of the BEQUEST Network to date is that in the pursuit of greater sustainability in buildings and cities, simple technical and economic analyses will prove to be inadequate, without better multi-modal assessment techniques and more thorough social and political integration. Thus society as a whole has to seek answers to the following questions:

* What can and should we be aiming-for in SUD?
* What targets should we set ourselves and which are the right sustainability indicators in any individual situation?
* What are the best environmental assessment methods to use where, to identify indicators and measure progress?
* How can these indicators and methods be integrated to reduce uncertainty in decision making?
* How can the results of a more integrated analysis be made more meaningful to all actors so that they can more clearly understand the options and thus effectively participate in the development process?

Answers to all of these questions are necessary for us, i.e. both BEQUEST and society in general, to begin to have a common language so that we can recognise whether affluent countries are really moving towards more sustainable patterns of living and working, rather than just thinking (or wishing) that they were there!

Acknowledgements
The authors thank the membership of the BEQUEST Network for their contributions to this paper.

Sustainable development in construction

T.E. Uher and W. Lawson
Faculty of the Built Environment, UNSW, Sydney, Australia

Abstract
A review of concepts of sustainable development and its assessment are given in this paper and some critical comments made. Considering the magnitude of the impact of the construction industry on the environment, a considerable improvement in efficiency and effectiveness of the construction process is necessary to help to restore the ecological balance. Further development of life cycle assessment techniques and social and economic aspects of sustainability will play an increasingly important role.
Keywords: Sustainability, sustainable construction, sustainability criteria, indicators.

1 Introduction

This paper attempts to review current thoughts on sustainable construction particularly with regard to the main elements of sustainable construction and sustainability criteria and indicators. It will also review environmental assessment methods currently in use and attempt to develop an agenda for future research in sustainable construction.

There is growing evidence that the earth's ability to sustain life as it has been known for thousands of years has been seriously eroded, particularly since the Industrial Revolution, and if unchecked, will result in an irreversible degradation of the planet, its ecosystems, resources and ultimately quality of life of its inhabitants in the not so distant future. Modern forms of human existence, associated with rapid economic development, have contributed to an over-exploitation of renewable natural resources such as land and forests, and the exhaustion of non-renewable resources such as minerals and fossil fuels. The generation of CO_2 emissions well in excess of the natural carbon storage capacity, ozone layer depletion, the contamination of air, water and land through pollutants and the weakening of the whole ecosystem are also apparent. Depending on regional and often political issues, the importance of such phenomena may not always be recognised. Often insufficient or inconclusive data is available on environmental problems.

While most countries have in the past 10 years committed themselves to work actively towards improving the environment, the challenge in the future will be to mobilise every individual and every business to embrace change through a range of activities. These may be as simple as recycling household wastes and products, energy and water conservation, rejection of disposable in preference to recycled products, and the demand for reduced packaging of products. At the regional and national level, more wide ranging changes may be expected such as lower emissions, use of renewable sources of energy, better land management and the reduction of population growth.

The research methodology adopted for this study is based on literature review only. An extensive search was carried out and relevant journal articles, conference papers and books summarised. Because of the restriction on the length of this paper, no literature review section is included.

2 Sustainable construction

2.1 Definitions

According to DuBose et al [1], "***sustainability offers a way of interacting with our world which reconciles the ubiquitous human desire for a high quality of life with the realities of our global context. It calls for unique solutions for improving our welfare that do not come at the cost of degrading the environment or impinging on the well-being of other people*".**

Sustainable development or ecologically sustainable development was defined by WCED [2] as development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

The term 'development' includes activities across different industry sectors. As the impact of the construction industry on the environment rates as one of the highest among all the industries, a close scrutiny of the construction industry is necessary to minimise its impact on the environment, hence the emergence of the term 'sustainable construction'. A clear definition of 'sustainable construction' as a subset of sustainable development will serve as a starting point for any such scrutiny. In the context of this discussion, the word 'construction' implies a process which starts well before the actual on-site building activity commences and extends to post site-building activities such as commissioning and asset management. In fact, it covers an entire project development life cycle.

The term sustainable construction was originally proposed to describe the responsibility of the construction industry in attaining sustainability, see Hill and Bowen [3]. They have singled out four attributes of sustainability – social, economic, biophysical and technical – to advance understanding of the concept of sustainable construction. Kibert [4] sees sustainable construction as creating a healthy built environment using resource-efficient, ecologically based principles. According to Lawson [5] and Wyatt [6], sustainable construction includes 'cradle to grave' appraisal, which includes managing the serviceability of a building during its lifetime and eventual deconstruction and recycling of resources to reduce the waste stream usually associated with demolition. Bourdeau et al [7] defined sustainable construction as the creation and responsible maintenance of a healthy built environment based on resource efficient and ecological principles.

2.2 Impact of construction on environment

Construction industry is commonly one of the largest industries in both developing and developed countries in terms of investment, employment and contribution to GDP. Consequently, the impact of the construction industry on the environment is expected to be considerable particularly as far as the loss of soil and agricultural land, the loss of forests and wildlands, air pollution, and the loss of non-renewable energy sources and minerals are concerned [8].

According to Levin [9] buildings' contribution to total environmental burden ranges between 12-42% of the eight major environmental stressor categories: use of raw materials (30%), energy (42%), water (25%) and land (12%), and pollution emission such as atmospheric emissions (40%), water effluents (20%), solid waste (25%) and other releases (13%). Buildings and building construction services account up to 66% of total UK energy consumption [10]. A similar level of energy consumption in the USA (54%) was quoted by Bonini and Hanna [11]. They further reported that the US residential sector is the highest consuming sector. Cooper and Curwell [12] estimated that in the UK the construction industry uses about 6 tonnes of building materials annually for every member of the population.

The above figures clearly support the notion that the construction industry imposes considerable loading on the environment and impacts severely on practically every environmental issue affecting sustainability. The challenge for the construction industry is to re-engineer its entire process in order to significantly reduce its impact on the environment.

2.3 The key principles of sustainable construction

The above definitions of sustainable construction are all framed towards creating a healthy built environment through resource efficient and ecologically sound processes, preservation of ecosystems and maintenance of natural balance between development and carrying capacity of this planet. The key principles upon which the above definitions have been phrased can be summarised into the main principles of sustainable construction. A range of models detailing principles of sustainable construction will now be briefly reviewed.

Hill and Bowen [3] aggregated the principles of sustainable construction into four pillars – social, economic, biophysical, and technical. These are supplemented with a set of over-arching, process-oriented principles. ***"These process-oriented principles suggest approaches to be followed in deciding the emphasis to be given to each of the four pillars os sustainability, and each associated principle, in a particular situation".***

Palmer et al [13] classified the principles underlying sustainable development as futurity, environment, public participation and equity. These were adopted as the principles of sustainable urban development by BEQUEST [12]. More definitions of principles of sustainability can be found in DuBose and Pearce [1], Graham [14], Wolley [15].

3 Sustainability criteria and indicators in construction

Performance criteria and indicators in sustainable construction are needed to assess the performance of a building/facility and measure its impact on the environment. They need to be comprehensive to address specific environmental issues/problems. These are commonly identified as population growth, availability and use of natural resources such as land, water and forests, depletion of non-renewable resources such as mineral reserves and fossil fuels, urbanisation, pollution, geopolitical problems, habitat destruction/deterioration (biodiversity loss), global warming, stratospheric ozone depletion, soil erosion, acid deposition, wastes, indoor environment.

A considerable effort will be required to translate the requirements for sustainable construction into specific, technical performance criteria for buildings, components, systems and materials. Cole and Larsson [16] defined performance criteria as the basic building blocks which formulate the specific characteristics of the building/facility that will be assessed. Performance indicators are then specific units of measurement that will be used to describe the performance criteria in both quantitative non-quantitative forms. They are parameters of values that provide information about a phenomenon. They gauge progress towards sustainability in a simplified and readily understandable way. However, they need to encompass the relevant environmental impact and other sustainability aspects, be verifiable and measurable, be mutually independent of each other, and be comparable to a reference level [17].

A hierarchy of performance criteria and indicators for specific environmental issues/problems in a matrix format is possible to develop, see DuBose and Pearce [1], Levin [9], Beetstra [17], Chatagnon and Nibel [18], Guy and Kibert [19].

4 A brief review of environmental assessment methods

The first generation of environmental development controls in Australia was known as an environmental impact statement of a new development. It was to show the impact of the proposed development over its lifecycle on the surrounding environment and how the development satisfied the local urban planning requirements. These controls were regional in nature and focused on issues such as traffic flow, noise, size and height of the development, pollution, landscape, rogue reflection, disposal of surface water, etc. Without any performance benchmarks, environmental impact statements were judged subjectively within the context of prevailing social, economic and political climate.

In the last decade or so, a wide range of environmental classification or building rating systems based on life cycle assessment (LCA) emerged in response to commitments to sustainable development by a number of developed countries. Among the best known systems are BREEAM (UK), BRE Office Tool Kit (UK), Home Energy Rating (UK), BREDEM (UK), Waster/Environmental Data Sheet (Europe), European Eco-labelling (Europe), SIB (Switzerland), BauBioDataBank (Germany), Ecocerto (Italy), EcoLab (Netherlands), BMES Index (Australia), Athena (Canada), BEPAC (Canada), LEED (US). A brief review of the above systems can be found in Cole and Larsson [16] and Wolley [15]. Beetstra [17] and Gay et al [20] criticised LCA, claiming that many environmental aspects have been left out and that LCA method is not capable of weighing different sustainable criteria and assess trade-offs among various environmental objectives. The method is said to be too complex when all building materials and components are considered and thus unusable unless various criteria and indicators are aggregated.

A growing need for a more rigorous and systematic assessment of projects has provided an impetus for the development of many new assessment methods. A brief review of some such new methods under development will now be given.

Beetstra [17] reports on the development of BEDS - Building-related Environmental Decision Support, a new integral assessment method in Netherlands. The method composed of a limited set of objectives, and quantitative and verifiable indicators, can be used in all phases of a project development cycle. In total eight indicators are used, three of which are site oriented (use up of space; accessibility; green balance), three are building-oriented (water balance; energy balance, HBF influences), and two are aimed at building elements (material use, reuse). Indicators will measure outcomes in numerical values between 0-100% with 100% being the maximum yet technically realised level.

Levin [9] outlines the development of SEABEP - Systematic Evaluation and Assessment of Building Environmental Performance model. "*SEABEP addresses* the *need for comprehensive performance evaluation and assessment based on life cycle assessment, comparative risk assessment, and industrial ecology*". It assesses the contribution of buildings to the total environmental burden, weighs various environmental problems on a global scale and on a local or project scale and establishes targets based on defined sustainability criteria.

Chatagnon and Nibel [18] describe a methodology for the development of a model in the form of a matrix for environmental assessment in the design phase of a project. It targets continuous assessment of the environmental quality of a project at different design stages. The evaluation model calculates the environmental effects due to the sources, and expresses them according to assessment criteria. The proposed procedure is iterative and allows each project to be assessed from the environmental quality point of view.

A different approach to assessing sustainability of projects is described by Gay et at [20]. This approach attempts to develop a sustainability index appropriate for assessment of buildings. The index is determined by *"expressing environmental impacts of a building in terms of external costs which represent either measurable or calculable costs of direct impacts such as health injuries, death of the forest, etc., or the costs of preventing these"*. The fact that the final result can be expressed as a monetary sum is being seen as an advantage. When added to the conventional construction cost, an easy comparison between different alternatives will be possible.

DuBose and Pearce [1] advocate the use of The Natural Step (TNS) method for environmental assessment of buildings that was developed by Robert [21]. The proposed methodology consists of interpreting specific TNS system conditions and finding building-specific indicators for each of the system conditions. The authors concede that while comprehensive, this approach is rather complex.

Cole and Larsson [16] present an overview of GBC 98 – 'The Green Building Challenge' project, which is being developed in Canada. The aim is to develop an environmental assessment system and establish internationally comparable benchmarks for building performance. The system will measure Basic Performance such as functionality, maintainability and economic performance, Green Performance such as energy use, land use, materials use, airborne emissions, etc., and Process Performance to evaluate whether certain protocols have been specified. The proposed system will be able to address global and regional issues, and will also make it possible to measure both potential and actual performance.

5 Future research agenda

It may be useful to consider this in two overlapping parts based on the type of building technology to which it relates.

Conventional building technology, based on bulky, common, cheap materials has led to initiatives in waste reduction, recycling, regulatory control and conventional life cycle assessment based on a building life of 50 to 100 years. Sustainability is largely seen as a question of balance between what can be extracted with minimal environmental impact and demand. It is assumed that these can be readily agreed and quantified and the relevant sums done. Design for deconstruction (DFD) to facilitate recycling [22] is based on reducing the quantity of virgin raw materials needed to be extracted and used or in reducing the need for landfill disposal.

New building technology, based on the use of fewer materials in a more sophisticated or 'clever' manner (Less is More) points in a somewhat different direction. Assessment of sustainability may focus on what is covered in assessment schemes rather than attempting to standardise and agree a fixed methodology. Life cycle assessment may be based on a much wider range of building lifetimes, from very short (accompanied by total recycling/reuse/renewability) to very long (where environmental impacts are 'written off' over the long life of the building). The focus of attention may shift to relatively small quantities of key resources or materials which play an important role in modem sustainable building. These might include the alloying agents in steel rather than iron ore and limestone, rare metals such as titanium and indium which may come from very environmentally sensitive areas (eg. beach sands) or because they are rare, generate an inordinate amount of waste in their production. These rare elements may play a critical role in the development of ecologically sustainable building and DFD will be based on the recovery of small quantities of critically important materials. They may become politically strategic further complicating issues of equity.

The issues of equity in the social and socio-economic aspects of sustainability, both within and between countries, will become more critical as populations continue to increase and demand higher material standards of living.

6 Conclusions

The ability of this planet to maintain an environmental equilibrium has been disturbed, perhaps irreversibly. Population expansion and the corresponding increase in consumption on one hand and the reduction in the carbon storage capacity through deforestation on the other pose the most critical threat. The construction industry is the major contributor to the environmental loading on the earth and needs to respond to by substantially improving efficiency and effectiveness of in its entire production process. However, with an inevitable increase in population and demand for buildings and infrastructure services, even a dramatic improvement in environmental management of the construction industry is unlikely to offset an overall rise in the environmental loading caused by the increased level of building activity. If the scientists are correct in warning that the carrying capacity of the earth has already been disturbed, then the major challenge will be to minimise the rate of consumption increase and match it with a corresponding improvement in environmental efficiency and effectiveness associated with human activities.

How this is achieved will differ according to circumstances. The development of life cycle assessment techniques and their role in the assessment of sustainable construction will continue to be crucial. As building technologies develop further the key elements of sustainability may change and researchers need to be aware of such developments.

Social and economic aspects of sustainability need to be further developed.

SUSTAINABILITY IN MANAGEMENT AND ORGANISATION: THE KEY ISSUES?

P. S. Brandon
Pro-Vice-Chancellor, Research and Graduate College, University of Salford, UK

Abstract

This paper provides an introduction to some of the key issues relating to the context of sustainability. It argue's for a more holistic approach to sustainability built around a consensus of an agreed definition and a philosophical framework to allow a meaningful discussion to take place, leading to improved decision making. It recognises that at this emerging stage of the topic, even these matters are research issues and that in parallel with this debate it is important that progress at the sub-problem level must continue. The paper points out the issues as a means of providing context for many of the papers in these proceedings.

Keywords: evaluation methods, framework, management, philosophy, research, sustainability.

Introduction

The purpose of this short paper is to provide a context to the research issues relating to sustainability from the perspective of management and organisation. This is a difficult issue to address. By its nature 'management' is engaged with intervention and yet it is often the intervention of human management and organisation in the past, which has led to an environment which many believe is unsustainable. This paradox can be explained, it is often said, by the absence of the 'right' criteria to take the long term view, the absence of knowledge concerning the manner in which man-made products and human settlements behave, and the prioritization of economic performance above all else. No doubt this is true, but even today the remnants of the debate between those who wish to conserve all the earth's natural resources at all costs, and those who believe a technological 'fix' can be developed, still rages on. Within these polarised stances is a whole spectrum of view which attempts to find a middle way responding to new crises, new knowledge and new developments in an ad-hoc manner. The advocates of this more pragmatic approach attempt to feel their way through this uncertain and opaque world by dealing with the issues as they arise. Nevertheless the short-comings of such an approach are evident as the response to one problem often exacerbates another. For this reason there has been a call, which has grown in momentum over the past decade, for a more holistic approach, engaging all aspects of the various systems which impact on the environment and endeavouring to assess the interaction between them. Out of this view has grown the concept of sustainability.

This concept is still poorly defined, but it seems to contain certain features which make it distinct. It is about endurance rather than conservation, although conservation, particularly of non-renewable resources, plays a large part. It is holistic and attempts to avoid the trap of reductionist approaches, but has yet to establish a framework within which there is a shared vision to which all can contribute. It implies both self-control and discipline within society which may well require sacrifice now in order to allow future generations not to be disadvantaged. It also recognises change as an essential ingredient of universal systems, including evolution within the bio-sphere and the impact of knowledge in human development, but suggests that a measure of intervention can be beneficial. These features will be seen to be embracing of some of the most complex issues known to man and it would be unwise to move down the path of setting specific goals with high expectations. It is likely to be an exploration, a journey, a revealing, rather than a conclusion which we can expect as we progress.

Within this overview of sustainability as a concept the built environment represents a subset. It is however a significant player in its own right, and also has a significant impact on the world in general. Looking in, it engages the most basic needs of man in terms of accommodation, comfort and social organisation. Looking out, it impacts on the quality of the natural environment, the quantity of non-renewable resources and the services needed to support human gatherings in any form. At its most prevalent, within the urban context, it permeates the whole fabric of human existence and extends into the eco-systems upon which all living species depend. No consideration of sustainability can avoid consideration of the structures human beings have developed to accommodate themselves.

Within the context of this symposium 'management and organisation' applied to sustainability has a major, difficult and maybe impossible task. If the aim of management is 'to bring about or contrive' or 'to direct or conduct the affairs' of something (as suggested by Websters Comprehensive Dictionary) then the discipline has a problem. At this moment it is not clear exactly what it is to 'bring about' and in most cases it does not have the authority 'to direct or conduct the affairs' of all the factors which would lead to a sustainable built environment. For obvious reasons the complexity of a built development means that the management task is divided. Those that exercise control encompass individuals, governments, local authorities, regulatory bodies, companies, suppliers and so forth, and these relate to public perceptions, media, global agendas and many more beside. What is it realistic to expect within this subject domain? Even within the more limited field of the environment this matter has been identified. Wolfgang Sachs (1993) wrote this:-

"Once, environmentalists called for new public virtues, now they call rather for better managerial strategies. Once, they advocated more democracy and local self-reliance, now they tend to support the global empowerment of governments, corporations and science. Once, they strove for cultural diversity, now they see little choice, but to push for a worldwide rationalisation of life-styles. Indeed, as ecological issues have moved to the top of the agenda of international politics, environmentalism appears in many cases to have lost the spirit of contention,, limiting itself to the provision of survival strategies for the powers that be. As a result, in recent years a discourse on global ecology has developed that is largely devoid of any consideration of power relations, cultural authenticity and moral choice, instead it rather promotes the aspirations of a rising eco-cracy to manage nature and regulate people worldwide. Ironically, a movement which once invited people to humility has produced experts who succumb to the temptations of hubris".

There is a default to 'regulation' to manage the complexity and a view that 'the expert knows best'. It is no wonder therefore that those of us attending this symposium relating to sustainability of the built environment proceed with some caution into the contribution that management and organisation can make to creating sustainable environments. Within the global picture what intervention can we make that aids rather than hinders this goal? If we are to manage in a sustainable way then there are many aspects upon which we must be clear. These can be summarised as follows:-

- A clear definition and understanding of what we mean by sustainability must be sought
- A philosophy which can lead to an understanding of the relationships between the different complex factors contributing to sustainability must be shared in a public consensus. This aspect cannot be exclusive to the construction industry and its clients alone.
- A robust classification system which structures the problem must be established in such a way that the complex inter-relationships can be modelled must to aid communication, understanding and the growth of knowledge
- A set of measures which allows progress to be calibrated and which is related to the aspects above must also be developed. Otherwise how do we know what progress has been achieved?
- A management framework must be developed which allows for planning, design, construction, monitoring and feedback on sustainability as an integral part of the development and occupation cycle. Without this framework the sustainability agenda is sterile and inoperable
- A protocol for decision making must be established within the above framework which challenges those involved in the decision process to respond to sustainability in a positive way. It must engage, where appropriate, the regulatory bodies and the

judiciary to enforce the public consensus

Definition

If there is one subject which still attracts debate, then it is the question of 'How do you define sustainability?'. This is surprising since the term is in common parlance and literally thousands of people across the world are studying it as a subject. Nevertheless what is included or excluded creates tension and vigorous discussion. David Pearce in 'Blue Print for a Green Economy' (Pearce D.W. et al) provides several definitions for 'sustainable development' and others have done the same. Perhaps the most widely accepted definition is that of Brundtland (WCED 1987).

.... '*sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs*'.

The problem with this definition is that 'needs' is left undefined - does it extend beyond survival and is so, by how much?

The Brundtland Report (WCED 1987) went further in trying to establish meaning

'*In essence, sustainable development is a process of change in which exploitation of resources, the direction of investments, the orientation of technological development, and institutional change are all in harmony and enhance current and future potential to meet human needs and aspiration*'.

Again the question of 'needs' arises, but also the question of 'harmony'. From whose perspective is 'need' and 'harmony' to be judged. These are not trivial questions and inevitably they lead to prolonged debate.

In an interesting paper Beckerman (1994) queried whether 'sustainable development' was a useful concept. He asks whether it is a technical condition or a moral injunction. He states that

"*The result of the fusion of technical characteristics with moral injunctions is that the distinction between positive proposition about the threat to the continuation of any development path and normative propositions concerning the optimality of any particular pattern of development is hopelessly blurred. Instead, a sustainable development path should be defined simply as one that can be sustained over some specified time period, and whether or not 'ought' to be followed is another matter. It should be treated, in other words, as a purely technical concept - not that this necessarily makes it easy to define operationally*".

This splitting of the two issues is interesting but it must surely be recognised that the moral imperative has been a major driving force behind the consideration of sustainability. Without it the discipline required in behaviour now, in order to address the needs of future generations, may be difficult to achieve. In addition it is far too restricting to just consider the 'technical characteristics' as it is often the political, social and economic domains which dominate whether something is sustainable or not. These factors are often driven by considerations arising from moral judgements. A simple technical 'fix' will not necessarily result in a more sustainable built environment. A much richer definition is required which encompasses all the factors and helps decision makers determine what 'needs' and 'harmony' mean from current and future perspectives. It may be that the 'Brundtland' definition can remain the objective and we further define it in terms of a philosophy and a framework.

Philosophy and Classification

The problem with sustainability (as opposed to some aspects of conservation for example) is that it engages the whole of human existence and the complexity of inter-relationships which make up this universe. 'No man is an island' can also be applied to every facet of nature and the systems we have created to tame and control it. The inter-relationship between systems, and between people and systems, means that the impacts are far reaching and their complexity suggests it is difficult to predict. Who knows whether the butterfly flapping its wings in Malaysia will eventually impact on weather patterns in the USA? The change in weather pattern may then impact on human behaviour and their life styles and hence create a new set of patterns eventually impacting on the life of the butterfly. This is of course an exaggeration, but the point remains that the myriads of combinations of 'happenings' result in change which it is difficult to predict.

How we view this world affects the manner in which we prioritise our behaviour and the way in which we make decisions. A philosophy which places human beings at the top of the agenda would be different to one which is not species specific. It is impossible to avoid facing this question if we are to take a holistic view. It is also one that has been a major debate among human beings for centuries, dividing East and West through religion and behaviour. Managers almost by definition are making decisions which are based on a set of assumptions about the world and the particular culture in which they live. It would be practically impossible to get all human beings to sign up to a common view even if it could be expressed. So what can be achieved? We could set out a framework which at least makes the assumptions upon which we act explicit. This framework would not be a discrete set of classes but would allow continuity, systems, classification, calibration and networking within a nested arrangement expressing a holistic view of the world to be captured.

This is an ambiguous target and the author has been working with Lombardi (1997) to at least find a starting point for such a holistic approach. For the moment we have settled on the work of the Dutch philosopher Dooyeweerd and his 'Philosophy of the Cosmos' as an attractive way forward. The main contribution of Dooyeweerd is that his theory is explicitly trans-disciplinary, yet provides integration between disciplines and systems; it considers different levels of information, nesting all aspects of reality in an ordered manner, yet provides structure and continuity; and it recognises the importance of multi-person action across different time scales albeit with a specifically western (and Christian) view. Consisting of fifteen modalities spanning the numerical to the credal it attempts to explain the world and its activities in an ordered and structured way. The paper by Lombardi in these proceedings outlines some of the key issues.

Without such a structure it is extremely difficult to approach sustainability in an ordered and systematic way. It would also be difficult to handle the complexity of different systems and place them in context or enable a dialogue with a common vocabulary to be established for all the many participants engaged in decision making related to sustainability. It would be dangerous to promote a single view or perspective of a problem which is so complex. Nevertheless some rationale is required. As we move to a better understanding, no doubt several philosophical frameworks will emerge. Philosophical approaches are sometimes seen as ethereal, but in fact their importance cannot be over-emphasized when seeking solutions within complex value-laden domains such as the built environment. The language which leads to classification and structure of such theories help to untangle the complexity and enable a sharing of the concepts.

Measures

If a structure based on a consensus around a philosophical framework can be developed then the calibration of the criteria found within the structure is the next step. Without some form of measure or assessment progress cannot be charted. Once again it is the complexity which creates many of the problems. How do we cope with the balancing of all the different factors which lead to the 'harmony' which in turn contributes to a sustainable built environment. Techniques, such as Cost-Benefit Analysis, which attempt to reduce all assessments to a common measure, eg. money, are inadequate in such a problem domain. Even techniques such as multi-criteria analysis, where ranking of criteria can be an output, only provide a step towards structuring the problem. Bentivegna (1997) in an excellent critique of environmental evaluation methods concludes by saying:-

"..... evaluation cannot be but a tool for argument within the comprehensive collective decision process relating to the environment because its conceptual framework is controversial, its methods are valid only within a narrow validity field, and its outcomes represent only a share of the interests in the game. Therefore the task is limited to clarifying ideas and allowing a better comparison among alternatives than ordinay language can do, so enriching the debate'!

It is important to realise that evaluation of any sort represents a particular view (which may or may not shared by many people) even when the evaluation is numerical. Collecting together many different evaluations brings together many viewpoints and the tools to integrate them into a single composite expression or, worse still, numerical measure are simply not available. It is unlikely that any one of the contributing perspectives could sign up to the composite in any meaningful way. Not only would the values and priorities be different between contributors, but they may well be in a conflict eg. economic activity may be essential to sustain the community which requires a built environment but this activity may also be in conflict with the need to protect non-renewable resources.

Nevertheless the viewpoints are expressed and articulated (however inadequately) and this in itself is a useful starting point from which improvement can be sought. If we can identify the components that contribute to sustainability then over time, we can seek appropriate measures. For the moment a 'profile' of performance, as far as we understand it with our current knowledge, is probably the best we can hope for. The various Environmental Impact Analyses for buildings tend to be of this sort and perhaps 'sustainabilty' requires a similar framework.

The role of evaluation changes therefore, from the difficult task of giving an improbable objective judgement, to one of representing different points of view, useful for reaching a 'good' decision and, importantly, developing a learning process. If we can stand back from the implied assumption that we have complete and full knowledge at any point in time and realise that we are creating a reference point which we can use an a datum to build, monitor and compare, then the concept of sustainability has a chance of remaining a feature of assessment for many years to come. By its very nature the evaluation is usually long term and we know that our knowledge is extremely unstable in terms of human activity. To expect an evaluation or even 'measure' to remain stable would be unrealistic. We must realise that change is inevitable and our systems must accommodate this. This leads us into the need for a management framework and protocol for implementation.

Management and Decision Protocols

It follows from the previous discussion that in order to create a sustainable environment, some level of intervention is required to seek the goals which are defined for a building or an urban environment. Indeed the papers in this symposium address largely these issues. It is most unlikely that leaving matters to the 'market' or 'survival of the fittest' will create the development which will comply with our requirement not to compromise the ability of the future generations to meet their own needs. Engagement of the needs of sustainability with the decision making process of development is therefore vital if it is to form part of the routine assessment of design and construction. Some of the requirements for sustainability will be found in legislation (which will demand a satisfying of certain standards) but not all. To achieve improvement we need a careful and rigorous modelling of process which allows us to identify when and in what form intervention is necessary. However even this can be inadequate, for while it is relatively easy to model activities arising from design in a systematic way, the process of design and creativity, at least in its conceptual stage is often a closed book. Most of the research into design suggests that the architect is wrestling in his mind with complex scenarios at various levels of detail and with several parallel lines of thought (Lawson 1993). The impact visually, spatially and technically (in the choice of services, materials, texture etc) will be significant to the contribution that building or neighbourhood makes to the overall environment and its sustainable characteristics. At the very least the 'intervention' at this stage must be through the education of the designer and his access to knowledge at the appropriate time in his thought process. It must be part of his or her philosophy on design. The closest we have come to such an input was the call in the 1960's to include the 3 L's concept into design decision making ie long life, loose fit, low energy. This concept is now being revisited.

The key to both education and knowledge is the feedback mechanisms and here there is a problem. Sustainability is about the long term and even with a willingness to gather information in occupation it is difficult to capture, analyse and feedback useful data to designers at the present time. To widen the data capture to all the stakeholders contributing to sustainability, is probably impractical. The pay-off is doubtful and the interest of both designers and clients in capturing such information appears to have a relatively short time span. Some partial information on performance could be obtained on the more technical aspects by remote sensing, but it is likely that it is the social/political/economic context which will have the major impact. Any analysis of these matters is almost certainly to be subjective and value laden. It may be that the discipline of facilities management has a major role to play in the future to study, observe, analyse and report on sustainability issues, but these are likely to be insights rather than hard data. They will be retrospective views and subject to the same biases identified in all recorders of history!

Construction management is likely to play a more peripheral role than design when considering sustainability, assuming that good design has been implemented through good quality construction processes. The focus for construction must be on improved quality which makes it natural and/or desirable to sustain a building or group of buildings. This 'quality' will encompass performance, energy, waste, emissions, longevity and all the aspects of current and future 'needs'.

The problems for those engaged in the management of development can therefore be summed up by asking firstly "How do I make a decision on sustainability where we are forecasting far into the future, we have no hard data and our evaluation techniques are inadequate?". One approach is that we need to create a dialogue leading to a consensus between those with expert knowledge and those who benefit from the built environment. This should take place within a framework which we all understand. It is a similar point to that made by Bentivegna (1997) quoted previously.

The next question is "When should this dialogue take place?". Here a consensus around a protocol would be beneficial. Some of the work on process protocols in the production industries could be useful here, Cooper (1998) has endeavoured to define such protocols for construction with the identification of 'soft' and 'hard' gates in proceeding through a development. It may be that sustainability issues should be placed alongside the more conventional development activities for consideration and forced into the agenda at each 'hard' gate. [The point at which the process cannot continue unless there is an agreed consensus or permission eg. planning given for the next stage to proceed]. In some cases compliance with statutory regulations will force the issue, in others it may be the demand of regulatory authority or client.

Finally there is a need for feedback mechanisms which provide useful and meaningful knowledge to both the designer and the owner/tenant of the building or, in the case of a neighbourhood, the local authority. Ideally this should be a continuation of the dialogue of the actors/participants/experts commenced at the planning and design stages.

Conclusion

The concepts expressed in this introduction will be familiar to all those engaged in the decision making process. The differences with regard to sustainability compared with other dimensions of the built environment management problem are primarily

- the even longer term perspective required on what is already a long term asset
- the wider social, political and economic context over this extended time period impinging on the evaluation of sustainability
- the greater number of actors, participants and experts engaged in the dialogue affecting the decision
- the lack of a framework in which that dialogue can take place and the difficulty of managing the discussion to ensure a proper balance between the competing objectives
- the absence of feedback mechanisms which can be relevant to informed decision making
- the weakness of evaluation tools to distil and prioritise criteria for effective decision making

At the 'building' level these issues are difficult to address, but they become far more of a problem within the urban context where the interaction between people, their social environment and their accommodation engages so much of the knowledge we know about the human world.

These proceedings contain papers which, in general, address various parts of the problem. They largely provide a way forward for decision making at the sub-problem level. It is hoped that this introduction has set these issues into the wider context and encouraged a holistic perspective on sustainability both at the individual building level and the urban contact. The subject is still in its embryonic stage and it will be interesting to see how it will emerge and evolve over the years ahead. It is most unlikely that it will disappear, but the degree of commitment with which it is addressed will reveal much about the seriousness with which we address it and the maturity of the research community to derive suitable models for the aid of all of us engaged in the development process.

Abstract
This paper focuses on Design-Build as a procurement strategy and attempts to outline the stimulants and impediments to its adoption as a dominant building procurement mode.

Previous research has identified procurement as a matching function between key actors on the demand side and those on the supply side. The relationships among these actors are subject to changes in the prevailing world view. In outlining the futures of the building process in North America, earlier research by the authors has identified shifts in critical paradigms which hold significant power for the evolution of the building process, in general and of the procurement strategies, in particular. A model previously developed by the authors is further elaborated to depict relationships that arise in the Design-Build mode. The dynamics of these relations are then analyzed using the critical paradigms and appropriate qualitative data. The qualitative data regarding trends in Design-Build is drawn from business, trade, professional and academic literature, as well as from field research.

The ensuing interdependence of the relationships among the actors in the procurement system offers a gauge of the dynamic complexity that underlies the Design-Build mode and affords a view for assessing its potential as a strategy of choice in the future.
Keywords: Building Procurement; Design-Build; System Dynamics; Models; Single-Point Responsibility; Stable Dynamic Networks.

1 Introduction

The construction industry is a powerful engine that contributes a significant force which drives the North American economy. In terms of GDP both in Canada and the United States, construction output is in the range of 13 to 16 %. To appreciate the relative magnitude of this figure, it is worth contrasting it to the output of the automotive industry in the United States which is approximately 3.5%. However, the construction industry and its subset, the building industry, while often used by statisticians and economists as indicators of the state of economy, are not as often the subject of organization and management studies at the enterprise level; rather research attention is focused at the project level or industry segment level. Yet the success or failure of the project often depends largely on the organizational forms of the participating firms, collectively ***and*** individually.

The organizational design of firms in the building industry has been dictated by a multitude of dominant and often contradictory factors. The building industry, characterized by Davidson [1] as a multi-industry, is a mature industry that has been subject to diverse traditions many of which have ultimately found their way to legislation. Thus, for example, architects and engineers are required to be licensed by professional regulatory bodies under the authority of provincial or state government. The general and specialty contractors are required to hold some form of license, insurance bonding: and/or union certification. While these requirements may vary from one jurisdiction to another, some form of control is exercised over the enterprise every where and this control is enforced by a variety of mechanisms including the process of building permits, administered by local authorities: Bidding requirements are another example of legislated tradition in some jurisdictions.

Technological progress and legislated tradition have not kept a pace, and the ensuing time lag has resulted in the creation of many artificial structural constraints and often costly devices to-overcome such constraints. The intense technical reauirements of the project have resulted in 'techno-polarities' that create a narrow focus of concern, resulting in the almost total exclusion of due attention to and appreci ation for business and management issues. In the midst of such apparent organizational disarray, it is understandable that there is a strong desire to embrace methods and techniques that seem to hold promise particularly if they seem to solve problems that are frequently encountered in the present situation. However one should be careful not to introduce new devils in an effort to get rid of the old ones.

The fragmentation of the building industry has given rise to the perception (i) that the building industry is something of an aberration when compared to the manufacturing process and (ii) that this 'anomaly' could perhaps be remedied if somehow the building process could be made to fit the mold of the manufacturing model. However, the building process appears idiosyncratic not so much as a result of anomalies to be eliminated but because of the unique requirements of the product this industry is called upon to supply with the requisite efficiency and competitiveness for the given environment [2]. The complexity of the building process is perhaps unparalleled by most other industrial processes – a situation that the building industry has learnt to cope with, despite the "apparent organizational disarray" we have referred to above.

A major impediment in exploiting the advantage offered by this situation is the inward view espoused by the building industry and the fact that perceptions and opinions it holds of itself may not accurately reflect current environmental demands and opportunities. Understanding the mechanics of the structural coupling of the participants and the strategies they employ, based on the prevailing organizational forms, holds the key to the effective deployment of innovative procurement strategies. However it appears that the developments surrounding Design-Build may be viewed by many as the catalyst for desired change, often to the exclusion of other approaches.

Nevertheless, the trend towards Design-Build does not by itself constitute an indicator of future success and long-term sustainability. Indeed we maintain that Design-Build is not the panacea that it is purported to be, and that the problems inherent in the design-build process far outweigh any advantages that may arise [3]. This perspective will be outlined as we answer the pertinent questions and provide a retrospective view of Design-Build. Broader environmental influences need to be surveyed if one wishes to understand the dynamics of reinforcing forces acting on these trends as well as the balancing forces most likely introduced by other factors.

2 Research Scope

This is the third in a series of articles on 'futures' of the building industry in North America [4, 5]. The previous articles focused on fundamental questions about procurement and the building process to the horizon of 2020. This article addresses specific questions about the future of a particular procurement strategy, Design-Build – again to the horizon of 2020.

The previous works followed accepted 'futures' methodological approaches about potential developments in the next twenty-five year horizon, as applied to the building industry; that approach is followed in this work as well. To summarize, the approach of Tait [6] combined with the application of General Systems Theory yields the holistic approach required for futures study, as discussed by Levy [7] and Senge [8].

3 The Building Industry and its Environment: A Paradigm Review

A model of the building industry and its regulating cycles, as influenced by the environment, was described by Katsanis and Davidson [4]. This model confirmed the view that the building industry is a system within a larger system and that the building industry is therefore subject to the prevailing forces in Society and will be under pressure to change as Society changes. Design-Build is representative of one such cycle occurring in the building industry, and as will be shown, is subject to the changes and regulating cycles of other future trends.

3.1 First Paradigm: Business Process Re-engineering (BPR)

BPR is a process defined by Hammer and Champy [9] as "the fundamental rethinking and radical redesign of business processes to achieve dramatic improvements on critical, contemporary measures of performance, such as cost, quality, service and speed". Its application to the construction industry is considered in a proposed framework for research by Betts and Wood-Harper [10], who argue that the philosophy of BPR is akin to encouraging innovation and establishing learning organizations; it would suit a project-oriented industry, where the scenario described by Hammer and Champy [9] for "virtual teams for specific assignments" fits well with the multi-disciplinary design and construction practices of the building process.

3.2 Second Paradigm: Partnering

In the last few years, partnering has emerged as an alternative way of carrying out projects in the construction industry, in response to concerns about poor quality, low productivity and costly litigation, all of which can be traced (at least in part) to the adversarial relations between the key actors in the building process.

3.3 Third Paradigm: Specialization and Integration

Winch [11], in his examination of construction firms and construction projects, arrives at the conclusion that "in spite of the alleged benefits of hierarchy [i.e., of-integration] there has been little or no shift towards hierarchy with the [...] construction industry". Eccles [12] sees the relations between the quasifirms as a situation where "[all] parties can benefit from the somewhat idiosyncratic investment of learning to work together".

Indications also exist to support the view that current technologies and market attitudes favor extreme specialization and the formation of single-person firms. Bröchner [13] uses industry statistics that point to the growth of market share for such single-person firms. The project-centered nature of the building process is very conducive to this kind of arrangements which have been observed and recognized in other industries; they have been called 'Rolodex'* agencies or firms and they are not uncommon in other industries where specialists are involved in carrying out tasks on a project-by-project basis [14].

It also stands to reason that in order to exploit the efficiencies afforded by specialization, it is necessary to have access to skilled manpower, both at the organization and at the project

---

* Rolodex is the trade mark of a rotating desk-top address file. The name: 'Rolodex organization' is derived from the fact that it relies mainly on a pool of resources to be assembled as the project needs require; it has no basic staff and is run by one or few specialists who lean on modern management techniques to make this kind of organization work.

levels. While unemployment is rising, the demand for manpower skilled in specific tasks is likely to rise until new and relatively stable patterns of demand result in the creation of new trades or disciplines.

3.4 Fourth Paradigm: Networks and Information Technology *(IT)*

Friedman [15] identifies a strong need for systems that transcend current organizational boundaries and allow the kinds of interaction that are now possible through computer-based communications systems. The technological feasibility of these systems already makes it possible to establish a new mode of organization, namely: the network. According to Best [16], networks of organizations are networks of lateral and horizontal interlinkages among firms, and they are the emerging antithesis of the old model of the large hierarchical firm. Such organizations are lean, agile, flatter organizations and are well suited to a project-based environment such as that of the building industry.New technologies have made possible the adoption of more disaggregated, distributed and flexible production arrangements, as well as of new ways for firms to organize their internal operations and to establish their ties with the firms with which they transact [17].

4 Design Build 2020: Questions to be Asked

Using the methodology outlined earlier, based on morphological analysis, and drawing from the lessons to be learnt from the current paradigms, we can posit answers to the following questions: 1) What is the assessment of Design-Build as a future strategy of choice for the building industry? 2) What are the stimulants to Design-Build as a procurement strategy?, and 3) What are the impediments to the adoption of Design-Build as the dominant procurement mode?

Clearly, Design-Build is not new; however this begs the question as to why it has not secured a more dominant place among available procurement strategies.

5 Design-Build: A Brief Retrospective

Design-Build as a method for procuring a built facility is not a novel idea. While in the last several years, Design-Build figures prominently among procurement strategies, its distinguishing feature, viz., that of 'single point responsibility' conjures up the practices of the master builder going back to Roman times [18]. It is the demarcation of professional domains of architects and engineers and those of the various trades that took place in the 19th Century that lead to what we call today the traditional approach of Design-Bid-Build [19]. While Design-Build was once prevalent primarily in large industrial projects [20], its use gained popularity in the U.S. in the 80s as governments opted for this delivery method in an effort to simplify the issue of who is responsible for what, i.e., for any claims that may arise in the course of the project.

In recent years, Design-Build has become a major strategic option and it has sparked keen interest on the part of both ***professional*** and ***commercial*** groups. We emphasize ***professional*** and ***commercial*** as if they were distinct, because one of the changes that the introduction of the Design-Build mode brings to procurement is the union of previously separate domains of responsibilities: that of the designers – professional, and that of the contractor – commercial. This change is significant as it breaks precedence with long established and zealously guarded traditions that delineate the respective jurisdictional territories of designers and contractors. We repeat that since the early 90s, there has been a noticeable move towards greater interest in Design-Build at a variety of levels; indeed at the institutional level, we observe a tendency to formalize the Design-Build practices.

In the United States of America, the recently established Design-Built Institute of America plays an important role in disseminating information. Also, promoting consistent practice within a range of accepted alternatives, it establishes in a formal fashion the 'rules of the game'. Similarly, in Canada there is a concerted effort on the part of The National Practice Program (NPP) – which is a partnership between the 10 Provincial Associations of Architecture and the Royal Architectural Institute of Canada – towards the compilation of what amounts to a code of practice, including a practice manual launched in 1996.

6 Stimulants to Design-Build

Procurement, according to Katsanis and Davidson [5], is quite properly seen as a set of key decisions in building – a set of decisions which establishes the framework for all subsequent building project activities: programming, design, manufacture, assembly and so on. Design-Build is viewed by many authors, [21, 22], as a building process or as a project delivery method, but according to Wundrum [23], Design-Build is not a process but rather an attitude. While there appears to be a consensus that Design-Build is a process, we also agree with Wundrum's assertion since it reveals a critical element in the understanding of this process.

Since procurement lies at the interface between demand and supply, procurement methods, to be successful, must match what the industry can offer with what the owners want. In other words, "procurers" (the intending building owners or their advisors) must constantly adapt their procedures to fit the organizations likely to work for them; conversely, these organizations are expected to be able to fit into the frameworks established by the currently prevailing procurement paradigms.

Nowadays, as is well known, owners, both public and private, are faced with an ever increasing challenge for obtaining maximum value for their construction dollars; this priority has a major influence on the demand side of the interface and consequently influences the forces on the supply side that aim at maintaining a balance in their favor. The unique and most important element of the Design-Build mode that is noted by the owners is the 'single point responsibility'. The organigrams shown on Figure 1 illustrate this feature and contrast it to the split responsibility under the traditional mode. However, in addition to singular responsibility, DBIA [24], lists the following benefits that arise from the Design-Build mode: 1. Quality; 2. Cost savings; 3. Time savings; 4. Potential for reduced administration burden; 5. Early knowledge of firm costs, and 6. Improved risk management.

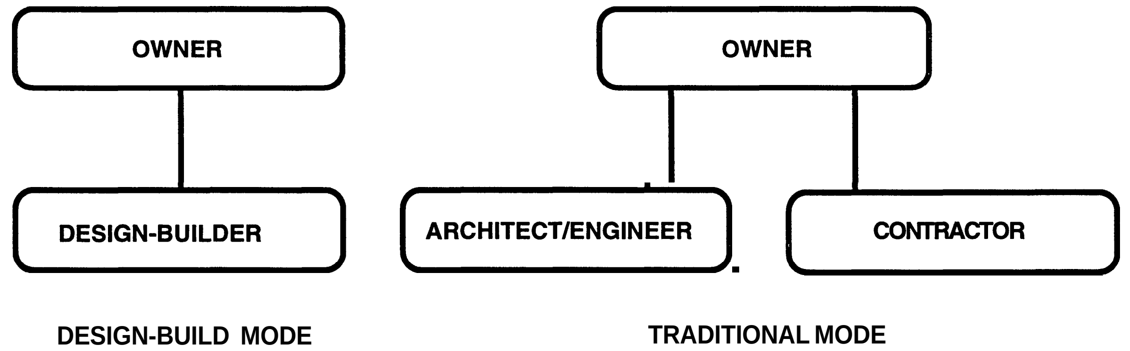

Figure 1. Organigrams indicating contractual links and ensuing responsibilities towards owners. Design-Build and traditional modes.

The models that describe the organization of Design-Build ostensibly emphasize, as we have said, the 'single point responsibility' assignment. The element of the single point responsibility has been identified by Katsanis and Davidson [4] as a desirable attribute and an influence in the shaping of organizational changes. However, in the case of Design-Build, for the owner to benefit from this arrangement, he/she must either have access to in-house expertise or retain the services of an independent consultant – a point we return to shortly. Furthermore these resources/services should be available and deliver the appropriate services in a timely fashion and with high a degree of completeness ***before the owner can make the decision to enter into the Design-Build mode.***

7 Problems with Design-Build

However, two levels of problems are associated with the practice of Design-Build. Firstly, the Design-Build process requires a high degree of sophistication on the part of the owner in order to deal with the complexity of drawing up contracts – a task traditionally reserved for the design professional. DBIA [24] states:

> "... The Owner should choose a design-build process variation based on factors such as project's complexity, funding, design intent, responsibility/risk allocation and other important issues. [...] For Owners who do not have in-house personnel with expertise in preparing and administering design-build request for proposals and contracts, an owner's design-build consultant may be retained to prepare scope definition and RFP documents, and to provide additional consulting services as needed."

Secondly, a major challenge exists in converting the owner's needs into adequate contracting language [24]. In effect, the expression of "what is required" in legally binding terms is increasingly difficult, if it takes place earlier on in the building functional analysis and design process. To develop and control a prescriptive technical specification is easy (even if the upstream steps leading to it may be complex). Developing and controlling a performance specification requires a considerable skill; producing and ensuring the respect of a functional program is extremely complex and indeed can often contain so many loopholes that almost any proposal may have to be accepted.

The owner has recourse to independent advice from the design professional on matters of need, functional performance and/or prescriptive specifications: The execution of these performance or prescriptive specifications becomes the responsibility of the builder. If a problem arises, the decision must first be made as to who is responsible for the problem - the designers or the builder. In the Design-Build mode, the owner, in exchange for having a single entity responsible for the designing and building phases, must assume responsibility for the preparation of the Design-Build RFP, which as we have just shown, is a very complex and risky task. Translating needs into functional specifications and then further translating them into performance and technical specifications requires a level of professional expertise-which are often outside the scope of the Design-Build team.

In point of fact, it appears that the Design-Build mode is an efficient organizational form which offers more benefits to the Design-Build team itself, particularly since it has become normalized to the point of becoming a well-defined processes. For example, Katsanis [25] found that Design-Build is preferred for a variety of reasons:

1. The inclusion of Design-Build in their repertory of work increases their market segment.
2. General contractors acting as builders in the Design-Build mode have a more prominent role in the building process and higher clout with designers. This situation works to their advantage when dealing with designers on other, traditional, projects.
3. Engineering firms also favor the Design-Build mode because it often means they receive functional or performance specifications and they can work on the final design with little or no risk of redesign effort.
4. Architects view Design-Build from a variety of perspectives as a function of the mission of their practice:
   a. Architects with a mission for "quality" architecture and "signature" type projects will shy away from Design-Build ventures unless they are granted "design license"; joint ventures (such as in Design-Build projects) are viewed as arrangements that take away control from the design process the architect must follow.
   b. Architects with professional experience on commercial real estate projects welcome the opportunity to take on Design-Build projects as it enhances their work portfolio and it is viewed as not much different from doing a project for a real estate developer with more or less "generic" performance specifications to be followed in the design:
   c. A third segment of architects views Design-Build as a delivery system that cuts into their professional domain by shifting the power to award a commission from the owner to the general contractor or developer. In such instances the response may be the formation of joint ventures to pursue Design-Build with entities that are deemed compatible with their professional status.

This reveals that, with the exception of architecture firms dedicated to "quality architecture", the principal participants of the building process, either willingly or by virtue of the market forces, are prepared to pursue the Design-Build mode. This observation combined with the difficulty of defining needs in contractually water-tight terms, raises serious concern about how the owners will go about getting from point A (the point in time when owners identify the need for a facility) to point B (the commencement of the Design-Build stage) i.e., providing the Design-Build team with clear and complete statements of required performance. It thus appears that Design-Build addresses single point responsibilities from the ***cost*** and ***time*** perspective but leaves out such issues as functional quality, appropriateness of a project and concerns over long term economic interests. Naturally, these issues are at the center of sustainability.

8 Will Design-Build be Practiced in 2020?

Let us now return to the paradigms that define the building industry environment. Katsanis and Davidson [4] have identified the complexity/specialization issue; they have shown how the dynamic reinforcing of complexity gives rise to specialization which in turn leads to fragmentation. The desire to overcome fragmentation by reducing the variety that one – the owner in this case – has to deal with endows the notion of simple point responsibility with great appeal

However, in assessing a new procurement method, it is essential to consider the idiosyncratic nature of the building industry. Groák [2] suggests that fragmentation is a normal attribute of the industry and that it arises from its intrinsic complexity. Attempting to deal with complexity by transferring complexity to another stage only increases the degree of fragmentation. Such is the effect of Design-Build. While it may group the designer and the builder into one entity, it excludes significant functions from the single point responsibility to the extent that new disciplines must now be created to take it over.

In other words, Design-Build creates some integration but, through the recognized shortcomings of its products, leads to countervailing "disintegration" through the isolation of the building owner, who is "left out in the cold".

How can this paradox be resolved? Either by wishing into being a new breed of sophisticated owner, skilled enough to establish and protect his/her interests against the Design-Build team, or – we suggest – by the spread of the network organization. We referred, earlier on, to the 'Rolodex' firm – a kind of ad-hoc network, established on a project-by-project basis from among a list of firms who feel able to work together. An extension of this idea is now emerging, namely the stable dynamic network of firms who are able to offer complete professional and technical services, but who, by virtue of their individual professional standings, are able to guarantee a balanced cooperation with the client-owner. Half way between the present-day fragmentation and the unwieldy integrated firms, we suggest that the network organization provides the vehicle of choice for the building owner as he/she approaches the problem of appropriate organizational design inherent in building procurement. Perhaps the present enthusiasm for Design-Build will be short lived.

Changing Consumption Patterns to Achieve Sustainable Development: Role of construction

George Ofori
School of Building & Real Estate, The National University of Singapore, Singapore.

Abstract
At the Earth Summit in 1992, the nations of the world, through their leaders, committed themselves to achieving sustainable development. They recognised that, to achieve this aim, current patterns of consumption of all resources should be radically changed. This commitment has been "renewed" and reiterated at subsequent international meetings. The construction industry is a well-known massive consumer of natural resources. However, in most countries, the industry's practices and medium-term plans show that it is either unaware of, or indifferent to, the current international declarations and global consensus on sustainability.

This paper reviews the resolutions, declarations and proceedings of recent major international conferences, and other meetings, on the environment. It considers the role construction is expected to play in the efforts to achieve the aims and objectives stated in these resolutions and proceedings. It focuses on the efforts to change current consumption patterns in order to achieve sustainable development. It cites examples from the practices of the construction industry in Singapore. The paper advocates a "cradle to grave'? approach to the construction process, and highlights the need for teamwork both within the construction industry, and between the industry and related sectors, such as manufacturers of materials and components.
Keywords: Changing consumption patterns, sustainability, role of construction, teamwork.

1 Relationship Between Construction Activity and the Environment

It is now acknowledged that construction activities can have a a serious effect on the environment [1]. The first of these is the impact on land-use. Every construction project on a green field site takes land away from other activities, notably agriculture [2]. Construction invariably involves a modification of the land on which the item is located and in some cases, its environs (for example, in order to provide access to the constructed facility). This can have an adverse effect on ecosystems [3,4].

Second, construction uses a large amount of natural resources, many of which are non-renewable [5,6]. Generally, construction materials are being used at unsustainable rates. For example, construction is a major contributor to the exploitation of forest products which is leading to rapid deforestation (and the related environmental effects such as soil erosion) [7, 8]. In Singapore, the construction industry persists in its use of timber formwork despite encouragement by public-sector clients to use alternatives. This is so although, as a result of a shortage of timber, its cost has risen sharply [9].

Another issue relating to the use of construction materials is the amount of avoidable waste generated. For example, it is estimated that the average wastage level for the Singaporean contractor is 8 per cent whereas Japanese contractors in Singapore (which also use subcontractors) can keep waste to within 4 per cent [10]. The Ministry of the Environment estimated that in the early 1990s, construction wastes in Singapore amounted to 200,000 tonnes annually; 40 per cent of this was from timber [11]. Also observed in Singapore is that owing to the very high waste disposal charges at landfill sites, some contractors try to dispose of their wastes illegally by dumping them at unauthorised sites, or burning them in open fires [12]. Moreover, poor housekeeping, carelessness or ignorance results in the spillage of substances which are washed into the environment, or which may form toxic fumes upon decomposition [13].

Third, construction leads to a high level of energy consumption [5]. Much of this is accounted for by the extraction and processing of materials. Some metals used in construction, such as aluminium, steel and zinc, as well as plastics are highly energy intensive. Smaller amounts of energy are used in transporting the materials to the construction sites, and in their installation during site processes. Moreover, with the completion of every new constructed item, additional demands are put on increasingly scarce energy and water supplies.

The final major environmental consequence of construction activity worth highlighting here is its contribution to air pollution. Particles of various sizes, some of which are harmful to humans, are released in the production and transportation of materials such as cement and quarry products. In Singapore, there are stringent regulations on the emission of dust from items being transported [14], and contractors and suppliers must take action to limit emissions from materials during transportation.

Following the realisation of the environmental impact of construction activity, some work has been done on how the adverse effects can be reduced. Some action has also been taken by governments, professional institutions and companies to address these issues. The concept of *sustainable construction* has emerged. It is pertinent to review, briefly, some recent works on the issue. This review in the next section focuses on the suggestions made by the authors with respect to the actions which the industry must take in order to attain sustainability in its operations.

2 Some Past Works on Sustainable Construction

Samuels and Prasad (1994) [15] discussed the interaction between the built and natural environments, and charted the developments in terms of social responsibility and environmental accountability, environmental and energy auditing, ecologically sustainable design and energy standards and labelling. They offered suggestions for reducing the negative impacts of socio-economic development on the environment. Ofori (1992) [3] reviewed the environmental consequences of construction operations and suggested that in order to develop a culture of environmental protection in the construction industry, the client must be motivated to adopt the environment as a project objective.

Moavenzadeh (1994) [16] considered the potential for positive contributions by the construction industry to efforts to protect the environment, and identified relevant business opportunities. Griffith (1994) [17] proposed a framework for a structured environmental management programme in the construction industry. Hill and Bowen (1997) [18] reviewed the concept of *sustainability* in general, and *sustainable construction* in particular. They stressed the importance of environmental management systems (EMS) within construction organisations to guide construction, operation and decommissioning, and offered an EMS framework.

The next section considers the themes and relevant main conclusions of some recent major meetings on environmental issues. After briefly discussing “sustainability” in general, it considers one of its main areas of focus, “sustainable consumption”, and finally, “sustainable human settlements”.

3 Sustainable Consumption

3.1 Sustainability

Following the work of the Bruntland Commission (1987) [19], which first offered a widely accepted definition for *sustainable development,* there have been several international conferences on *sustainability.* At the United Nations Conference on Environment and Development in Rio de Janeiro-, Brazil in 1992, the world’s leaders committed their countries to *sustainable development.* They adopted Agenda 21, whose principles have guided actions and discussions on sustainability. Whereas there have been some achievements, there is a lack of progress in many of the objectives, targets and actions set at the Rio Summit [20]. The failure of the follow-up meeting, Rio Plus Five in 1997 to produce a final document shows the continuing controversy and difficulty in these matters. In recent years, an aspect of sustainability which has received much attention is the issue of *sustainable consumption.*

3.2 Changing Consumption Patterns

The concept of *sustainable consumption* is based on the realisation that current levels of consumption, and present production methods are leading to the depletion of the known resources [21, 22]. They are also producing by-products and wastes which are adversely affecting the quality of the environment. Thus, it is argued that consumption must be sustainable, and that a change in current consumption patterns is vital [8].

Agenda 21 did not specifically define *sustainable consumption* but noted that policy should focus on: "the demand for natural resources . . . and the efficient use of those resources consistent with the goal of minimizing depletion and reducing pollution". The first Oslo Symposium on Sustainable Consumption in 1994 [23] observed that current resource flows induce pollution, resource depletion, energy consumption, biodiversity and landscape destruction which appeared unsustainable by any standard. It defined *sustainable consumption* as:

> ... the use of services and related products which respond to basic needs and bring a better quality of life while minimizing the use of natural resources and toxic materials as well as the emissions of waste and pollutants over the life cycle of the service or product so as not to jeopardise the needs of future generations.

The main working document of the second Oslo meeting in 1995 [24] expanded this , definition and described *sustainable consumption* as:

> ... an umbrella term that brings together a number of key issues, such as meeting needs, enhancing the quality of life, improving resource efficiency, minimizing waste, taking a life cycle perspective and taking into account the equity dimension. Integrating these component parts is the central question of how to provide the same or better services to meet the basic requirements of life and the aspirations for improvement for both current and future generations.

The Discussion Paper of an Expert Group Meeting on "Changing Consumption Patterns in Human Settlements" in New York in April 1997 [25] cited the following trends in the consumption of natural resources: (i) rapid growth in energy consumption, with a high proportion of losses through inefficient use and resulting in environmental externalities which affect human health, ecological stability and economic development; (ii) expansion of the transport sector owing to increased urbanisation; (iii) acute shortage of water in many cities and regions, with rapidly decreasing reserves; (iv) rapid loss of both tropical and temperate forests, resulting in erosion, soil degradation and loss of biodiversity; (v) depletion of mineral resources and the wide and major resulting environmental impacts; and (vi) increasing levels of waste generation owing to these high volumes of consumption. It suggests that the main forces driving these trends are global increases in population and economic growth resulting in rising income levels. A major contributory factor to stress is poor efficiency in usage (as in the use of energy inefficient vehicles), and inadequate management (as in the waste of water through leakage during distribution).

The Discussion Paper notes that under there are particular areas of stress in several countries. Many of the resources identified as being in short supply, such as timber, minerals and water, are direct inputs of construction, although the shortages are at various levels of criticality with respect to different materials and countries. Construction activity can also contribute to the better management of the other resources, such as water (through the repair and maintenance of distributing systems).

3.3 Sustainable Human Settlements

A recent gathering of national leaders which is of greatest relevance to construction researchers and practitioners is the United Nations Conference on Human Settlements (Habitat II) in Istanbul, Turkey in June, 1996. The main document, the Habitat Agenda [26], presents the goals, principles, commitments and Global Plan of Action of the conference. As at all major United Nations conferences, the participants made some bold declarations. They declared that they were:

> … committed to political, economic, environmental, ethical and spiritual vision of human settlements based on the principles of equality, solidarity, partnership, human dignity, respect and cooperation. We adopt the goals and principles of adequate shelter for all and sustainable human settlements development in an urbanizing world. (p. 6)

The contents of the Habitat Agenda are of direct concern to construction as the industry plans, designs, constructs, maintains, reshapes, upgrades and ultimately, demolishes the human settlements. Construction also obtains much of its inputs from these settlements. As indicated in the above quotation, Habitat II stressed the concept of *sustainable human settlements* which it defined as follows:

> Sustainable human settlements development ensures economic development, employment opportunities and social progress in harmony with the environment. It incorporates, together with the principles of the Rio Declaration . . ., the principles of the precautionary approach, pollution prevention, respect for the carrying capacity of ecosystems, and preservation of opportunities for future generations. Production, consumption and transport should be managed in ways that protect and conserve the stock of resources while drawing upon them. (p. 7)

The Habitat Agenda elaborated on the concept of *sustainable human settlements:*

> Sustainability of human settlements entails their balanced distribution . . . in keeping with national conditions, promotion of economic and social development, human health and education, and the conservation of biological diversity and the sustainable use of its components, maintenance of cultural diversity as well as air, water, forest, vegetation and soil qualities at standards sufficient to sustain human life and well-being for future generations. (p. 8)

Thus, construction activity must be *sustainable*. Indeed, among 14 "objectives" stated in the Habitat Agenda was the following:

> Promoting locally available, appropriate, affordable, safe, efficient and environmentally sound construction methods and technologies in all countries . . . at the local, national, regional and subregional levels that emphasize optimal use of local human resources and encourage energy-saving methods and are protective of human health. (p. 12)

The next section considers possible future directions in construction in the light of the conclusions of major international conferences outlined above.

4 The Future

Ensuring a change in current patterns of consumption is a key issue to governments, most of which are taking measures on both the supply and demand sides. These include statutory and regulatory measures, as well as economic instruments (charges, taxes and subsidies. Action is required several areas. Among the objectives under the goal of *sustainable human settlements* in the Habitat Agenda is the following:

> Promoting changes in unsustainable production and consumption patterns, particularly in industrialized countries, population policies and settlement structures that are more sustainable, reduce environmental stress, promote the efficient and rational use of natural resources – including water, air, biodiversity, forests, energy sources and land – and meet basic needs, thereby providing a healthy living and working environment for all and reducing the ecological footprint of human settlements. (p. 14)

The United Nations Centre for Human Settlements (1997) [25] suggests that the following should act as indicated: (i) governments – introduce natural resource accounting, encourage industry to improve efficiency of resource use, promote sustainable consumption through pricing., incentives, and eco-labelling schemes; (ii) industry – lead the drive to achieve eco-efficiency by improving efficiency in resource usage, minimising waste in production, recycling waste, and increasing research and development on low waste and cleaner technologies; and (iii) international community – establish and promote energy and material efficiency standards, assist developing countries to acquire eco-efficient technologies, and support the exchange of information on indicators and best practices.

On the basis of the principles of sustainable consumption outlined above, the United Nations Centre for Human Settlements (1997) [25] suggests that consumption in human settlements must fulfil the following minimum criteria: (i) it should meet the basic needs of populations and contribute to raising the quality of life; (ii) it should not irreversibly degrade or deplete the stock of resources; and (iii) it should not lead to irreversible degradation of the environment through the accumulation of emissions and wastes. This summary is a useful framework for evaluating construction activities.

The greater international focus on efforts to change consumption patterns should give greater impetus to the drive towards *sustainable construction.* The construction industry must play its part in the effort towards sustainable development in general by changing the levels at which it consumes resources, as well as the types of resources which it uses. The industry must consider every aspect of the construction process, from the extraction of the material inputs to the eventual demolition and disposal of the completed item. It should study all the inputs, both direct and indirect, as well as all the outputs, by-products and wastes. The industry must find substitutes for where acute stress is evident , and where the consequences of non-sustainability is serious. It should also minimise wastes through improved management on site.

The industry should respond in a more co-ordinated manner. So far, in each country, the responses have been by individuals, companies, or professional bodies. Much can be gained from synergistic action. The Habitat Agenda [26] stresses "partnerships", among countries, among all interested or concerned parties within countries: public, private, voluntary, community-based organisations, co-operatives, non-governmental organisations and individuals. These can integrate and mutually support objectives of broad-based participation through forming alliances, pool resources, share knowledge, contribute skills and capitalise on the advantages of collective action.

5 Conclusion

The construction industry should follow the discussions on environmental issues at the international level, since the commitments made, and conclusions reached at these meetings indicate imperatives for action in all countries and all sectors. These inform and shape policy, and will eventually form the basis of competition among business enterprises. The concept of changing consumption patterns in the context of sustainable human settlements offers a useful framework for developing good practice in construction, and should propel the drive towards *sustainable construction.*

Sustainable Building - a Swedish national research program

Anne Marie Wilhelmsen
School of Architecture, Chalmers University of Technology, Sweden

Abstract
The Foundation for Strategic Environmental Research (MISTRA) was established in 1994. The purpose of the foundation is to fund research of strategic importance for a good living environment, and it is distinguished by the special nature of its activities: concentration of efforts, projects and programs that span the boundaries between disciplines, establishment of networks nationally and internationally, promotion of training and recruitment of researchers, collaboration between universitites and industry.

In 1997, a total of 18 MISTRA program had been granted funding. One program, *Sustainable Building*, is linked to construction industry and property management. The program started in January, 1997, and is planned to run for six years. The program focuses the building as a system, composed of technical sub-systems, in a life cycle perspective, and the buldings impact on the out-door environment. The goal of the program, condensed into two major issues are: *Resource efficiency* and *Emission control.* The program comprises three scientific subprograms:

1. Resource Economy - The Building as a System
2. Adaption of Materials and Components to an Eco-Cycle System
3. Implementation of Sustainable Building,

as well as an additional subprogram dealing with program coordination and knowledge dissemination. Four universities and one research institute cooperate within the program. Departments of Architecture, Civil Engineering, and Building Economics take part.

Cooperation between the projects and subprograms is extensive, and synthesis discussions form an important part of the program. Project results are scarce so far, due to the limited time the program has run. The experiences from this kind of cooperation, interdisciplinary within the program and between research and practice, are favourable, especially in the network of PhD students.
Keywords: Sustainable building, multidisciplinarity, industry cooperation, implementation

1. Introduction

The Foundation for Strategic Environmental Reserach, MISTRA, funds research of strategic importance for a good living environment. Activities promoted by the foundation aim at:

- concentration of efforts
- projects and programs that span the boundaries between disciplines
- establishment of networks nationally and internationally
- promotion of training and recruitment of researchers
- research centres in close association with universities
- collaboration between universities and industry
- mobility of researchers.

In the beginning of 1998, MISTRA has approved 18 large research programs, covering various industrial sectors as well as broad environmental and societal issues. One MISTRA program is aimed at building and real estate management - “Sustainable Building”. The first program period comprises years 1997-99. A second period is planned 2000-02.

2. The Program

Researchers at Schools of Architecture, Civil Engineering, and Technology Management and Economics, of the universities of technology in Göteborg, Lund, and Stockholm, and at the National Testing and Research Institute cooperate in this program. The program is managed by a group of three subprogram coordinators chaired by a program director, all four professors at the universities of technology. The executive committee of the program is formed mainly by leading industry representatives.

2.1 Range and scope

The program deals with the building and its environmental impact from a life-cycle perspective. “Building” here denotes primarily housing and commercial buildings, not, in the first place, road construction and other civil engineering artifacts. The building is regarded as a system, including its immediate surroundings, such as foundation work and the building’s connection to urban infra-structure. The emphasis is on the outdoor environment. The entire lifetime of a building includes programs, plans and briefs, design, construction, use and maintenance, reconstruction and changes, final demolition or dismantling followed by the handling of residue products and waste material. Products and processes are equally important.

Building materials and parts composing the building all have a history before they are contained in the building, as well as a future after the lifetime of the building. Life-cycle aspects of this kind are treated in the program insofar as they are needed to establish the total environmental load of the building. Aspects of technology, architecture, economics and management are studied. A basic knowledge of the mass and energy flows in the building stock and the building sector is necessary.

2.2 Goals

In late 1997, the Swedish government's commission on ecologically sustainable development set three goals for ecologically sustainable development (Government Communication 1997/98: 13):

"Environmental protection: Emissions must not harm human health or exceed the capacity of nature to absorb them. Natural cycles must be protected; harmful man-made substances should not occur in nature. Biological diversity and valuable cultural environments must be protected.

Efficient utilization: Energy and other natural resources must be used much more efficiently than is the case today.

Sustainable supplies: Agriculture, forestry and fisheries must be managed in such a way as to allow regeneration of resources. The aim must be to recycle materials in ecocycles and to use renewable raw materials."

We use the goals set by the government for sustainable development as a framework when defining goals for the Sustainable Building program:

Environmental Protection: Building materials and processes may give rise to harmful emissions. Important issues in this respect are:

- the amount and distribution of known harmful substances in existings buildings and the handling of such substances
- the identification of harmful emissions from building materials.

Efficient Utilization: This is the core issue in the development of sustainable building, comprising:

- the use of energy during the entire life-time of buildings
- the use of materials, inclusive of the life-cycle of materials and issues of recycling
- the use of land property for buildings and waste deposits.

Sustainable Supplies: Within the field of sustainable supplies, relevant issues for the program are:

- service life and recycling of materials, components and whole buildings
- renewable resources.

The goals described above are valid as a whole, but can be condensed into two major issues:

- *Resource Efficiency*
- *Emission Control*

2.3 Priorities

In a program devoted to a field as complex as building and real estate management, it is a challenge to find suitable ways to substantial and visible results within the limits set by time and money. We want to choose research subjects according to the anticipated impact of the results in total on practice. Several aspects are then considered:

- The strategic importance for industry/society in terms of quality and/or quantity
- The potential for penetration into practice
- The target group and its ability to utilize the results
- The public interest
- The importance in the context of the program.

With regard to these aspects, the program particularly stresses measures concerning the existing stock of buildings, energy use during the life-time of buildings, recycling issues, materials of special environmental influence, strategic methodology development, and implementation issues.

The training and recruitment of researchers - one of MISTRAs expressed goals - is of special importance in building and real estate management. We want the program to furnish the future industry with highly competent persons able to cope with complex environmental problems and to act as intermediaries between building practice and research. To this end, projects within the program are adapted to PhD study programs. Each project is led by a senior researcher and allows for one or more PhD students.

3. Program Structure

The program comprises three scientific subprograms:

1. Resource Economy – the Building as a System
2. Adaption of Materials and Components to an Ecocycle System
3. Implementation of Sustainable Building.

Each subprogram is held together by a coordinator. Projects within one subprogram are closely connected to each other, not least methodologically. Contacts between projects from different subprograms, however, are equally important. Aspects treated within Subprogram 3, for instance, will penetrate the program as a whole.

The structure of the program allows for, and invites, new projects. New projects of high priority are meant to be initiated, some of them with substantial commitment from industry. A capacity for project leadership, tutoring and supervision is reserved for such projects. Closely related projects with other principals are invited to join in comprehensive program activities, for mutual benefit, in the capacity of liaison projects.

3.1 Subprogram 1: Resource Economy - the Building as a System

The main purpose of this subprogram is to formulate conditions for an effective use of resources throughout the life cycle of buildings, to promote the use of renewable resources and to efficiate the use of non renewable resources. The building in its entirety is studied, and the research work is focussed on both new and existing buildings. The impact of various measures on the building stock as a whole is considered. Input of environmental data is needed, for instance, on life-cycle assessment of building materials and components, and on the pollutive effects on air, soil and water of the used resources (Subprogram 2). The prerequisites for the implementation of obtained results, for instance economic consequences, will be studied in cooperation with Subprogram 3.

Research fields specially addressed within subprogram 1 during 1997-99 are:

- Building stock studies, mass and energy flows
- The environmental impact and resource effectiveness of building engineering and services systems
- Resource effective practice of recycling
- Assessment and process studies of green projects.

3.2 Subprogram 2: Adaption of Materials and Components to an Ecocycle System

Eco-cycle adapation includes resource cycles of different types in building, maintenance and management as well as the adaption to the eco-cycles of nature. This subprogram aims at preventing building activities to generate systematically increased amounts of hazardous substances in the environment, and to make it possible to eliminate, isolate or treat in closed loops any hazardous substances present in building processes. Life Cycle Assessment methodology applied to building processes and products form an important part of the subprogram. The emission of more or less hazardous substances from building materials are studied, both with respect to their impact on the assessment process, and as a part of the deterioration mechanisms. The environmental impact of building materials is studied with respect to, e.g., service life, recycling potential, and chemical treatment.

Research fields specially addressed within subprogram 2 during 1997-99 are:

- LCA methodology studies
- Emissions from building materials
- Groups of building materials: concrete, polymerics, timber.

3.3 Subprogram 3: Implementation of Sustainable Building

Under this subprogram organizational, economic and other factors influencing the implementation of sustainable building are studied. Often it is not only a lack of technical know-how that hinders environmentally adapted building, but rather the economic and organizational systems which influence decision-making and actions. The picture becomes complicated by the great number of organizations with distinct objectives, values and fields of competence, all of which are active in the building process. For this reason, systems for spreading knowledge and information to and for motivating groups of actors involved in the building process are studied. Subprogram 3 applies social science and economics on building and construction. The aim of the program’s studies of the steering systems and economy in building is to obtain greater understanding of the decision-making process in building, and of appropriate measures which will motivate the actors in the building sector to act in a more environmentally sound way.

Research fields specially addressed within subprogram 3 during 1997-99 are:

- Decision-making processes and environment monitoring systems in organizations
- Economic analysis applied to the program’s technical projects
- Life cycle economy
- Decision-making processes in the design stage with a focus on factors influencing the choice of materials and technical solutions.

3.4 Projects, Agenda 1997-1999

		Start
1.1	The Building Stock - Resource Deposits and Resource Flows *Project Leader AA4 Wilhelmsen*	March 1998
1.2	Assessing the Environmental Impact of Building Engineering Systems *Project Leader Arne Elmroth*	
1.2A	Modern Buildings *PhD Student Karin Adalberth*	Jan 1997
1.2B	Older Buildings *PhD Student Anders Almgren*	May 1997
1.3	Building Services Systems *Project Leaders Lars Jensen, Anders Svensson* *PhD Student Mats Dahlblom*	Jan 1998
1.4	Design for Recycling *Project Leader Bertil Fredlund* *PhD Student Catarina Thormark*	Jan 1997
1.6	Environmental Design Strategies *Project Leader Michael Eden* *PhD student Paula Femenias*	March 1998
2.1	LCA Methodology for Sustainable Building *Project Leader Kai Ödeen*	
2.1.1	LCA in the Usage Phase *PhD Student Jacob Paulsen*	Jan 1997
2.1.2	Allocation and Boundary Setting *PhD Student Wolfram Trinius*	Jan 1997
2.2	Hazardous Substances Emitted from Building Materials *Project Leader L-O Nilsson* *PhD Student Åse Andersson*	Aug 1997
2.3	Recycling Concrete *Project Leader Ralejs Tepfers* *PhD Student Mats Karlsson*	Apr 1997
2.4	Polymeric Products in Sustainable Buildings *Project Leaders Thomas Gevert, Ignacy Jakubowicz* *PhD Student Nazi Yarahmadi* *PhD Studies Supervisor Thomas Hjertberg*	Aug 1997
2.5	Environmental Impact of Treated Wood *Project Leader Kai Ödeen*	March 1998
3.1	Obstacles and Incentives to Implementation of Sustainable Building *Project Leader Gösta Fredriksson* *PhD Student Jonas Birgersson*	May 1997
3.2	Economic Analysis in an Environmental Context *Project Leader Gösta Fredriksson* *PhD Student Pernilla Gluch*	March 1998

Liaison Projects

1.7	Resource Economy Design *Project Leader Jan Gustén* *PhD Student Eva Johnssson*	1997
2.1.3	LCA and Indoor Environmental Assessment *Project Leader AM Tillman* *PhD Student Åsa Jönsson*	1997
3.3	Design Choices and Service Life *Project Leader Gösta Fredriksson* *PhD Student Thomas Björklund*	

4 Subprogram 4: Program Coordination and Knowledge Dissemination

This fourth subprogram is concerned with cross-disciplinary communication within the program itself and between the program and the users of its results.

The aim of activities within this subprogram is to bring researchers, PhD students and subject matters in different disciplines togther, to develop knowledge traversing disciplinary boundaries and to initiate joint enterprises. Program seminars are held regularly, where all researchers active in the program meet. Seminars deal with, for instance, methodological issues common to several projects, or review state-of-the-art within one subprogram or within the program as a whole. Synthesis discussions form an important part of the seminars. PhD courses are arranged, during 1998 on LCA methodology and on the development of building engineering and services systems during the twentieth century. Common databases on reference buildings, literature, and LCA data are set up.

Activities turned outwards aim at building bridges between building practice and research, to engage researchers in development projects and to involve people from the industry in the program. This ambition stretches beyond the actual research program. Projects with other principals and focusing on issues of vital interest to the program are invited to attach to the program as liaison projects, and to take an active part in all activities in subprogram 4.

Economic support from industry is a two-fold benefit, in that an organization investing money in the program also invests interest and will ask for results. One form of support especially favoured in the program is called "industry linked PhD students". In such cases, a young civil engineer or architect employed by an industrial or consultant company is assigned to complete a PhD program at a university department within the scope of his/her employment. So far, one industry linked PhD student is engaged in the program, and discussions are on their way in a second case.

5. Results and conclusions

This program has run only for one full year, and research results are scarce so far. Some of the projects will be presented at this Congress (2.1, 3.1). Forthcoming results from projects will be published according to disciplinary traditions. However, the results in total from this program are intended to give more than just all single project results added together. Synthesis discussions form an important part of the program from the very beginning, and will be stressed more and more. The synthesis work is one of the responsibilities of the Program Management Group, and the Executive Committee plays an important role in the discussions.

Our experiences from the work so far show both difficulties and advantages connected to cross-disciplinary networking. Holding together a group of thirty researchers and PhD students, active in half as many projects in different university departments, takes a lot of time and creative thinking. It is essential, to motivate people to work towards a common goal, that everybody knows and acknowledges the aims, content and goals of the program. This calls for frequent meetings, virtually and in reality, where experiences and problems can be shared. We have found the network to be especially valuable for the PhD students, who play a very active role.

The cooperation and respective roles of the Executive Committe and the Program Mangament Group is another important issue which has to be further explored in future, in order to take full advantage of the possibilities this kind of organisation of sectorial research gives for promoting the integration of research and practice.

6. Management Structure

Executive Committe

Gösta Blücher, Chairman	Director General, National board of housing and planning
Roland Akselsson	Professor, Industrial Engineering, Lund University
Bernt Johansson	President, Skandia Real Estate
Per Westlund	Vice-president, Skanska AB
Knut Wickberg	Director, Scancem
Karin Wiklund	President, Stockholm Cooperative Housing Association

Program Management Group

Anne Marie Wilhelmsen, Program Director	Professor, Building Design and Construction, Chalmers University
Arne Elmroth, Coordinator Subprogram 1	Professor, Building Physics, Lund Univerisity
Kai Ödeen, Coordinator Subprogram 2	Professor, Building Materials, Royal Institute of Technology
Gösta Fredriksson, Coordinator Subprogram 3	Associate professor, Build. Economics & Construction Management, Chalmers

Scientific Advisory Group

William Addis	PhD, Dep. of Construction Management & Engineering, The University of Reading
Roger Baldwin	Head of Department, Building Research Establishment, Garston, Watford, UK
Erik Christophersen	PhD, Danish Building Research Institute, Hörsholm, Denmark
Niklaus Kohler	Professor, Institut für Industrielle Bauproduktion, University of Karlsruhe, Germany

Sustainable construction in Finland: approach and best practices

P. Huovila, T. Häkkinen and I. Aho
VTT Building Technology, Espoo, Finland

Abstract
This paper describes:

- the state-of-the-art of construction and environment in Finland
- current status of the national environmental technology program
- selected best practices along sustainable building process
- recommendations to the building sector for the future.

The building sector represents almost half of the primary energy produced in Finland: 34 % is consumed for space and domestic hot water heating and electricity used in households and 10 % for building production. Construction and demolition waste is produced at a rate of 1,5 million tons annually. 20-30 % of the building waste is currently recycled.

Our main ongoing research and development effort is the technology program: Environmental Technology in Construction (1995-1999), coordinated by the Technology Development Centre. It has an estimated budget of 20 million USD, of which industrial cofinancing share is about a half. The program aims at developing methods and technologies for environmentally sound construction to be implemented in enterprises. The program consists of five research and development priority areas: ecobalance and life cycle, design guidelines and procedures, products and production technologies, pilot construction projects and environmental geotechnics.

Different actors within the building process have already established their sustainable best practices. This paper presents selected examples of ecological and energy-conscious buildings, ecological criteria for experimental construction, business based on waste recycling, and electric and district heating energy plant. Finally, the issue of environmental management systems is touched, and recommendations to the building sector are given for the future.
Keywords: building, environment, sustainable construction

1 Construction and environment

The most significant quantifiable environmental impact of the construction sector is emissions due to energy consumption. The building sector in Finland presents 44 % of the total energy consumption: 34 % for heating of buildings and electricity used in households and 10 % for building production (out of which 70 % comes from manufacturing of products and 30 % from transportation and building sites). In addition, 3 % of the total energy is consumed by production of building materials and products for exportation.

Over 80 million tons of building materials and natural resources are used annually in construction in Finland. The amount is fourfold compared to municipal waste. About 7- 10 million tons of waste are generated every year at demolition and renovation sites, in new construction, and in civil engineering. The goal is to increase the utilization of construction waste from the current 20-30 % to 70 % by 2005. [1]

In Finland, the availability of free space, and air and water of good quality, is not seen as a problem to be solved and that is not striving us towards environment-saving solutions, like in some other countries. The climatic conditions in the North of Europe are cold stimulating us to energy saving thinking and acting – also because we are depending on imported energy. Sustainable development as a target is accepted and the means for co-operation and large-scale responsibility exist. The starting point for developing and implementing sustainable construction is good for us both within our borders, and abroad.

2 Sustainable construction

Sustainable development is often considered to contain ecological and economical, social, and cultural aspects. In this paper, sustainable construction stands for ecologically sustainable construction, which means essentially management of biodiversity, tolerance of the nature, and saving use of resources. Achievement of ecologically and economically sustainable construction enables socially and culturally sustainable construction.

According to our current definition [2], sustainable construction in its own processes and products during their service life aims at minimizing the use of energy and emissions that are harmful for environment and health, and produces relevant information to customers for their decision making. To building construction this means:

- intensified energy-efficiency and extensive utilization of renewable energy sources
- prolonged service life as a target
- saving of the natural resources and promotion of the use of by-products
- reducing waste and emissions
- recycling of building materials
- supporting the use of local resources
- implementation of quality assurance and environmental management systems.

The desired state prevails environmentally responsible industry and building owners together with environmentally conscious consumers.

3 Environmental technology in construction

Technology programs are an essential part of the Finnish innovation system to encourage the technological development in industry. Environmental Technology in Construction [3] is one of these technology programs coordinated by the Technology Development Centre (Tekes) [4]. It was launched in 1995 to aim at developing environmental-conscious techniques and methods in the field of construction. It has an estimated budget of 20 million USD to be covered by about 50 % by the participating companies.

The program deals with: .

- environmental impact assessment methods
- ecological design methods, data bases and programs
- utilization of industrial by-products in construction and geotechnics
- reconditioning of contaminated soil and protection of ground water
- production methods and products that save energy, reduce emissions and make use of recyclable construction materials
- manufacturing equipment, machinery and testing methods for the above.

Alongside this program, the Academy of Finland launched a basic research program for Ecological Construction. Development work for ecological urban construction is carried out in cooperation with the Ministry of Environment and the Finnish Association of Architects, whose ecological urban development is part of this technology program for pilot construction of new solutions.

The ongoing research and development projects are focused to the following five main areas:

- environmental assessment of buildings and building products
- design guidelines
- products and production technologies
- experimental construction
- environmental geotechnics.

The projects within the first area deal with the framework, procedures and methods for the environmental assessment of buildings products together with the structure, format and quality of the environmental information to be used by designers and manufacturers. The second area results in guidelines, methods and tools for clients and designers. International information and technology transfer with organizations, such as CIB, RILEM or Green Building Challenge form part of that work. The third area focuses on improving production processes, waste management, recycling technologies and new products. The fourth area aims at implementing urban environment following the principles of a sustainable future. It consists of experimental construction of new buildings and renovation.

4 Best practices

The following examples are presented to illustrate how different aspects of sustainable construction have been implemented into practice:

- environment-conscious buildings

- criteria for ecological neighbourhood
- business based on waste recycling
- sustainable electric and district heating energy plant.

4.1 Environment-conscious buildings

An ecological single-family house was developed and built to disturb the processes of nature during its life cycle as little as possible, e.g. to exist in harmony with nature. The house should be a simple and cheap basic house for everyone, still having good architectural quality and providing occupants good quality and flexible living spaces.

The Marjala house [5] is built largely of wood and wood products. Other keywords are local products, simple technical solutions, repetition of same details and components, thus decreasing the number of different components. The inner surfaces are coated with so called ecological materials from nature, such as wall paper, paintings and waxes. The outer paints are cooked on site or made of skimmed milk as a base material. It gets its energy for heating and hot water from firewood and sun. There's one stove in the house and 10 m^2 solar heating panels on the roof. Heat from firewood and sun is collected and stored in a 1.500 liter hot water tank. Standby heating is provided by a 6 kW electric heater at the bottom of the tank.

The heating energy of the Marjala house is 42-50 % of that of eight reference houses. It is supplied with an owner's manual and service instructions for the next 50 years.

Another sustainable building example is an energy-conscious dwelling. The purpose there was to find out the actual influence of structural and technical systems on construction costs and comfortable dwelling when ecological alternatives are favored. The goal was a 30 per cent reduction of annual heating energy without significantly increasing construction costs. First, performance and costs of various exterior walls and windows were calculated. A trade-off comparison between a better thermal insulation of exterior walls and windows and, on the other hand, building costs and dwelling comfort was performed.

The results indicated the fact that a better insulation gives an opportunity of using floor and air heating based on low temperature technique. An experimental apartment was constructed, based on the results obtained. This was a block of flats containing 15 apartments in Helsinki. Eleven of the apartments were equipped with air heating and four with floor heating. All of them had individual ventilation and a heat recovery unit. In humid rooms there was an additional floor heating facility (integrated in the heating system).

Room temperatures and dwelling comfort were studied in two air heated and two floor heated apartments. Energy consumption was measured from November 1995 to October 1996. The results were reassuring: The energy consumption of the heating system was 59,1 % lower than in the reference building and 30,4 % lower than the original goal. The energy consumption (hot water included) of the experimental building was 49,7 % lower than in the reference building. The annual temperature efficiency of the heat recovery systems was 42,7 % in air heated apartments and 40,8 % in floor heated apartments.

Due to the good indoor climate the apartments are suitable for allergic persons. Some additional research on air conditioning and water systems is still needed.

4.2 Criteria for ecological neighbourhood

The City of Helsinki and the Eco-Community Project organized a design competition for experimental building in a rural area including ecologically sensitive and valuable protected waterfronts at Viikki near the centre of Helsinki [6]. The competition aimed to save nature and natural resources, to have a high quality with regards to their architecture and functionality of the dwellings, and to be feasible to construct. The competition also was a means for a search for solutions which follow the principles of sustainable development and which could be more generally applicable. A group of building consultants devised a tool for the ecological assessment of building plans.

Viikki's ecological criteria for ecological construction [7] is a method that defines minimum ecological levels for building and estimates the ecological degree of various development projects. Minimum ecological levels for building have been dimensioned to enable their implementation in residential construction to be carried out at a reasonable additional cost. The fulfilling of ecological criteria will also achieve cost savings during the use period. These criteria, whose purpose is to serve as a guide for design and implementation, shall be appended to regulations concerning building practices at city cites.

In Viikki, increasingly ecologically conscious building will progress as a four-step process: a minimum level of ecological criteria applied to all projects, supportive PIMWAG points for significant trial projects with a high expectation value, experimental image buildings representing radical ecological construction, and follow-up studies for mapping information about projects under construction. Examples of the required minimum levels are as follows (difference from reference building):

• CO_2	3.200 kg/grm^2, 50 years	**(- 20 %)**
• waste water	125 l/resident/day	**(- 22 %)**
• construction site waste from building	18 kg/grm^2	(- 10%)
• waste produced by residents	160 kg/residence/year	(- **20** %).

4.3 Business based on waste recycling

The annual steel production in the world equals ca. 700 million tons. At the same time the steel industry produces approximately 400 million tons of by-products, solid residues and sludge. In addition to the reduction of waste and emissions, the effort towards a waste-free steel industry has created business activities based on the useful application of by-products. Recycling in the steel industry means primarily either returning by-products into metallurgical processes or utilization of the by-products elsewhere.

In Finland there are two steelworks based on blast furnace hot metal production and two steelworks with electric arc furnace technology. The integrated steelworks in Raahe and Koverhar produced 2.6 million tons of steel, and 0.8 million tons of blast furnace and steel slag. Besides this, approximately 0.15 million tons of dust and mill scale were formed as by-products of the process. In Tornio approximately 0.3 million tons of Ferro chromium slag and 0.16 million tons of electric arc furnace slag were formed.

SKJ Companies, a subsidiary of the Finnish steel group, Rautaruukki Oy, is responsible for utilizing the by-products of steel industry. Activities cover the whole range of the by-product business from by-product treatment to product development, marketing and export. SKJ has developed into products and is marketing approximately 90 % of the above mentioned by-products of Finnish steel industry totaling about 1.4 million tons. Slag, that is the largest product group by volume, is marketed to road construction, agriculture and the building materials industry. SKJ companies have activities in the fields of by-product treatment, product development and technology know-how. With regard to the technology know-how SKJ also has activities within export. The primary export countries have been Russia and East European countries.

4.4 Sustainable electric and district heating energy plant

The new energy plant of Helsinki City uses natural gas as its fuel and produces a nominal electric power of 450 MW. The fuel is fossil, but offers the advantage of practically no particle and sulfur emissions. The NO, emissions are low: for NO_2 only 35 mg /MJ of fuel. In comparison, modern coal-fueled plants emit ca. 50 mg/MJ, and 10 years ago typical emissions for coal were above 200 mg/MJ. Also carbon dioxide emissions are low, only 56 g/MJ (more than 90 g/MJ for coal).

The power plant produces both electric energy and district heating energy. The electric energy is produced in two stages by gas and steam turbines. The remaining useful energy (about half of the yield) is then available for district heating. The amount of unused heat (e.g. outside the heating period) is cooled by seawater. When all available energy is used the total efficiency of the plant is about 90 per cent. About 50 % of district heat is used in the densely built area of Helsinki. The heat from the energy plant is lead outside of this area, to North and East parts of the city, via a new 20 km long district heat tunnel (an investment of ca. 500 million FIM). About 90 % of the building volume in Helsinki is covered by district heating.

5 Considerations for the future

One of the concrete measures towards sustainable construction is the development and implementation of environmental management systems. The basic idea there is continuous environmental improvement of activities with the help of measurable targets. By means of an environmental management system, it is also possible to benchmark the environmental level of an enterprise to others. The building up of the environmental management systems is increasing in Finland.

Consequences of sustainable development on the construction industry by the year 2010 were studied in a CIBW82 project Sustainable development and the Future of Construction [8],[9]. That project resulted in the following recommendations to the Finnish building sector [2]:

<u>Building owners</u>:

- to set concrete environmental demands to the parties involved in the design process, as well as to the final product, during the initial design phase
- to set concrete goals regarding building maintenance that are based on environmentally friendly methods and include these goals in, for example, the building maintenance agreements

- assure of the productivity of one's own business by emphasizing environmental issues, quality and preservation of property values.

Building users:

- to act as a demanding customer when selecting spaces and considering the environmental qualities of the building over it's life span as one selection criteria
- to see the environmental issues as one aspect of comfort and consequently as one factor that affects the productivity of the use of the spaces
- to develop one's own activities to be more environmentally friendly in the occupied building.

Clients:

- to inform and analyze the owner's environmental demands regarding the construction project, as well as make sure they are adhered to
- to select the parties involved in the building project based on their expertise on environmental issues
- make sure that environmental goals are part of the owner's demands and implementation plans and, if needed, set them together with the owner.

Designers:

- to consider the environmental qualities of construction materials as a starting point of the design and to develop design solutions from the point of view of environmental goals of the final product
- (one can also set goals, even if the owner is not yet doing it)
- to develop the design process together with other professionals in order to achieve the optimal situation
- to develop methods and tools which will enable the designers to control not just the statics and cost but many other variables, such as life span and maintenance intervals, pollutants and health factors, heating and moisture technology etc.

Manufacturers of building products:

- to see the life cycle considerations (environmental impact, life span) as the basis of product development
- to explain in the product information the environmental qualities based on life cycle analysis, together with information regarding use and conditions of use, recycling and – and bear responsibility of that information
- to minimize actively the environmental harms of one's own production processes.

Contractors:

- to see environmental consciousness as a factor of competitiveness and to develop one's own services to be environmentally sound
- to reduce the environmental impact of one's own business processes regarding, for example site operations, logistics and material selections
- to require readiness from the other parties (sub-contractors, material and product suppliers) to work in cooperation towards environmentally sound goals.

Building maintenance organizations:

- to see environmental consciousness as a factor of competitiveness and to develop one's own services to be environmentally sound
- to correct one's own processes so that they are based on sound environmental thinking, show initiative and give feedback to the building owners regarding environmental issues

- to expect cooperation from suppliers and partners regarding environmental issues.

Officials:

- to confirm the creation and existence of mechanisms that lead to life cycle thinking
- to consider environmentally sound construction as one criteria in all building
- to use appropriate guidance (regulations, supervision and sanctions) in order to achieve environmental goals.

Researchers:

- to produce, together with other parties in the construction business, environmental qualities for entire buildings and building parts as well as methods and means to calculate them, to be used by owners, builders, designers and contractors
- to aim in one's own activities to introduce life cycle thinking as the guiding principle of design and construction process and actively implement research results in, for example, experimental construction projects
- to produce research based information to contribute to the ethical discussion on environmentally sound construction.

Education of Construction Engineers for Sustainability

T. M. Lewis
Department of Civil Engineering, The University of the West Indies, St Augustine, Trinidad & Tobago, West Indies.

Abstract
The issue of sustainability has become more and more important as people have begun to realise that environmental and social degradation have begun to adversely affect their life styles. Sustainability implies that the condition should be capable of being maintained over the lunger term, and this means that the broader macro-economic and social perspectives must be taken and that the needs of future generations must to be accounted for. Engineers do not currently have the appropriate training for this, However, it is felt that engineers are the appropriate professionals to be undertaking assessments of sustainability. In order to give engineers of the future the appropriate training and skills it will be necessary to change and upgrade the curricula fur their degree programmes. One approach to curriculum design is to start by deciding what the required body of knowledge comprises, and to use that as the basis, Some ideas have been drawn from recent literature as to what the appropriate body of knowledge may contain.
Keywords: Body of knowledge, curriculum design, sustainability

1. Introduction

In **1992** the United Nations held a conference on Environment and Development [10]. Its objective was to address the concern that both the natural environment and the social fabric of society appeared to be in a state of accelerated deterioration. The situation had reached a point at which the quality of life of people throughout the world was being degraded and threatened. The outcome was an agreement to try to balance environmental and social issues with the economic imperatives, in order to achieve a form of development that was more sustainable.

Although a great deal of valuable work has already been done in this area, there is still a lot to do. One of the most significant problems delaying the advancement of knowledge has been a lack of consensus on what sustainability involves. Clearly mankind cannot stop using up the limited stocks of non-renewable resources, and his very existence is non-sustainable in its current form. Hence, sustainability is not about preserving the current status quo, it is concerned with the search for efficiency in the use of resources, for integrity of the environment and the ecosystems that inhabit it, and for social stability and growth. In each of these areas, the needs of future generations must be given due weight.

When the implications of sustainability are considered in the context of an industry, it is clear that there will be interfaces with other industries and implications that will require a broader perspective than has traditionally been taken.

2. The Role of the Engineer

The construction industry is inescapably linked with the problems of sustainability. On the one hand, almost without exception developmental projects have a major constructed element, and on the other, the design, construction, and maintenance of buildings have a significant impact on the environment and on natural resources, Typical buildings using traditional materials consume more resources than necessary (partly because they tend to generate a large amount of waste), and impact negatively on the environment. Often, these buildings are also expensive to operate, throughout their life cycles, in terms of energy and water consumption.

The objective of sustainability in the context of the construction industry must be to try to develop an integrated approach to building design that takes into account the diverse needs of the environment, economy and such other political and socio-cultural factors as are considered appropriate. The target will be to produce a 'Green building' design which will "promote resource conservation, including energy efficiency, renewable energy, and water conservation features; consider environmental impacts and waste minimization; create a healthy and comfortable environment; reduce operation and maintenance costs; and address issues such as historical preservation, access to public transportation and other community infrastructure systems. The entire life-cycle of the building and its components is considered, as well as the economic and environmental impact and performance." [S]

The issues involved are much more far reaching than those traditionally involved in the technical and economic analyses that investment decisions usually undergo. If projects are to be asessed in terms of their "sustainability' then clearly, firstly some sort of index has to be available by which their performance can be judged, and secondly somebody has to be capable of undertaking the task accurately and objectively.

A number of commentators have addressed themselves to the inadequacy of existing measures of 'development', and have proposed alternate "indices of sustainability'. The web site produced by Maureen Hart [5], for example, has a lot of valuable discussion and information on this issue.

A number of the parameters that are relevant to these indices and to the concept of sustainability require an understanding of engineering principles [2]. In addition, civil engineers are already required to understand the economic and financial implications of the decisions they make, as well as being able to undertake basic environmental impact assessments and elementary social cost-benefit accounting, These capabilities suggest that engineers are the ones who should be at the forefront of the 'sustainability' thrust.

This, of course, has implications for the training of engineers, and on the curriculum that is taught at universities. The basis for a properly considered curriculum is the 'body of knowledge' that is deemed necessary to practitioners of that discipline, and as yet there has been little published discussion of the 'body of knowledge' appropriate in this context.

3. A Body of Knowledge

It is clear that one very important aspect of the body of knowledge must be related to the environmental implications of sustainability. The question is, what else needs to be included? One reference point must be the agencies that have stated a position on this matter. For example the World Bank indicated that "any project proposal should be economically and financially sustainable in terms of growth, capital maintenance and efficient use of resources and investments. It must also be ecologically sustainable in maintaining ecosystem integrity and biodiversity. Finally, it must be socially sustainable in that it should promote equity, social mobility, social cohesion, participation, empowerment, cultural identity and institutional development ." [1]

From this statement it can be seen that the World Bank sees three major categories of parameters that need to be considered when sustainability is at issue – the economic, the environmental and the social. Other organisations propose that different categories should be used when assessing sustainability, a selection of these is shown in the table below (from Cole [4]). As Cole indicates, these categories can be expanded to show the criteria considered important under each assessment method. The Canadian International Development Agency (UDA) published a paper in 1991 (3) suggesting that there are five 'pillars of sustainability' – the economic, environmental, political, social and cultural – each of which needs to be addressed when developmental projects are being considered Simmons and Cumberbatch [9] subsequently added a sixth 'pillar' that of institutional sustainability to this list.

BREEAM [6] *New office building*	**BEPAC [7]** *New and existing office buildings*	**Green Builder Program [8]** *Houses*
Global Issues and Use of Resources Local Issues Indoor Issues	Ozone Layer Protection Environmental Impacts of Energy Use Indoor Environment Resource Conservation Site & Transportation	Water Energy Materials Solid Waste

If 'sustainability' is to be a part of the training for engineers then it is necessary to define a structured 'body of knowledge'. It would seem appropriate to take the work done by the various bodies mentioned here as a starting point in this exercise,

It is clear that sustainability can be addressed at two different levels, that of the project and that of the broader community. These are not separate, discrete entities, as obviously the impacts of the project will be felt at the community level However, it is equally clear that the socio-cultural impacts of projects are not considered on most projects and, for example, are not amongst the criteria used in the Green Builder Program. When 'developmental' projects for developing countries are being considered, this issue becomes important, as recognised in the CIDA paper. The impact of a project in terms of its social and cultural acceptability will make all the difference between its success and failure. The 'Third World' is littered with the remains of projects which reflect the socio-cultural arrogance of the 'First World' in ignoring the relevance of such issues.

As a starting point, the six 'pillars' or dimensions of the extended CIDA structuring of sustainability could be used to provide a first structuring of the body of knowledge. However, in practical terms the elements that are involved in the cultural and social elements of sustainability are so close as to suggest that these two dimensions could better be combined. The same logic extends to the political and the institutional dimensions. These four, regrouped dimensions can be used to structure the elements that are essential parts of a possible curriculum for each.

Economic Sustainability

- Introduction to economic theory
- Elements of supply and demand
- Economic Development Theory
- Time value of money
- Investment analysis
- Cost-benefit analysis
- Shadow pricing
- Economic policy choices and implications
- Supplier subsidies vs. user subsidies
- Energy cost studies
- Life cycles cost studies

Environmental sustainability

- ***Global issues***
  - Acid rain
  - Ozone depletion
  - CO_2 emissions
  - Renewable resource depletion (e.g. tree felling)
  - Non-renewable resource depletion (e.g mining)

- ***Local issues***
  - Water use/pollution
  - Air pollution
  - Noise
  - Local wind effects
  - Heat source/pollution
  - Lighting
  - Materials - the 4 "R"s - Reduce, Reuse, Recycle and Rebuy
  - Solid waste management
  - Site accessibility & transportation

- ***Indoor issues***
  - Water use & waste disposal
  - Solid waste disposal
  - Air ventilation/pollution
  - Noise control
  - Heating/cooling (solar etc)
  - Insulation
  - Building envelope design
  - Building operating sensors/controls
  - Lighting/shading

Social and cultural issues

Maureen Hart's book "Guide to Sustainable Community Indicators" and her web site [5] argue that "In a sustainable society, people are connected to other people, care for others, respect the rights and feelings of others, and enjoy the diversities of multiculturalism. The subcategories of society are related to these issues and include:

Abuse - Number of people, young and old, who are mistreated and the steps taken to prevent these types of problems

Children - How well children are supported and cared for emotionally and financially

Connectedness - Extent to which people feel like they belong in their community

Culture - Availability and use of museums, libraries, theater and other cultural events by all segments of the community

Diversity - Extent to which differences within the community are not only accepted but also encouraged and celebrated

Pregnancy and birth **-** Rate at which children under **18** or unmarried women give birth to children; a negative indicator
Volunteerism **-** Willingness of the members of the community to participate in making the community a better place to live

The emphasis of society indicators of sustainable community is on improving the lives of people, not through more money or more bureaucracy but through people caring for other people."

Political and institutional issues

Again Maureen Hart [5] suggests that A sustainable community is one that will have high rates of participation by all residents and an efficient, well-managed local government. The subcategories for government indicators include:
Diversity **-** Balanced ethnic, racial, and gender representation at all levels
Leadership - Effective leadership
Participation **-** Active participation from all members of the community
Services - Well run, well used public services

The emphasis of the government indicators of sustainability is on the effectiveness of government agencies and the voluntary and active participation of the citizens."

4. Conclusions

There is increasing need for society and its representatives to become more attuned to the concerns of sustainability. In practice this will mean that professionals like engineers will have to start taking into account issues that they have not bothered with before now, It will also call for them to revise their approaches to project assessment. The needs for sensitivity to these issues will cause engineers and educators to reconsider the content **of** the curricula for degree programmes. One approach to redesigning curricula is to start from what is considered to be the essential 'body of knowledge' of that aspect of the discipline. Thus it is useful to consider what the appropriate body of knowledge may contain, The dimensions, parameters, elements and criteria mentioned here constitute a suggested starting point for developing an appropriate body of knowledge for sustainable development.

The Concept and Context of Sustainable Development in the Caribbean

T. M. Lewis,
Department of Civil Engineering, The University of the West Indies, St Augustine, Trinidad & Tobago.

Abstract

The concept of sustainability in the context of development is problematic, because they tend to be driven by different imperatives, Sustainability seeks the long-term continuation of a process or state, whilst development seeks change and improvement. Although not necessarily in conflict, in practice these two objectives do tend to pull in opposite directions.

In the setting of a developing country the process of development is usually dependent on the exploitation of natural resources. This sets the requirements of sustainability and development more directly at odds. Unfortunately, the costs of natural resource depletion are rarely accounted against a project's economic benefits, so environmental degradation is consistently undervalued. The trade-off between the use of resources for the benefit of today's pour and concern for the interests of future generations, is also one that is very difficult to make.

In addition, it is not just a question of balancing the demands of economy and the environment. Development only has meaning within the context of a society, and for a society to be sustainable a number of socio-cultural needs must be satisfied.

These broader issues of sustainable development need to be understood, and their implications also built into benefit cost analyses.

Keywords: Caribbean, feasibility studies, sustainable development, pillars of sustainability

Introduction

Most governments have an understandable objective of trying to improve the economic and material well being of the people they serve. This political imperative has traditionally been met by 'development' initiatives, which measure relative 'development' largely in terms of economic parameters.

In addition, these initiatives tend to adopt a "copy-cat' approach, in that newly emerging economies are expected to follow the same route to development as the mature industrialised countries. Unfortunately, the interests of the environment and development tend to be opposed, and it is the environment that has had to give way. The conflict and the compromising of the environment have been so profound that efforts have had to be made internationally to try to improve the situation.

The purpose of these efforts has not been to stop development, but to find ways to redirect or redefine development in such a way that the environment can be protected too. For example, in **1987** the World Commission on Environment and Development sought to define development in terms which would allow it "... to meet the needs of the present without compromising the ability to meet those of the future" [4]. The clear objective of "development in this light is that it should be 'sustainable'. Development implies improvement, or 'bringing to a more advanced state'. Sustainable implies 'capable of being continued without decreasing'

In the developing world, there are very close links between economic growth and the environment, because a large percentage of development initiatives exploit natural resources. As a result, 'sustainable development' increasingly means achieving economic growth without damaging the environment, Because of the limits on the levels of production and consumption that can be borne by the environment, the concept of sustainable development involves sensible limitation on the exploitation, of natural resources especially those that are non-renewable.

The concept of sustainable development is, of course, anthropocentric in that its objective is to provide long term support for human habitation. But man is a social animal, so the issue is not just life support, but also the long-term preservation of 'civilisation'. Thus sustainability must take a broader prospect than that of economics and environment.

A **1991** discussion paper put out by the Canadian International Development Agency [1] indicated that sustainable development should involve sustainability in five dimensions, the economic, environmental, social, cultural and political, dimensions. These dimensions were called 'the five pillars of sustainable development', Subsequently, Simmons and Cumberbatch [3] suggested that the CIDA paper had ignored a key sixth pillar, that of institutional sustainability. The issues involved with each are discussed below.

Economic Sustainability

The interests of economy in development projects have been well served by investment analysis and cost-benefit analysis over the years. However, these approaches have their shortcomings when it comes to sustainability issues. There are two specific problems, one is the failure of the measures to take account of the depletion of natural “capital’, and the other is their inability to distinguish between a disaster and a windfall.

In most analyses the stock of a natural resource is treated as a ‘free’ consumable. Exploiting natural resources, without any need to acknowledge that the resource base has been depleted can enhance current economic performance. As a result, the rights of future generations are ignored.

Even where a more enlightened approach is attempted, the analysis of projects tends to use discount rates that are close to the social opportunity cost of capital - which tends in the Caribbean to be greater than 10%. Such discount rates tend very heavily to favour returns in the short-term. Projects that have relatively high current costs, and benefits that are enjoyed some significant time in the future, are heavily disadvantaged. This means that environmentally oriented projects, like those associated with reafforestation, are almost impossible to justify on economic grounds. Clearly this is inappropriate when sustainability becomes important.

The second problem with current economic measures is that an ecological disaster, like an oil spill, only shows up in national accounts as an increase in economic activity. In other words, it has a positive economic effect, without its negative environmental consequences being accounted. Even the outbreak of a disease can appear economically favourable in that it enhances medical activity without its negative effects necessarily showing up in the accounts anywhere.

These shortcomings are not insurmountable. The challenge is to achieve economic sustainability whilst ensuring that natural resources are used efficiently and with due recognition of the rights of future generations. Also, where there are negative environmental, social or cultural consequences, these should be fully accounted as costs, and set against the benefits of the project or activity

Environmental sustainability

The state of the environment is a matter of growing current concern, It is not a philanthropic concern, It is a concern based on the observation that degradation of the environment is already affecting the quality of life of people throughout the world. Mistakes of the past are revisiting the present with unanticipated and unacceptable consequences. Thus, protection of the environment must be factored into the decision making process.

There are three basic services that the environment provides. The first is that it is the source of the natural resources (like Jamaican bauxite, Trinidad oil or Barbados’ beaches) that are the raw materials used as the inputs to human activities. Secondly, it serves as a ‘sink’ which absorbs, and often recycles, the waste products of human activity. The third service the environment provides is in a range of virtually irreplaceable functions that are often life sustaining (like the stratospheric ozone layer which filters the ultraviolet rays that are harmful to humans).

The recognition that damage to the environmental was reaching a level at which it was becoming unable to sustain these services has led to a reappraisal of how to integrate the costs associated with environmental degradation into conventional economic decision-making. The basic approach has been to value environmental assets and to put a cost on their degradation that can be accounted in project level cost-benefit analyses. There are still problems associated with the valuation of public environmental assets (like a reef, for example) and with appropriate discount rates, but at least a start has been made in the recognition of environmental costs within projects.

Once environmental economics become accountable at the national level it is likely that effective systems of management will be introduced. These systems would be directed towards trying to use scarce resources in a more sustainable way, assisting nature by attempting to rehabilitate and restore damaged or degraded ecosystems and natural resources, and by enhancing the productive capacity of 'natural' ecosystems,

Social Sustainability

Large sectors of society, particularly in the 'developing' world, have failed to benefit from conventional development initiatives. The large and growing populations of poor have become relatively worse off, as the anticipated "trickle-down" of benefits has failed to materialise. This has led some commentators to demand that efforts should be made to directly improve income distribution [2]. The concept of 'equity' has become an issue in sustainability, as, clearly, a social situation that is perceived to be inequitable will not be sustainable in the long term.

The principal goal of 'social sustainability' is improvement in the standard of living of all members of a society. In a developing country, this will be tempered by the need to bias the improvement towards the needs of the poorer members of the society. This requires that opportunities for human development should be available to all, and this calls for special attention to be paid to:

- improving the distribution of income;
- striving for equity regardless of gender or race;
- removing unfair barriers to land ownership, employment and education
- ensuring adequate access for all to the social infrastructure (e.g. schools, hospitals, housing, and community centres).

Social cost-benefit analysis has attempted to incorporate social equity concerns by "weighting' the benefits (and costs) of development projects according to the income level of the beneficiaries, However, this is not a satisfactory process, because it is prone to subjective distortion, and it is more normal to keep the economic and social analyses separate, but with the economic objectives being moderated by the social objectives.

Cultural Sustainability

Culture can be defined as the self-identity and creativity of a people. It is the sum of the beliefs and customs, traditions and ways of expression, it is constantly under pressure but also it is always evolving as a society develops and has intercourse with the rest of the world.

Caribbean culture has certain characteristics. It is comparatively young, very diverse and draws its heritage from the various Amerindian, European, African, and Asian ethnic groups that make up the population. Its immaturity and the insecurities of many of its people make it particularly vulnerable to outside influences.

Cultural sustainability rests upon the recognition of these threats and requires that the arts and other aspects of culture (language, music, dress, and folklore) are not degraded, diminished or crowded-uut by foreign influences. Ideally, at the end of a development initiative the self-esteem of the people, and their culture, should be intact [3].

Political Sustainability

In the broadest terms, political sustainability involves the absence of political conflict (civil and guerrilla warfare, excessive criminal activity), democratic governance and a respect for human rights, Lack of overt conflict does not mean that the people are satisfied with their government, as there may be a very strong desire for more accountability, and for greater efficiency in the public service and in the use of public funds. Political sustainability is more than free and open elections. It means freedom of speech and expression, respect for human rights, the pursuit and practice of 'good government', the absence of corrupt government officials, honest and competent public administrators, and efficient public services.

Although the rhetoric may suggest that there are very wide gaps between the political parties, this is not really the case in the Caribbean. Most of the territories have systems of governance that are politically sustainable, despite the occasional hiccups like the attempted coups in Grenada (1983) and Trinidad (1990) and the post-election unrest in Guyana currently (January 1998).

Institutional Sustainability

The term 'institutional sustainability' refers to the procedures that are established to determine and execute government policies. Institutional sustainability is analysed on the basis of a capacity for policy making, for policy implementation, and for monitoring and enforcement.

Caribbean countries have largely followed the Westminster system of government, under which policy is formulated at the top and handed down. Policy making is initiated more by the 'collective wisdom' of the ruling party or the dictates of a Prime Minister than in response to public expressions of concern Economic policy which requires 'development assistance' from international agencies is influenced by the policy measures that the donor agency believes are in the best interests of the country, or that satisfy other agendas of the agency.

The policy making process itself has many defects and shortcomings, but these problems are compounded by the ineffectiveness of implementation. One reason is the inadequacy of the legal systems to respond appropriately with adequate laws and regulations. This is particularly the case with environmental legislation, which in the Caribbean, is by-and-large both outdated and redundant. The situation is improving, however, with the recent creation in Trinidad, for example, of an Environmental Management Agency charged with coordinating and rationalising public sector environmental activities.

In general terms, institutional sustainability involves:

- the articulation of national policy;
- the creation and encouragement of inter-sectoral and cross-sectoral coordination among agencies whose policy/development actions interact;
- the formulation or strengthening and enforcement of appropriate legislation;
- the integration of responsibilities;
- the creation of adequate data bases to support planning and management processes; and
- the provision of relevant training for staff.

Interaction

These six "pillars' of sustainability are inter-connected and the attainment of sustainability in any one is closely linked to activities in the other five. This becomes clear when the development process is examined, because it is rare when issues arise that they do not cross over two or more boundaries. For example, there is little doubt that economic activity can have a negative impact on the environment and likewise, that environmental damage will have negative economic consequences, The challenge is to promote economic activity in such a way that the level of environmental quality remains intact or that there are appropriate compensations for its loss, and that any other negative impacts that the initiatives have on the socio-politico-cultural complex are compensated for.

Although a framework is beginning to emerge for addressing the issues surrounding the different 'pillars' of sustainability, the problems of practical implementation still remain. Although there is growing need for methods of evaluating the costs and benefits of initiatives in each of the areas defined by the 'pillars the problems will not easily be overcome, at least in part because they are both cross-disciplinary and multi-disciplinary.

The best model for addressing these issues that exists currently is that of the feasibility study that is used widely in the construction industry. An effective feasibility study for a major project nowadays must include a benefit-cost analysis and an environmental impact analysis. It will also usually address issues like marketing, manpower planning, management structure, risk and sensitivity issues, foreign exchange issues and any major political, financial, social or other susceptibilities of the project to its environment. Many of these issues are only touched upon, but they do lead very directly into the requirements of the 'pillars' of sustainability that have been discussed. The emphasis of the feasability study currently, however, is more one of ensuring that a project is technically possible and economically justifiable (usually in present value terms), than that it is itself sustainable in the longer term, or contributes towards broader national sustainability. For public sector projects it should not be difficult to change this emphasis. The problems involve the practical estimation of value of damage to the environment and (even more so) to socio-cultural attributes and the implementation of procedures that can help avoid or alleviate such damage.

Summary & Conclusion

The countries of the Caribbean area can broadly be considered to be developing economically. As a result they are undergoing significant changes in terms of infrastructure, industrial structure, and economic growth. Whilst these changes have their positive aspect, they also bring with them potential problems. The problems can take the form of environmental degradation, or may by more related to unwelcome socio-cultural changes. The objective of 'sustainable development' is to try to anticipate unfavourable changes and to moderate the project parameters to try to avoid these unwanted consequences.

The construction industry is actively involved in almost all development projects. As a result, the traditional construction industry feasibility study appears to be the appropriate context for an assessment of sustainability in all its various dimensions. The process of assessing sustainability has not yet been properly developed, and it is an area in which active work is needed.

Life cycle assessment of building-components - concentration on the phase of use

Karin Gruhler
Institute of Ecological and Regional Development, Dresden, Germany

Abstract

In order to analyze and assess components according to the standard of the LCA (life cycle assessment), at the beginning of the investigation, the necessary boundary settings must be defined and described. These settings should be carefully considered between the product to be investigated and the future user (in this example the planner). For this purpose, it is required to try to get to the bottom of specific features and characteristics of components and to find out what kind of analyzing and assessment criteria are of interest for the planner or to what phases of life cycle of the components he is paying special attention.

In the LCA, there are various evaluations which, with regard to their contents and principles of consideration can be „reduced“ to two basic types of assessment. These are the product-related LCA and the company-related LCA. Because of the long life expectation of components, their assessment is a combination of product statement and operating statement.

For low-cost building and building activities with ecological awareness, not only the decrease of non-recurring expenditures (for the product) are of interest but it is necessary too, to influence and reduce the current expenditures. Thus, for the planner the company-related LCA of components is of greater importance. The company-related LCA should take into account important functional and economic aspects, which are of interest for the planner. Settings worked out in the design can be shown and assessed in the planning stage with regard to their usefulness and their environmental effects (testing of design qualities).

In this context, for the planner an LCA that emphazises the operating statement of the phase of use during the life of components could possibly be of greater importance than a merely produkt LCA.

Preliminary remarks

Building processes are linked with considerable transformations of material and energy. Proceeding from the demand to economize nature and showing environmental consciousness, persons involved in building processes are expected to cut down these transformations of material and energy as well as the resulting impacts on the environment. So, in the field of building efforts are made to influence the ecological impacts of building products and building processes. Increasingly, technologies and methods are searched for which can illustrate and assess the environmental impacts of building products and the impacts caused by their utilization. In this context, the LCA moves into the centre of discussion.

1. LCA - stage of development

LCA are tools for the analysis and assessment of environmental impacts. The phases of an LCA study are goal definition and scoping, inventory analyses, and impact assessment. Within impact assessment, there are three elements: classification, characterization, and valuation. They are to investigate, demonstrate and assess products „from-cradle-to-grave" with regard to their environmental impacts.

Within the scope of international standardization, in recent years a standard model of LCA (EN IS0 14040 - 14043) was worked out. As the LCA is related to interests and subjects and, the settings required at the beginning of each balance considerably depend on the product to be investigated and on the user (see Figure 1, next page), international standardization does not go beyond general settings and guidelines: the EN IS0 14040 *„specifies the general framework, principles and requirements for conducting and reporting life cycle assessment studies. This International Standard does not describe the life cycle assessment technique in detail. " [5].* Therefore, more detailed hints and settings (balance unit, balance limits: in factual, spatial and temporal aspect) must be elaborated by experts on the basis of the standard for various products and related to the user.

In order to assess building components according to the standard of LCA, the settings required for the investigation must be defined and described. For this purpose, it is necessary to try to get to the bottom of the specific features and characteristics of components and to find out what criteria of analysis and assessment are of interest for the planner or to what phases of life cycle of the components he pays special attention.

2. LCA - different approaches

The different approaches are similar in principle, however, differ in the mode of consideration or directions of consideration (upstream, downstream), in the necessary boundaries (scope and boundaries of considerations) and in the modes of calculation (contents, principles). The differences between the various LCA mainly arise from different subjects of consideration. In this context, product-related, process-related, company-related, business related or trade- related balancings should be mentioned. Within the scope of the ecological balancing of components, the most appropriate valuation among those possible simplifications and balancings should be found out.

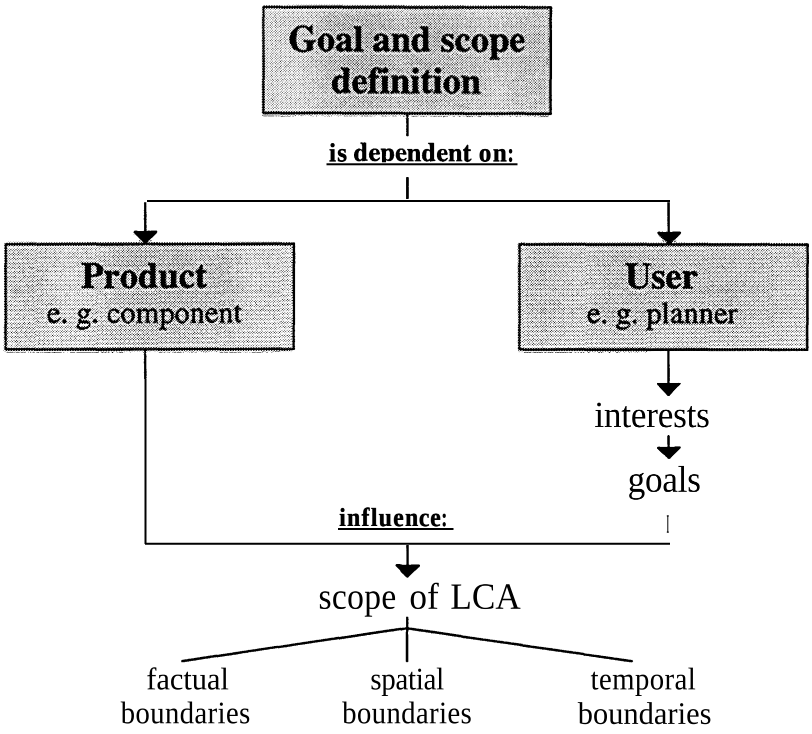

Figure 1: Dependences of „Goal and scope definition"

Though there are various and different approaches of simplifications and valuations when investigating them in greater detail, it turns out that with regard to their contents of consideration they can be „reduced" to two basic types of balancings, i.e. the product-related and the company-related LCA.

In the **LCA of a consumer product,** physical products are considered which were generated by a different number of steps of production, they can be seen as a „ready-made piece". All the relevant quantities of material and energy are calculated for a definite quantity of the respective product in the sense of a **„one piece consideration".** As the considerations refer to the total product's life, no special temporal boundaries result. A spatial boundary is scarcely possible because the product moves during its life cycle and therefore no definite site is given.

In the **LCA of companies** processes of production are investigated where one or several physical products are made. It is not the product which is in the centre of considerations, but the entirety of the processes of production of an economically independent functional and organizational unit (enterprise). To assess its environmental impacts, all the relevant quantities of material and energy are investigated, distinguished in environmental categories for a definite period of time. In general, the period of time refers to a calendar year and is repeatable in regular intervals. So the balancing is equal to a **„periodical calculation".** Due to physically given limits of enterprises or companies, a spatial delimitation can be defined easier. The relevant data are measured and investigated for an economic functional unit or organizational unit at a definite site.

To answer the question asked at the beginning, to what extent LCA can be used to illustrate and to assess the environmental impacts of components and of their use, it should now be found out what type of LCA should be used and what product-related and user-oriented specialties should be taken into account.

As shown in Figure 2 by a model, the life of components is subdivided into various phases of the life cycle.

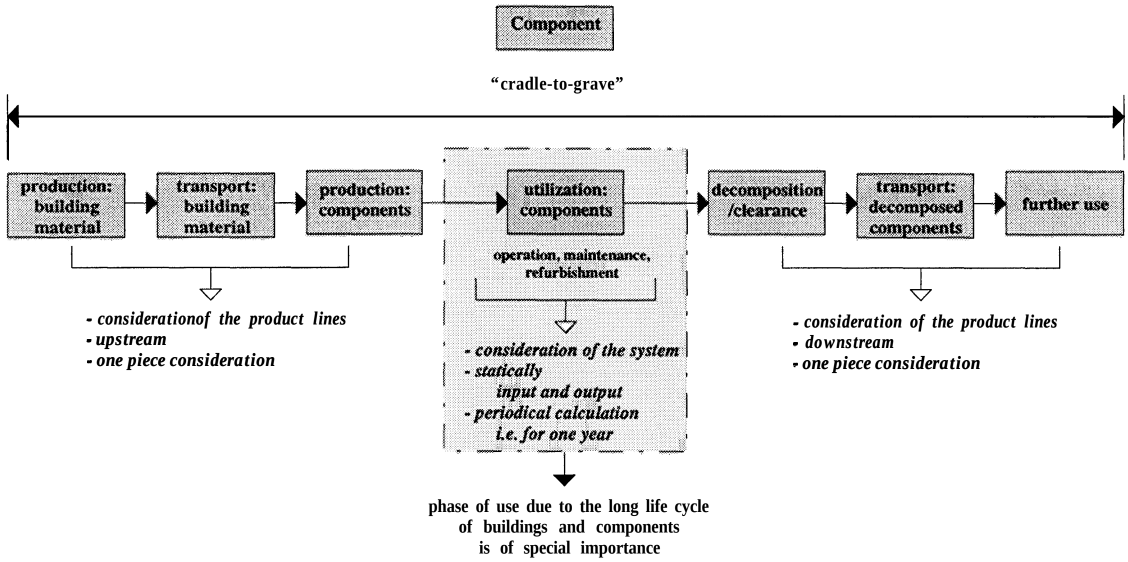

Figure 2: Various modes of consideration within the product line ,,component“

Starting from the ,,production of the building material“ up to the ,,production of the components“, the building product is considered in the sense of one piece along his product line ,,upstream“. In the phase of ,,utilization of the components“ including maintenance and repair, material and energy flows arising from the production of the components are transferred into a "stock of material and energy“. Material and energy flows which arise from the production of the components are terminated, however, flows arising from the utilization of the components occur. It is necessary to heat the buildings, to clean the buildings and to preserve and refurbish the buildings in regular intervals. Depending on the good or poor quality of the building components of the total system ,,building“ and on the functioning ,,when acting together“ (basement, floors, walls, ceilings, roof, elements which close openings), the necessary expenses will be higher or lower. Within the operating phase, the material and energy flows of the building components which arise from the utilization are in the centre of considerations. Inputs and outputs coming up are investigated in the sense of an input-output-calculation and can be periodically (e.g. annually) determined (periodical calculation).

After the ,,utilization of the component“ is finished, the building product - from decomposition to clearance - is considered again as one piece along his product line ,,downstream“ in the sense of a consideration of one piece.

3. LCA for “building components”

As a result, the assessment should always be a combination of product- and company-related. Because of the long life of the components and the total system “building” where they are integrated, the operational statement gains in significance. Here, the settings of design and production of components by the planner are shown and elucidated with regard to their long-term effects on service life. So differences in materials, combinations of building materials and principles of construction have strong influence on various aspects of the usephase, whether

- they are convenient for repair of components (e.g. uncomplicated mounting and demounting of outdated or damaged layers and parts without damaging otherlayers or parts of the components),

- they provide stability and support a long life of the components (e.g. combination of layers and parts of similar stability and durability in order to avoid mounting and demounting in the meantime and thus, additional costs),

- they offer weather resistance, protection from parasites, cleaning, chemical resistance (e.g. mounting of components which are frequently to be cleaned at places where they are accessible without great efforts),

- they allow the realization of technically perfect individual solutions (e. g. avoidance of building faults and thermal bridges),

- and disposition possibilities (connections, design) in length, width and height: with regard to the ground plan, the storeys and the sizes of rooms.

Describing these aspects, conclusions may be drawn with regard to necessary and additional measures of preservation, maintenance and refurbishment. In the phase of use they can be reflected by the expenditures concerned and give the planner indications of potential corrections to planning and implementation. In addition to the presentation of expenditures, effects can be shown which characterize and influence the appreciation of the components. So for example, different modes of construction - with profit or loss - will have an effect on the size of the living-space.

Analyzing the product “component” and the research results on the "LCA interest” and “information needs” of planners [1], the following becomes clear:

- as a result of the long useful life and service life of components and of the fact, that the functioning of a component in the phase of use can be compared with the operating expenditure of the higher system “building”, the LCA balance to be carried out is always a combination of a product-related and process-related balancing (assessment of the single and regular expenditure),

- looking at the total product’s life, a building with environmental awareness does not only mean the reduction of single expenditure (for the product) but influencing and decreasing the regular expenditure (for operation). Hence, for the planner the analysis following the principle of the company-related balancing should become the focus of attention,

- the decisiones made by the planner in the designing phase about materials and the production of components in the long run will show their effects in the phase of use. These can be illustrated and assessed within the company-related balancing (testing of designing qualities). Then the planner should incorporate into the balance such functional and economic aspects which have influence on the ecological impacts (extended operation statement).

It is scarcely possible to set up a complete and universally applicable ecological balance for components showing and assessing all the relevant environmental impacts "from the cradle-to-the-grave". As the components have to come up to functions (services), for the planner it is of interest to know the effects of coming up to these functions during the "operational phase" and where within the planning and production there will be possibilities to influence these impacts in advance. In this respect, an extended operation statement for the analysis of the useful life service of components would be of possibly greater importance than a pure output statement.

The influence of the use-efficiency on the resource-efficiency of housing

C. Deilmann
Institute of Ecological and Regional Development, Dresden, Germany

Abstract

Within the debate of sustainable development there is far to much emphasis on technical issues and to little concern about the use of services and patterns of consumption. The presentation will prove, that even without change in consumption patterns, the resource efficiency of housing can be improved more easierly by means of good housing management than by technical improvements and energy savings. The extention of the life periode of a building (durability, social acceptance) and use-factor per year (avoided vacancies, a better managed occupancy) might be a significant contribution to higher efficiency in the housing sector.

The author developed a calculation methode, which enables to compare benefits (in energy and mass flow) by better management with those by technical improvements of buildings. [1] The calculation methode is explained in the full lengh paper.

The following example of a calculation result can illustrate the approach in brief A flat that's used by a family over 35-40 years shows periods of higher and lower occupancy rates. The move of a 'remaining' widow(er) to a smaller flat can improve the use-efficiency of the "service-unit" by 10-20% depending on how long she (he) would otherwise have stayed alone in the flat. The contribution to savings in energy and materials by a successfull management of ocupancy will be in the given example more effective than an energy saving measure that reduces space-heating demand by 50% over the whole periode of occupancy of the building.

The calculation methode and the results open up the mind for the importance of housing management, of flexible housing market and building restoration. Whether materials, energy, capital and human labor are used efficiently can only be judged, when the object of concern is not the product (house), but the service (provision of living-space). So, the investment of a large housing estate in a good occupancy-management can save up as much natural resources as a thermal insulation campain for the housing stock.

Keywords: resource-efficiency, use-efficiency, occupancy-management, housing as service

1. Housing demand and housing provision

The concept of sustainable development asks the industrialized countries for a reduction in resource-consumption per capita. In the case of housing even a zero-growth-scenario will be difficult enough to reach. It means, that the relative savings per floor-area by energy conscious design and retrofit must outweight the absolut growth of floor area caused by a growing demand. It is therefore worth looking at both sides: the quality of the offered building products and the demand for housing.

The ressource-efficiency of products like houses or towns is far more determined by the consumption-periode than by the construction and demolition periode. Ecological orientated building research has always looked at the improvement of the efficiency per constructed floor area (material flows to construct and to run the building). It was mostly not questioned, whether the product is used adequate and efficient. But the extention of the life periode of a building (durability, social acceptance) and use-factor per year (avoided vacancies, a better managed occupancy) might be an even more significant contribution to higher efficiency than technical measures.

Todays lifestyles and types of households are characterized through a great variety. The classic average-type familiy belongs to the past. Households with one or two kids are in modern society a minority group. The individual passes along his life different phases. In each of those it is member of a different typ of household and is looking for an adequate place to live. This causes a great variety in types of demands, which are increasing accordingly to the differenciation of ways of living. It seems obvious, that only a more flexible housing market, an occupancy-management and incentives or support for people wanting to move can help to match the demand more closely.[2]

2. Calculation methode and examples

The calculation methode wants to illustrate the effects of good management in terms of energy and mass-flow, and pin-point the potentials of organizational measures which can guide the demand more resource-consciously

To begin the calculation, one has to define a dimension, which allows to compare different types of housing and households regardless of the ways of living. As a basis for comparison a service-unit of 35 m^2 per Person could be defined. (For the comparison it is unimportant whether 30 m^2 or 40m^2 are the basis of calculation. And: It is not at all the aim of the approach to deliver arguments for a limitation of individual consumption. A discussion that would head towards regulation of personal consumption would find no acceptance in democracy based countries.) The calculation orientates only on a comparison in terms of resource-efficiency between technical and organizational measures of housing provision. For a defined service unit one can then calculate the resource intensivness of construction, maintenance and other efforts. On this basis the resource-consumption of different uses of a given service-unit will be calculated.

First one multiplicates over the life-cycle of a dwelling the different occupancy-periodes in years (a) by persons (P) and the agreed service-unit-area (m^2/P) and adds them up to a total theoretical floor-area consumption. By division with the total time of the cycle one gets a floor-area-equivalent ($Wfl_{äq.}$).

$$\sum (35\ m^2/P \cdot P_{1\ldots} \cdot a, \ldots + 35\ m^2/P \cdot P_n \cdot a_n) / \sum a_1 \ldots + a_n = WFl_{äq.}\ [m^2]$$

The division of floor-area-equivalent $(Wfl_{äq})$ by floor area of the dwelling leads to the use-intensity of the dwelling (NIPWS). (Tab. 1, 2)

$$\frac{WFl_{äq} \quad [m^2]}{WFl \quad [m^2/WE]} = NIPWS \; [-/WE]$$

Household	**years**	**Persons**	**P · 35 m²**	**P · m² · a**
Couple + 2 Kids Couple + 1 Kid Couple Widow(er) Vacancy	14 2 14 10 0,25	4 3 2 1	140 105 70 35	1960 210 980 350
	40,25	100 Pa		3500
floor-area-equivalent			86,95	
use-intensity	1,087			**NIPWS**

Tab. 1: flat with 80 m² - family-cycle without move-management

Household	**years**	**Persons**	**P · 35 m²**	**P · m² · a**
Couple + 2 Kids Couple + 1 Kid Couple Widow(er) Vacancy	14 2 14	4 3 2	140 105 70	1960 210 980
	30,0	90 Pa		3150
floor-area-equivalent			105,00	
use-intensity	1,312			NIPWS

The use-intensity and the resource-efficiency per offered service-unit increases by 20 %.

Tab. 2: flat with 80 m²/WE - family-cycle with move-management

In a second step one multiplicates use-intensity with material-input for building construction, maintenance (in kg) and the energy-use (in SKE -coal- kg). The result is the specific material intensity per service-unit and year (in t/WS·a). (Tab. 3)

The data base for input is here an average over different types of construction in Germany (mostly solid, heavy-weight construction). It doesn't contain sideeffects of previous process-chains or soil movements.

The energy consumption represents the average input for space-heating, warm water and electricity in Germany. It is primary energy, including the energy that was needed to win the fuels. The data was then converted into coal equivalents (kg).

flat -30%-10%UI.	21,2	22,9	70	99,0	1,498	1,619	3,117

Abbreviations:

(1)	=	energy standard 1994
flat 100a	=	flat with life-expectation of 100 years
flat- 10 % UI	=	same flat with decrease in use-intensity by 10 % through vacancies
flat - 30 % space.h	=	reduction of energy use for sate-heating by 30 %
flat - 30 % -lO%UI	=	sate-heating - 30 % and Use-intensity minus 10%, taking in account, that the unoccupied flat is only "passiv" (by neighbours) temperated

Tab. 4: Comparison of the effect of vacancies and of energy-saving measures in terms of the resource-efficiency per flat (in tons per year and flat)

3. Conclusion

If in this given example the widow(er) can find an other smaller apartement and is prepared to move, it will increase the possible use of the former flat by 20%. (Tab. 2) Interesting is, that a move-management might bring more increase in resource-efficiency than the prolongation of the building-life-time by 50%. It is even as effectiv as a 50% energy-saving measure in space-heating through thermal insolation over the whole lifetime of the building or the energy-conscious selection of building materials (Tab. 3).

Further examples can prove the effects of vacancies in housing stock in terms of waste of resources. (Tab. 4)

As part of the housing policy the german government offert in the past six years a phantastic tax-incentive for investment in housing projects in eastern germany. As a result, yearly housing production increased by almost 50 % compared to 1988. At the same time the dramatic economic change in eastern germany did set off a migration from east to west germany. Today some municipalities and housing associations have vacancies in their housing stock of 15-20%. In the whole of east germany 500 000 dwellings are unoccupied, a tremendous waste of money and resources.[3]

If 10% of dwellings in a block of flats are unoccupied, or a flat is only over 90% of it's lifetime occupied, then energy-saving measures of 30% are outweighted by the effect of vacancies, because the loss of use is put on as a burden to the remaining flats. It means as well, that about 1,7 tons of building materials per flat and year are "consumed" without use. From this point of view one can say, that even an unoccupied flat emitts 1 ton of CO_2 per year in form of lost energy-input in materials and uncontrolled passiv heating. This takes even into account, that the flat is only passiv temperated by the neighbours. In the case of east germany this means a waste of 830 000 tons per year.

There will be great differences in significance of the issue for the different european countries, because of their different housing policies and loan-systems. But the calculation can show, that a good occupancy-management or a flexible housing market can in any case be an important contribution to higher resource-efficiency in the housing sector.

Environmental seal of quality for buildings - European experience

A. Blum, C. Deilmann, F.-S. Neubauer
Institute of ecological spatial development, Dresden, Germany

Abstract
The dynamic character of the concept of sustainable development requires in the building sector a continuous improvement of the specific environmental performance. Ecological construction, that goes beyond general standards therefore needs voluntary engagement at the highest possible level. At the same time outstanding ecological "better-practice" in the construction industry can not sufficiently be distinguished from the growing number of exaggerating private eco-labeling. The (self-)declaration "Ecological", "Environmentally Friendly" or "Sustainable" building(-product) often appears widely arbitrary or highlights just single aspects of the overall environmetal impact of a building.

Therefore in the center of the here presented project stands the question, to what extend a neutrally embodied "Environmental Seal of Quality for Buildings" can contribute to solve this problem and which conceptual demands are to be set up for such an instrument.

For a best practical use and a contribution to further development and harmonization the approach will base on existing instruments. In a first step already practised attempts and existing experiences were documented, evaluated and compared. In the inquiry were included experiences from the FRG, Great Britain and the Netherlands. The analysis covered systems of indicators, methodological construction, methods of implementation, framing structural social, political, cultural and economic conditions, addressee and stratgies of marketing as well as the degree of independence, frankness and transparency of the methodology itself. Parallel to these empirical works fundamental conceptual aspects of eco-labelling were explored theoretically.

The paper sketches the essential theoretical basics and empirical cornerstones of an instrument, that serves as a guidance for the target groups (planner, clients, owner, user, financiers) and as a tool for strengthening the competitiveness of extraordinary voluntary environmental performance in the building-practice.

Diskussed are questions of institutional embodiment and conceptual elements like handling comprehensive sets of criteria for evaluation (e. g. "dual-track-approach": symbolic "signaling" with detailled information available in the background) or ways of marketing-effective and social respected awarding (e. g. certification and labeling under involvement of social groups of interest).
Keywords: Building, criteria, ecology, eco-labeling, environmental assessment, evaluation, marketing, sustainability

1 Introduction

The dynamic character of the concept of sustainable development requires in the building sector a continuous improvement of the specific environmental performance. Ecological construction, that goes beyond general standards therefore needs voluntary engagement at the highest possible level. At the same time outstanding ecological "better-practice" in the construction industry can not sufficiently be distinguished from the growing number of exaggerating private eco-labeling. The (self-)declaration "Ecological", "Environmentally Friendly" or "Sustainable" building(-product) often appears widely arbitrary or highlights just single aspects of the overall environmetal impact of a building.

In addition even the scientific basis of the ecological assessment of buildings is still uncertain. Because of the complexity of the structure of effects in the environment, possible side-effects and effect-chains are by no means finally recognizable. Still more difficult is a weighing of the different effects and side-effects.

In the everyday-practice genuine innovative building practice therefore can often not realize market-advantages when competing with simple "green-washing". With the growing common european market this problem furthermore tends to become a question of supranational regulation and equal opportunities in the European competition.

The support of exemplary ecological performance therefore requires a continuous further development of scientifically found and socially acceptable orientations for the estimation of the ecological effectiveness of the construction industry and their products as well as incentives to their transformation into everyday-practice. Therefore in the center of the here presented project stands the question, to what extend an "Environmental Seal of Quality for Buildings" can contribute to solve this problem and which conceptual demands are to be set up for such an instrument.

For a best practical use and a contribution to further development and harmonization the approach will base on existing instruments. In a first step already practised attempts and existing experiences were documented, evaluated and compared. In the inquiry were included experiences from the FRG, Great Britain and the Netherlands. The analysis covered systems of indicators, methodological construction, methods of implementation, framing structural social, political, cultural and economic conditions, addressee and stratgies of marketing as well as the degree of independence, frankness and transparency of the methodology itself. Parallel to these empirical works fundamental conceptual aspects of eco-labelling were explored theoretically. The results are brought together to a blue-print or framework for a comprehensive general "Environmental Seal of Quality for Buildings".

2 Why an eco-label?

It is a fundamental phenomenon, that observable features of a product in general have a stronger influence on market decisions than rather hidden characteristics. This potentially causes a continuing "adverse selection". In consequence buildings or building-concepts with extraordinary environmental (and health) characteristics can not use their higher quality to succeed on the market as they should do. This problem especially is expected to arise in the case of 'Innovators', which newly appear at the market with their products [Rubik et al.]. At the same time however 'Innovators' are required, since existing standards of environmental quality and performance in the construction industry are to be greeted of course as first steps, but do not suffice for a development of the building stock that is oriented towards the concept of sustainability.

Innovative developments can not or at least only on detours be supported by normative regulation (e.g. if actors are threatened with more restrictive legal standards to be expected in future). ‘Soft’ instruments like (financial) incentives, information and advice can be brought together in an environmentally oriented product-labelling. Environmental labelling therefore fundamentally offers the possibility, to support particular ecological performance on the building market. On one hand the supplier is given the possibility, to point out their particular ecological quality (“Signaling”). On the other hand the demand-side gets a first orientation about often invisible and rarely tangible qualities, which can so be included into the decision preparing information gathering process (“Screening”).

Different demands are to be fulfilled (criteria of ‘usefulness’) to let eco-labelling become effective.

First of all the target group of an eco-label must have a lack of information concerning the particular environmental qualities of a product. Such a deficit can be absolute (because of the innovativ character and the novelty of a product) or arise, if the required informations exist in principle, but however can not be processed by the individuals because of their multitude. Regardless of the reason of the actual deficit of information the requirement of information rises with the involvement which again rises with the longevity and the price of an asset. Trying to come to environmentally oriented decisions in the construction industry these aspects all become noticeable. Therefore it can be assumed, that from principle there should be a high demand for an environmental labeling of buildings.

To satisfy this requirements the mark or seal of quality must dispose of different characteristics. Generally we can say, that it mediates between the poles of “no information” and “information-flooding” by transforming the factual necessary information-input into an acceptable information-output. According to the concept of the label this transformation contains a more or less strong condensation of the information-input.

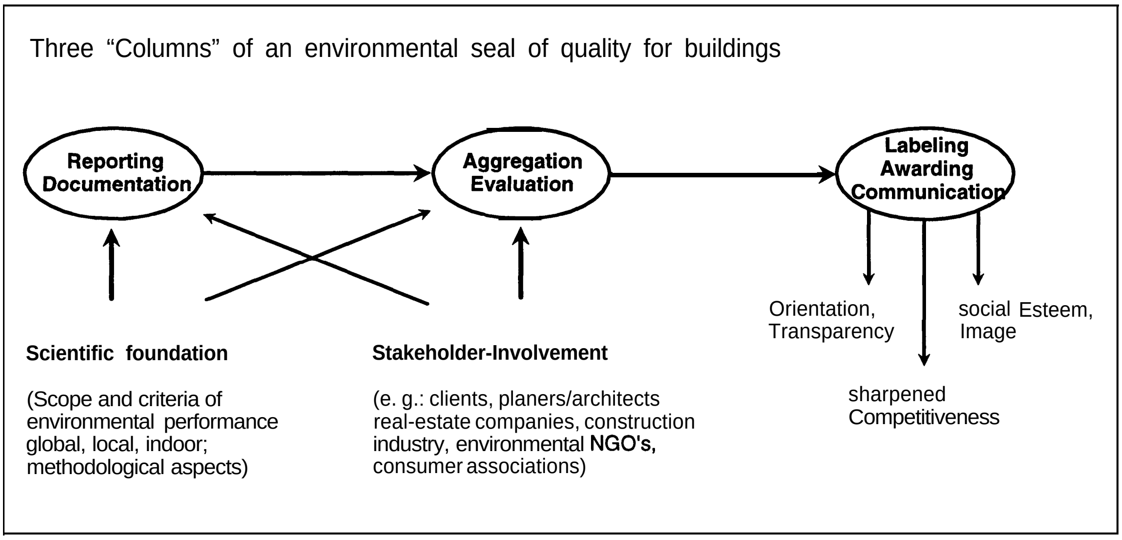

Fig. 1: The main elements of an environmental label for buildings (Blum, 1997)

On the input-side (Fig. 1: Column 1, “documentation”) first of all environmental labeling must record the material relevant environmental impacts as completely as possible. In the case of estimating environmental impacts of buildings this means for example to broaden the product-related scope with site-specific criteria. Especially regarding the concept of sustainable development it can furthermore be necessary, to include aspects of social usefulness and economic feasibility. In addition and since environmental impacts are by no means completely and finally recognizable even a seal of environmental quality with a comprehensive scope has to remain open for revision and adaptation of the used framework of criteria.

The completeness of the recorded information is an important condition of the acceptability of the instrument for the target group of the labeling. But indeed the criterion of completeness hereby is not only related to the actual fact of scientific knowledge but also to the specific requirements of the target group, to the relevance and usefullness of the information. The different possible levels of the aggregation or condensation of information within the process of product-labeling are corresponding with different demands on the recipients of the information. In the case of complex information that is not aggregated at all or aggregated only to a small extend a considerable effort is necessary for the interpretation and drawing of conclusions ("think yourself "). For various reasons (time, required background of knowledge etc.) in general this effort is hardly to handle in the every-day-practice. Highly condensed symbolic information (the typical symbolic eco-label) represents "pre-thought thinking". It requires to a wide extend the (blind) trust of the adressee of the information in the processed expertise. Labels of this type suit especially "for consumers with low involvement and for decissions concerning the purchase and use of products with low information requirements" [Rubik et al.]. Accordingly such symbolic labels alone will not be sufficient for the purpose of representing extraordinary environmental quality and performance of buildings. Rather instruments are needed in the practice of planning and building, that are able to give a quick orientation but at the same time keep accessible detailled information in the background if required. Thereby the instrument gains transparency and it is to some extent made possible to "follow the thoughts" while at the same time the necessary efforts for coping with the information are limited to a bearable extend. Moreover the transparency of steps of aggregation and evaluation (Fig. 1: Column 2) helps to strengthen the credibility of the labeling instrument.

Credibility is a further criterion of the acceptability of a seal of environmental quality. Beside the transparency of the instrument its credibility depends essentially on its institutional embodiment and probation and furthermore on the degree to what it is known to the public. It is directly obvious, that individual, company- or even product-related labels are recepted as less credible as such, which are organized through neutral institutions. This especially when the latter dispose of corresponding knowledge and reputation.

Looking from the point of view of the suppliers of extraordinary environmental performance ("applicants for labeling") an eco-label first of all should be acquired with acceptable expense and secondly emphasize the positive features of the offered product in a marketing-effective way. A seal of environmental quality fundamentally meets this requirements, since it does not enact a duty of declaration, but offers a voluntary instrument. By awarding only outstanding performance it helps to distinguish from other competitors. At the same time however thereby is said, that a labeling-approach is not suitable to separate out environmental unfriendly practices. The expense for the applicants for labeling is dependent on the applied concept of labeling. Here are some differences, which are presented in the following section.

3 How do existing approaches work

It is a common asset of already practised methods for the estimation (and awarding) of the environmental performance of buildings, that they do not wait for a last scientific clarification or evidence proving the one best way of ecologically correct building production. They rather emphazise, that despite uncertainty and scarce time-ressources nevertheless a consensus-based "better practice" has to get started and must be supported. Corresponding instruments build on a combination of scientific knowledge and political objectives of the institution that holds the label. The latter aspect once again refers to the significance of the institutional embodiment for the performance of an environmental seal of quality.

(Environmental) seals of quality for buildings are today already found with very different backgrounds. First of all three types of organisation can be distinguished by the degree of their public embodiment:

- Purely private eco-labels which are tailored to a special product of an individual company (e. g. a certain type of prefabricated building)
- Half-public eco-labels managed by superordinated (public) commercial associations as for example the so called "Quality-Communities" in the case of the german RAL-Quality-Certification and designed for a product line (e. g. wood-frame construction)
- Public or publicly authorized eco-labels (e. g. the german "Blue Angel", state-organized environmental competitions)

With each of these different approaches respectively different interests are joined:

Product-related private eco-labels try to reach an advantage on the market for the special product as directly as possible and with the slightest possible expense. "Seal of quality" may mean here, that terms like "Low-Energie-House" or "wood-frame construction" for instance are stiled to an inclusive symbol of environmental performance through corresponding advertising and often graphic emphasis although the underlying facts cover just single aspects at best. Of course there might as well be true environmental engagement to be found behind private eco-labeling, but the public acceptability however will allways be smaller, since the label will not be easily be able to prove its necessary objectivity.

Half-public eco-labels, for example in the administration of commerce-oriented public corporations, as well intend to further the competitiveness of the applicants for labeling. At the same time however the competition among the participants as well is stimulated through the independence of the label from individual firms and products. The primary objective is not to improve the chances of an individual supplier on the market, but the improvement of the transparency within a (qualitatively outstanding) segment of the market. Commercial but not company-related superordinated seals of environmental quality offer the applicant for the higher expense a higher credibility and with it a higher effectiveness.

Public eco-labels first of all aim at the advancement of initiative and innovation. Since especially innovative attempts frequently have to face disadvantages on the market (the phenomenon of "adverse selection") one can speak of an attempt of market-regulation if together with the outstanding environmental quality of a building or building-concept also a certain supplier is awarded. With the help of a seal of environmental quality the public intervenes in the competition of the market. An other case is given, if together with a (single) building at the same time the respective household or more generally the user (client or occupant) is awarded. So on the one hand we have the objective to support an outstanding and exemplary product and supplier and on the other hand the support of an exemplary (consumers) behaviour. Thereby this behaviour may also include the production of a building if this happens for the own use and not for the market ("user-client"). A distinction in this case primarily aims at social appreciation of an altogether exemplary conduct, but can however also be joined with the grant of individual advantages. Conceivable are here for example the award of state subsidies or also relief at the contact with the (building-)administration.

The different existing (authorized) approaches of (environmental) seals of quality for buildings now however do not only differ in the type of the institutional embodiment, but essentially also in their conceptual construction. The following fundamental elements can be derived in different combination from the up to now explored instruments:

- Certification based on a so called "building-passport" (formal frame of the documentation of technical and ecological data, partly under account of qualitative data).
- Completion of the "building-passport"-approach by adding extended technical documents and references for the use of the building ("operating instructions").
- Method of political appraisal. Offensively substantiating the selection of criteria according to political objectives on the basis of preparatory expert- and stakeholder-involvement
- Scoping and gathering of criteria under participation of stakeholders / "interested circles".
- Combination of building-ecology- and building-biology-related (concerning health of users) criteria.
- Linkage of the evaluation of technological and environmental quality.
- Modular construction of the programme of evaluation. The catalogue of criteria is subdivided in obligatory and additional voluntary elements. The certificate then refers to the chosen scope of evaluation.
- One-dimensional approach (e. g. use of energy) but very dedicated objectives in detail (e. g. high rates of reduction of the output of CO_2) as pragmatic attempt.
- Deviations from standing norms and rules (e. g. in the case of innovative building technology or materials) are documented and regulated in private contracts.
- Methods of relative evaluation. The scale is not defined by (individually) alleged objectives or limits. Measured is the extent to wich existing average environmental performance is met or exeeded .
- Temporal limitation of the validity of the certificate/award.
- "Cheque-book"-method for the organization of contacts with executing companies ("cheques of quality": quality demands, documentation of execution) as well as with a (contracted) office for advice and certification ("cheque of certification"). This method was introduced referring to a repeatable building-concept.
- Inclusion of the period of the use of the building into the evalution. Linkage of the assessment of the environmental quality of the product (building) and the ecological responsibility of the consumer (owner/occupant of a building). Special emphasis hereby is given to the aspect of social appreciation of good examples.
- Opportunity of developing the evaluation-method into a component within a tool for building-/facilitymanagement.
- "Positiv List" of ecological friendly building materials as an element of the criteria of

evaluation as well as of good advice.

- Certificates of evaluation in some cases completed by symbolic elements (e. g. "Green Street Number").
- Combination of the evaluation/certification with a competition, that promises further public awarding of the most outstanding examples ("the Best of Best").

4 Drafting the basics of a general environmental seal of quality for buildings

The first overview over existing approaches of evaluating and awarding environmental performance within the building sector elucidates their heterogeneity. The main differences are found looking at the systems of criteria/indicators and the above sketched conceptual particularities. The span of the possible sets of criteria ranges from single-media-oriented approaches (soil-sealing, use of energie) over media-integrated "ecological" (land-use, water, air, resources . ..) up to sustainability-oriented attempts (trying to integrate ecological, economical and social questions).

In order to distinguish and award outstanding voluntary performance in the building sector the scope of a comprehensive environmental seal of quality should be as wide as possible. Even aspects of social usefulness and economic feasibility may be taken into account when the longevity of buildings, their impact on the environment and the concept of sustainability are to be considered. Furthermore because of the interaction of the building with its (direct) environment/surrounding the used framework of criteria has to be open for the inclusion of site-specific criteria.

For the practical use of an environmental seal of quality it should be helpful, to evaluate environmental features together with more general aspects of building-quality. Hereby interrelations are given to the discussion on "Total-Quality-Management" in the construction industry (linking of environmental-, quality- and safety-management).

At the same time however a comprehensive scope leads to the problem of handling the instrument. With the extent and the complexity of the system of indicators increases the effort of recording and documentation for the applicants for labeling as well as the effort of interpretation and conclusion for the target group. Of course the effort of interpretation can be reduced by aggregating and condensing the numerous indicators to a symbol, but at the same time however the instrument will lose transparency and thereby credibility. This counts especially for such complex products like buildings. Conceptual approaches have to be found, which face this dilemma. But by no means too pragmatic attempts, such as structuring the instrument along the disposable data-sources, should be pursued.

A possible approach is for example, to use a comprehensive system of indicators within a modular concept, that differentiates the aspects to be considered according to the particular case and circumstances. Unquestionable such an approach (of "conscious chosen incompleteness") should be prefered in comparison with short-sighted pragmatic attempts. It also offers great advantages concerning the credibility of the evaluation(-instrument). In the first case the aspects, that were not considered, remain as a future duty, while in the second case the gaps of the consideration come to the fore either not at all or at best by chance. Another possibility of handling a complex information input is a "dual-track-approach". Hereby selected criteria can be aggregated and condensed to a symbolic eco-label while a the same time in the background comprehensive information is kept available. Such a construction especially is recommended in the case of complex products like buildings with high "consumer''-involvement, where consumers are expected to ask for detailed information. A “dual-track-approach” offers the addressee of a seal of quality a symbolic pre-interpretation (like the british “Green-Home standard award”) and at the same time reduces the dependence on experts by allowing own conclusions on the basis of comprehensive background-information (e. g. so-called “building-pass-ports”).

The decision for (selected) criteria that have to be refered to within an evaluation method is allways a political decision. It may be be prepared but not replaced by scientific work. Therefore the used scope and systems of criteria must be open for regular revision and/or adaptation. It is important for the meaning and effectiveness of the instrument who is entrusted with this process of criteria-gathering and -revisiting. Fundamentally one can distinguish the work of an internal or external commission of experts from a jury-process under participation of social groups of interest / stakeholders.

Public instruments certainly should prefer a jury-process. A well known example is the german “Blue Angel”, which though is occasionally critizised for its too little dynamic. Beside the regular revision and adaptation of the scope and criteria the dynamic character of an environmental seal of quality for buildings schould furthermore be ensured by a suitable form of temporal limitation of its period of validity. Only by this way the currently most outstanding environmental performance of building-practice can be distinguished and awarded without devaluating earlier examples.

Regarding the above sketched essential cornerstones we can go further to develop an instrument, that serves as a guidance for the target groups (planner, clients, owner, user, financiers) and as a tool for strengthening the competitiveness of extraordinary voluntary environmental performance in the building-practice.

Project Management - the agent of sustainable production?

D. Baldry
Research Centre for the Built and Human Environment, University of Salford, Salford, United Kingdom

Abstract
The construction process follows an identifiable life cycle, beginning with the initial conceptualisation by the project sponsor, through to the commissioning and operation of the completed facility, and ending with ultimate demolition and disposal or refurbishment and remodelling for an alternative use. Project management is that discipline which is engaged for the greater part of that lifecycle and occupies a unique position to exercise influence over the conduct of the process and the characteristics of the product. This function provides project management with the opportunity to be significant in the determination of design criteria, methods of production, resource allocation, and operational standards, and the identification and analysis of risk. As such it may be argued that the discipline of project management may be the primary agent for the realisation of significant change in the manner of construction to achieve objectives of sustainability whilst meeting the performance requirements of the project sponsor.

This paper examines the influence of the project management role as follows:

- the means by which consonance may be achieved between the expectations of project sponsors and the capability to conduct the project in a sustainable manner
- how the comprehensive relationship between the project manager and the project over its lifecycle may be exploited to achieve significant change in the planning, resourcing, and execution of the production process
- how conflicts and ethical dilemmas which occur in the project process may be satisfactorily resolved, and how project risks may be identified and interpreted and their impacts influenced, whilst maintaining the pursuit of sustainable construction

This discursive paper has been based upon a review of contemporary literature in the fields of project management, sustainability, and risk management, and applied to the context of construction practice. The argument is proposed that the pivotal position of the project manager in the project process, and the vital relationship which occurs with the project sponsor, result in the project manager becoming the most likely agent for the realisation of sustainable construction practices. The paper concludes with the identification of the profile of a sustainable construction project which is more likely to be realised as a consequence of the influence of project management.
Keywords: construction, project management, project manager, risk, sustainability.

1 Introduction

The construction of buildings invariably results in the extensive, often profligate, consumption of resources and materials, and substantial, often irreversible impacts upon landscape, amenity, and ecosystems, whilst meeting social and economic needs for shelter, investment, and the satisfaction of corporate operational objectives. The process of construction can be seen to pass through a recognisable life cycle from the original conceptualisation of the project by the project sponsor, through construction and commissioning, to eventual occupation and operation up to the point of evacuation, demolition, or renewal and refurbishment. This cycle is largely the subject of project management which seeks to achieve the realisation of the built entity, primarily in a manner consistent with the needs of the project sponsor, but increasingly in a way which meets the expectations of an increasingly diverse and influential body of project stakeholders [1]. These stakeholders will hold a range of expectations of the project and employ a diversity of performance criteria against which the success of the project will be measured. Increasingly the ability of a construction project to meet objectives of sustainability in its design, formation, and operation are coming to the fore.

An essential element of the project management role is the resolution of conflicts and ethical dilemmas which arise when stakeholder objectives are not in concordance with each other or all capable of mutual satisfaction. In particular the project manager is responsible for advising upon or executing critical project decisions, including specifically the opportunity to promote a sustainable approach to construction activities, which would be undertaken within the context of explicit project sponsor requirements which will vary in their degree of support to a sustainable approach. The issue to be debated in this paper is to what degree the project management discipline may be the active champion and implementer of a sustainable approach.

2 The role of project management

There is a growing awareness that industrial and business practices will have the most significant impact upon the future well-being of natural systems. It has been that noted (2) that *"sustainable development....... recognises that economic growth and environmental protection are inextricably linked, and that the quality of present and future life rests on meeting basic human needs without destroying the environment on which all life depends"*. This view identifies a critical responsibility that is placed upon those responsible for structured productive activities to execute these in such a way that there is a commonality of interests and expectations amongst both industrial and environmental sectors.

The extension of the above argument is that the role of project management for construction is the planning, acquisition, and application in a controlled manner of all the resources, both material and intellectual, needed to bring about the organisational objective of creating a built entity, in such a manner that does not consume resources in a wasteful manner, has at worst a neutral visual impact, and does not become the source of unacceptable emissions.

The role of project management in construction is to act for the project sponsor in such a manner as to seek to optimise performance criteria in respect of the technical performance, investment realisation, and operational satisfaction of the completed facility. This pursuit of optimisation inevitably results in the sub-optimisation of certain outcomes which may include environmental impact. However the success criteria for evaluating project performance is increasingly extending beyond compliance with technical standards to embrace some degree of social responsibility and demonstration of ethical behaviour. Sustainable construction practices are capable of being delivered in a project context where a condition of mutual benefit can be created. Where a sustainable approach can be recognised as coincident with sound business practice then a natural stimulus for this occur will be present but the mobilisation of ethical behaviour can receive further impetus from such drivers as state legislation, market incentives, and stakeholder pressures (3).

Each of these spheres of activity present the medium in which the pursuit of sustainable construction may occur and demonstrate the potency of the project management discipline to exercise influence over the environmental impact of the construction process at a number of levels and on a range of occasions as it exploits its significant position to determine critical principles of execution. This role may, however, present ethical, professional, and managerial issues arising from the project manager/stakeholder relationship where there is little coincidence between the commercial, technical, and functional requirements of the project and the promotion of sustainable means of delivery and the diminution of environmental impact.

3 The case for sustainable construction

Any rational case for the promotion of sustainable construction practices must initially be founded upon an ethical justification, that is *"the attempt to apply moral theory to the human treatment of natural objects"* (4). This basis is further reinforced by the views of the environmental pessimists that changes in patterns of consumption, recycling, and conservation of resources are vital for the long term viability of mankind (5). However this gloomy prognosis is neither universally recognised or accepted, resulting in sub-optimisation of resource utilisation and environmentally efficient practices. The ultimate stimulus towards the wider acceptance of environmentally sensitive practices is only likely to occur when such approaches become coincident with good business practice. The position that *"good business is good ethics"* (6) seems to be powerful and engaging even though the reverse of that position is frequently not found to be true.

A critical role of the project manager who is charged with the responsibility for achieving the realisation of a built entity is to resolve the conflicts and ethical dilemmas which emerge and to make critical strategic and executive decisions, many of which will have a profound impact upon the sustainability profile of the process. For the construction process to achieve a significant orientation towards sustainable practices an adaptation of Thorsby's principles ('7) is of value:

- *advancement of material and non-material well-being* - the development of buildings not only as stores of value and generators of economic activity but also as promoters of enhanced standards of health, education, amenity, and security

- *inter-generational equity* - modifying the land and executing buildings in such a way, and employing such technologies, as to leave no hazardous or wasteful legacy for future generations
- *intra-generational equity* - conducting the process of development and construction in such a manner as to be an instrument of equnable trading practices and resource distribution
- *protection and maintenance of ecological processes and systems* - the design, management and execution of a constructed facility in such a way as to protect, value, and cherish, even enhance, local environments
- *dealing cautiously with risk and uncertainty* - adopting a cautious and well-informed approach to risk identification, assessment, and exposure, which arise from construction activity, particularly where an environmental risk impact would be harmful
- *recognition of global dimensions* - adopting practices for resource acquisition, energy consumption, and emissions control which are not harmful or damaging either locally or beyond national boundaries

The above implies the prevailing view that there is an inherent conflict between commercial and environmental interests in which the commercial or organisational benefits arising from a project accrue to the project sponsor whilst environmental costs are defrayed over a widespread population and ecological system The project manager holds a pivotal and influential position in the project delivery process and thereby acquires the opportunity and means to establish a balance between commercial and environmental interests and to be innovative in promoting sustainable practices as an important component of the commercial process of construction.

4 The project management of sustainable construction

The project management function is that which is consistently present throughout the life cycle of the construction project process and as such holds a unique position of influence over the manner in which a project shall be conducted. The project manager is central to the decision and information passing network of the project and has a direct relationship with the project sponsor. The project manager executes his responsibilities by means of the powers vested in him which are derived from a combination of the formal powers transferred to him from the sponsor and the influence he is able to exercise over other participants in the project process. The extent of this influence is determined by the personal effectiveness of the project manager and the degree to which the ambitions and objectives expressed by him are accepted and endorsed by others. The project manager's function is to search for points of agreement, to examine the situation critically, and to think reflectively, and only then to take a decision based on the perceived superiority of his knowledge (8).

The implementation of the principles of sustainable construction can only be achieved where there is an active acceptance of the concept by all participants in the project process, primarily the project sponsor and key members of the design and production team, operating under the motivational and directional influence of the project manager.

Historically the realisation of a constructed entity has been interpreted as an application of technological actions and processes which present an array of technical solutions from which a considered selection can be made. The adoption of a sustainable approach has the effect of eliminating some options, generating new alternatives, and modifying others. The application of technology is not always benign and exponential technological growth can not always be relied upon to create an ever-expanding resource base ahead of demand. Effective leadership emanating from the project manager who enjoys the support of an enlightened project sponsor and is empowered with the appropriate level of delegated authority to direct the design, procurement, and construction process, is the manner in which appropriate technologies may be harnessed in the pursuit of sustainable construction.

The direct relationship which exists between project manager and sponsor offers the opportunity for critical policy decisions to be made during the project life cycle which can form the pathway for project delivery based upon sustainable methods and minimal environmental impact. The key contributions made by the project manager can include:

- The provision of leadership and direction to the project process to establish a project team culture consistent with the intention to conduct a project in a sustainable manner
- The articulation of clear goals and project outcomes in terms of sustainable construction processes
- The identification, appointment, and assembly of a construction project team of like-minded collaborators to further the realisation of the sustainable objectives
- The influencing of the project sponsor towards the opportunities and benefits of a sustainable approach and how this may promote enhanced value and user satisfaction
- The establishment of the guiding principles by which a project may be delivered in a manner consistent with sustainability and ethical responsibility
- The planning of a procurement and resource acquisition route based on equitable commercial relationships and the pursuit of efficient resource conversion

These contributions are consistent with the 'precautionary principle' that demands th.at preventative action should be taken to avoid environmental damage as far upstream in the project delivery process as possible, a function which falls directly to the project manager who has the empowered opportunity to determine the design and manner of construction of a built entity.

5 The management of the risk of project non-compliance with sustainability

General risk has been defined (9) as *"exposure to the possibility of economic or financial loss or gain, physical damage or injury, or delay, as a consequence of the uncertainty associated with pursuing a particular course of action." An* extension of this definition may be that which encompasses the prospect of a construction project falling short of standards of sustainability which are being sought. The risk impact of such a shortfall would be distributed over a wide range of recipients, the majority of whom did not voluntarily place themselves at such risk. Risk management, or the process of dealing with risk, implies some form of measurement of uncertainty based upon informed predictions of outcomes.

For a construction project the environmental impact of certain processes or activities may be predicted with confidence and certainty, others may be chance outcomes dependent upon a host of operational variables. The greatest uncertainties occur during the early conceptual phases of a project when decisions of the greatest impact upon project outcomes are concluded (10). Risk management of sustainability may be viewed as a three stage process:

- Risk identification - the recognition and assessment of the environmental risk impacts which are expected to occur as a direct consequence of intended construction activity. Once a risk has been identified it becomes a quantifiable managerial problem
- Risk analysis - the disciplined gathering of data to permit the systematic and reliable interpretation of the probabilities of environmental risk impacts occurring and the scale of their impact. It is likely that a range of occurrences will be identified which are likely to present a spectrum of potential risk impacts upon the environment as a direct consequence of construction project activity.
- Risk response -the development of an appropriate response to the identified and analysed risks to the environment in order to seek to mitigate or eliminate the adverse effects by the promotion of sustainable practices

The response to the potential for environmental risk occurrence can take a number of forms dependent upon diverse factors derived from the orientation of the project sponsor and the project team towards the objectives of sustainable construction, the dynamics of the economic, legal, and social context in which the project is to take place, and the scope for risk impact mitigation, transfer, or avoidance. These factors can be generalised as:

- awareness of the impact of risk events beyond immediate project boundaries
- capability to recognise both generic risks and project specific risks
- level of expertise in risk evaluation techniques
- ability to evaluate unique risks or benefits arising from novel procurement, resourcing, or execution arrangements

For commercial organisations the impact of the incidence of almost every risk event can be measured in financial terms as the effect upon turnover, market share, and profitability, even if the initial risk impact falls upon an operational feature such as product or service quality, reputation, or technological advantage. In the context of sustainable construction activity a risk impact will occur at a number of levels:

- specifically within the boundaries of the site or existing building e.g. material conversion inefficiencies, hazardous processes, energy intensive product
- locally in the immediate environs of the location of construction activity e.g. vehicle movements, building emissions, aesthetic impact
- remotely where the demands of the construction process influence methods of resource provision e.g. material extraction, transport movements,

The authoritative and influential role of the project manager allows for the establishment and implementation of measures to identify and analyse the prospects for risk occurrences which may arise and which would conflict with the expressed aims of sustainable construction. It is the project manager who holds the organisational role and capability to implement procedures to ensure that methods of construction, the means of resource acquisition, and the impact of the process and product of construction, are sustainable at every level of impact and that any harmful legacy of construction activity is diminished or eliminated. The project manager is equipped to fulfil this role due to the managerial and technical sills possessed, the ability to impose methods of operation upon participants and collaborators in the construction process, and the capacity to direct and select modes of delivery due to the delegated authority derived from the project sponsor. By these means risks to achieving objectives of sustainable construction will most certainly be more assiduously identified and analysed and their impacts avoided, mitigated, or transferred, with the result that the construction practices carried out and the characteristics of the product of this activity may be consistent with declared sustainable criteria.

6 Conclusion

The critical position of the project manager in the construction process means that the holder of this role is uniquely qualified to be the primary determinant of the mode of execution of construction activity. Sustainable construction is most likely to occur where there is a synergy arising between the aspirations, value systems, and sense of social responsibility of both project sponsor and project manager who have the most intimate relationship within the project process. Under the project managers expert stewardship the performance standards may be formed in such a way as to permit the optimisation of all elements by a careful process of matching and balancing. The project manager who is acting in an agent role in respect of the project sponsor is the most likely project participant to achieve a profile of sustainable construction to include:

- a balanced mix of performance criteria including technical conformance, economic viability, aesthetics, environmental harmony, and user well-being

- an extensive range of solutions to design, construction, and performance issues derived from innovation and creativity
- a broad vision of risks to successful sustainable construction delivery and the consequences of project decisions

The project manager should be able to promote a sharing of objectives and values amongst project participants which are consistent with organisational requirements and economic performance criteria. This is most likely to be achieved when appropriate managerial skills are applied and allied with technical competence and a breadth of vision of the impact and legacy of sustainable construction activity. As noted by the CEO of a major industrial organisation a common ground between sustainable practices and commercial goal achievement is identifiable (11): *"Far from being a soft issue grounded in emotion or ethics, sustainable development involves cold, rational, business logic".* Project management is the organisational discipline which is capable of bringing about this commonality of interest.

Analysis of the primary process for efficient use of building components

H. Tempelmans Plat
Eindhoven University of Technology, Eindhoven, the Netherlands

Abstract
Sustainable construction as such is not additional factor in building decision making, but an essential part of the prices which should reflect scarcity of the resources. It should not only be focused on avoiding pollution and use of exhaustible recourses in (new) construction and demolition. Important is minimised environmental effects as an annual average over the life span of the technical solution. This needs annual cost calculation and proper (functional) demand period definition. Technical life span has to be reduced or lengthened by using the flexibility principles of open building. Analysis of the primary process in terms of performances and demand period should be the starting point of decision making.
Keywords: sustainable construction, open building, performance concept, service life, functional demand period.

Introduction
A building is a technical solution to fulfil1 demand for services to be used in a primary using process. The solution has to be considered as a stock of services which usually can be supplied over a period much longer than demanded for. This causes inefficient use of resources; which especially becomes clear when transformed to an annual basis depending on the economic life span.
It has to be tried to minimise negative consequences by using a good basis for decision making and demand definition as well. A systematic description of the demanding process is essential.

1. Sustainable construction
For a long period construction was focused on the maximisation of the life span of a building; like in the Roman era [9]. In this century, especially after the Second World War, construction most of the time had to be cheap and as a consequence buildings lasted rather short for the purpose initially meant. Both types of construction goal mostly are in conflict with sustainable construction.
Sustainable construction is a new problem area, since the responsibility for the existing stock of buildings is now becoming to be actual.

In fact this problem depends largely upon on the stage of development of a country. As showed by Bon [5] and Batten [2], the share of construction activities in the national production of a country can be described by a 'bell-shaped' curve. On the right hand side of the bell it is the quantity as well as the quality of the construction activities which is changing (see figure 1). As soon as enlarging the stock will be substituted by maintenance and replacement we become aware of the consequences of service lives shorter than initially expected and/or solutions which cause high disposal costs.
This effect is even stronger in countries which have enlarged their stock of buildings at high speed after the Second World War. Focus was on fast and cheap construction (sometimes initiated by the government), without taking long run cost and environmental consequences into account [2].
Sustainable construction has to concern the period from 'cradle to grave' [28], and as a consequence the 'sustainability scale' has to include time: i.e. the service life.

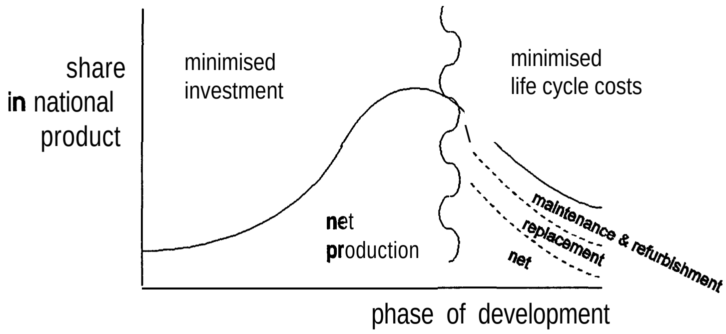

Fig. 1 A quantitative and qualitative change in building production

2. Focus on service life

Environmental consequences of the need for a built environment have to be minimised in the long run. So it makes no sense just to minimise the negative effects at the moment of new construction and of (partly or final) demolition, because they have to be related to each other and to future construction and demolition activities which are meant to generate new supply according to continuously changing demand.
The period over which a building or a component will be used is very important information when an investment decision has to be made. It is really a shame, that it is not an exception that a building is demolished before half of the potential service life [28]. An important goal should be to extend the life of non-renewable resources by reuse and recycling and as a result to minimise the environmental effects of having buildings available [8]. As a consequence, it is the life cycle operation which should be our concern [12], which should include the environmental effects of demolition in order to be able to consider a long but realistic planning period. However, we have to face the contradiction that on the one hand the expected life span is overestimated [17], while on the other hand the period of (financial) interest of the investor/decision maker in the building usually is very short since they consider a building as a

speculative investment [19].
Minimisation of environmental consequences in the long run means that the consequences have to be transformed on an annual basis; a realistic planning period taken into account. In some way the sacrifices, to have a built environment available, have to be measured in financial terms, so consequently we may focus on -properly calculated- minimised annual costs [18].

3. Prices reflect scarcity

It is a problem of environmental economics to transform the various consequences of our production and consumption processes into prices. The compensation for pollution and the use of exhaustible resources to guarantee an acceptable environment in the future should be incorporated in the price of the built environment. As a consequence sustainability should not be added to performance, quality and costs [12], but is an essential ingredient of the costs. We need full-cost at real-cost-prices as meant by Hill and Bowen, as has been defined within their economic principles [9]. Only when prices are determined in such a way, they can be used as an allocating parameter in decision making like the choice out of technical solutions to fulfil1 our demand for adequate shelter over a well-defined period. It is essential that disposal costs are -as a consequence of one of the construction activities- included in the annual costs of a component or of a building, since they have to be paid by the user of that component or of that building [25].

4. Activities and costs

The activities which have environmental consequences have to be transformed into annual costs in order to be able to choose the best solution in the long run [24]. All activities, which result in an usable built environment have to be taken into account, as well as the activities which bring us back to the initial situation. The letter activities are essential in sustainable building, of course.
The annual costs to be calculated should concern (only) the components which are present at the moment of calculation. We have to take into account all disposal costs of these components, since we want to create in he future a situation of free choice for components to be installed at a moment of adjustment; like upgrading or refurbishment. To the construction and disposal costs have to be added the expected maintenance costs over the expected service life.
By means of annuity calculation these costs will for each component or group of components be transformed into annual costs over the expected service life. The structure of the cost picture of a building is illustrated in figure 2. Each moment of choice for construction activities is a moment at which we start from ‘relative’ scratch. The expected service life is a parameter in decision making, which influences the level of annual costs.

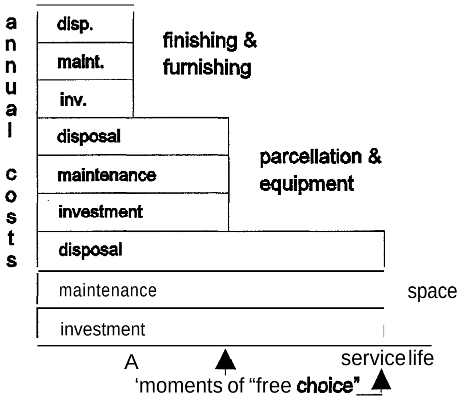

Fig. 2 Cost structure of a building; split up in three service lives

5. Economic life span as optimum

The optimal life span concerns the period over which the annual costs are minimised and in which the solution will really be used as meant initially. From the technical point of view several solutions are able to supply the services over a much longer period than demanded for, and in fact such solutions usually are chosen and produced. However, solutions have to be chosen which can live not much longer than the expected useful life [11]. To put it differently: the life should be determined by the earning power of the using process [16] or the stock of services should not exceed the desired life span [28]. As stated by Rutter [15] and Wyatt [28] the designed life has to be matched with the economic life.

Three 'periods' have to be defined in order to be able to find the optimum [23].

We have to be sure, that demand is defined without regarding to technical solutions in order to be able to choose the best solution from the cost and quality points of view. The demand period concerns the period over which a function is needed and does have to be the same as the life span of the solution; we will use he term functional demand period, which is not connected to an object. To each technical solution a technical life span is connected. The choice concerns the economical life span, which can be equal to the technical life span, but usually equals the functional demand period, but can be shorter as well.

The various periods defined are illustrated in figure 3.

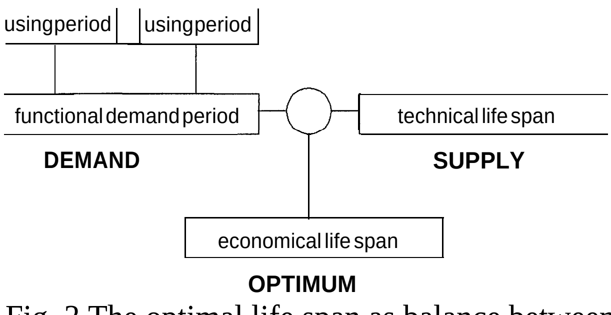

Fig. 3 The optimal life span as balance between demand (fdp) and supply (tls)

6. Balancing costs over life span

The annual costs can be minimised by influencing the costs of construction activities, but the result depends heavily on the related life span. From the demand side a more simple solution than usually chosen would be acceptable, and probably cheaper on an annual basis. In many cases the functional demand period is decisive and equal to the period over which the optimal solution will be used: the economic life span.

It may happen as well, that the technical life span is shorter than the functional demand period, in which case the solution will be replaced identically one or more times within the functional demand period.

Some times -this is important for sustainable construction- a technical solution may be used in different positions by several users. In this way the economic life span as well as the underlying functional demand period incorporates several using periods (fig. 2). In that case we have to add the cost of transfer of the (group of) components to the initial construction costs, the final disposal costs and maintenance cost over the range of using periods.

When the functional demand period for the services of a group of components is very long, it may be realistic to spend more on construction and disposal, since the costs will be spread over a long period. Another option is to fulfil1 demand by identical replacement of a technical solution, which is realistic when the costs of activities will diminish more than proportional, compared to the shortened life span.

When we have to do with short functional demand periods there is no reason to try to build for the very long run. This only can become clear when we really transform costs of activities to annual costs on the basis of realistic demand periods; not the basis of the technical life span which can be met.

The best solution can only be found when demand has been defined properly; the functional demand period included.

7. Complex demand definition

The functions we need for our production or consumption processes are very complex of character; they concern a group of functions which can be chosen rather freely from he technical point of view. Although we can only choose those combinations which fit within our budget [14], there still is a lot to choose. Since we have argued that the period over which functions will be demanded for (functional demand period) is important for decision making based on annual costs that time has been added to demand definition.

We agree with Masters [13], that service life prediction is not easy. To make it even more complicated, we have to deal with a range of planning periods (fig. 3). Demand for floor space can be defined for a longer period than the demand for e.g. climate or the parcellation of space. As a consequence the technical solutions serving different demand periods have to be made technically independent as well.

A dynamic program of functions -a scenario- has to be defined to make an efficiently flexible or adaptable environment possible.

For each function or type of performance a functional demand period has to be defined.

8. Building as set of technical solutions

As a consequence of a wide range of functional demand periods we can expects a range of technical solutions and economic life spans as well. Since some solutions will be used over a longer period than others, the building will be adapted constantly [6]. Buildings can only be used properly in the long run when a deconstruction and disassembling analysis has been made [29] and a replacement without impair of functions of others can be accomplished [10].
At the moment of new construction we have to take into account that some components will be removed after a short period and it may be advantageous to install them in later stages of the construction process (fig.4) and to make decomposition easily possible by introducing connecting components [7]. Open Building is still actual, if focused on future adaptations.
A building is a complex durable means of production, while for each part of the complex costs have to be calculated more or less separately.

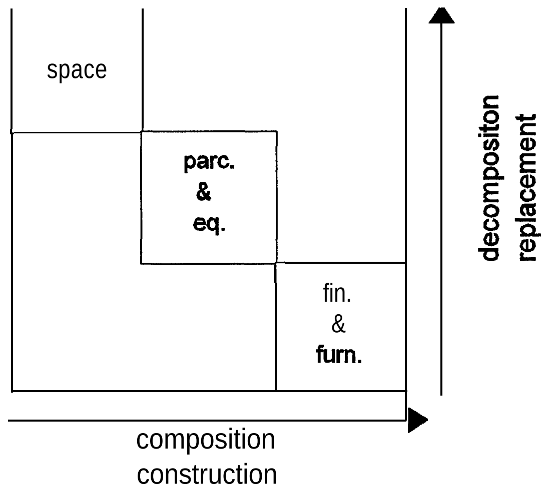

Fig. 4 Construction in view of future replacement

9. A demand and replacement scenario?

Information about future demand is necessary to create a sustainable built environment. However, we have to decide whether we have to formulate demand over the expected life of the building or over a shorter period. It has to be decided to which extent future demand has to be predicted in a scenario.
Since we know, that changed demand (at least a change which results in misfit which needs an adaptation) will result in rehabilitation activities, the decomposition of the building can more less be predicted.
However, we do not have to know which replacing components will be installed in the future. It is enough to know which components will be removed and after which period. As than can be decided about the materials to be used and additional investments to make easy removal possible; the connecting components. Concerning

the building as a set of technical solutions, a decomposition scenario is needed; a replacement scenario is not essential (fig. 5).

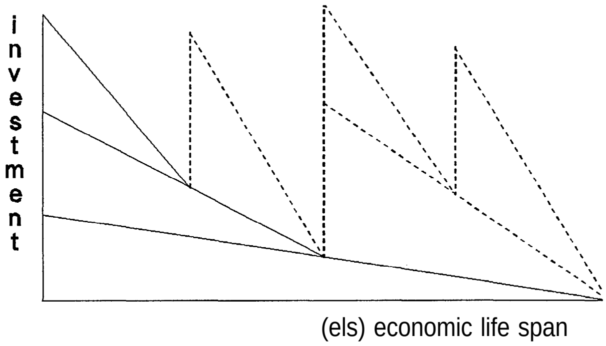

Fig. 5 Building as changing set of technical solutions (Tempelmans Plat, 1985)
-----------------------------------decomposition scenario
________________replacement scenario

Consequently a demand scenario over a long period is not needed; information of the functional demand periods at the moment of new construction or of adaptation is enough (fig.6).

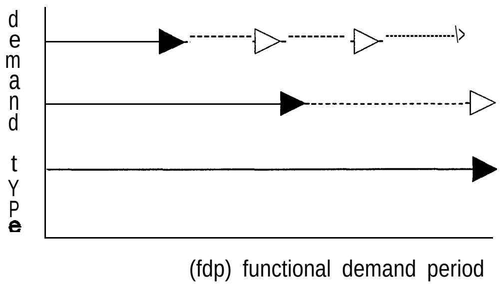

Fig. 6 A “constant” demand scenario at the moment of new construction

10. Symmetry of supply and demand
After the balancing procedure of supply and demand, we find a solution in which the set of functional demand periods is mirrored by a set of economic life spans of the solutions (fig.7). For each combination of demand and supply the annual costs are minimised.
Such a result can only be obtained when for each function the demand period has been defined. However, since we want -because of reasons of economy- to combine future adaptation activities the range of periods has to be limited, see figure 6.

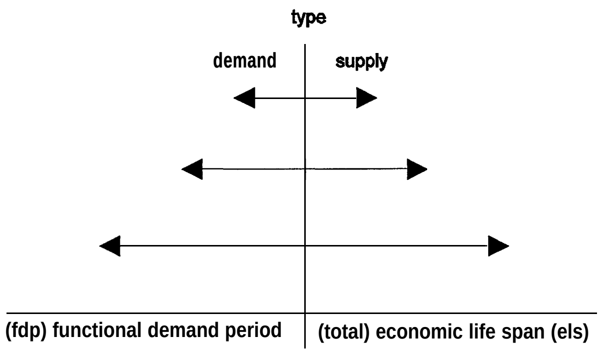

Fig. 7 Symmetry of demand and supply to minimise waste

11. Analysis of the primary process: performance concept

To make the choice out of technical solutions as free as possible, demand should not be defined in terms of solutions. This is the basic idea of the performance concept, which however -according to Becker [3]- is hardly used in practice in the proper way. The first problem concerns the demand definition from the point of view of the user. He should be able to define the functions which are needed for the activities as part of the using process; demand defined in business language. These functions have to be translated into performances to be supplied by the technical solutions; defined in building language [1] We can not expect from the user that he is able to transform his demand in the best technical solution. It would even not be wise, since the user is an amateur in that field.

The second problem is to define performances which can be measured and to which costs can be allocated. When climate is needed as a function, we can measure it in e.g. degrees temperature and percentage of relative humidity. Costs can only be added when the space and period over which he climate is needed is know to the decision maker. Figure (8) illustrates the transformation from function to solution and the reverse concerning cost allocation.

The third problem concerns the complex relations between performances and solutions. Climate can be measured in e.g. two types of performances, but for these performances several components may e needed. We need in his example outside walls, a roof and a heating system. Above that complication we have to face the fact, that a component may be needed for the supply of more types of performances, like components connected to sound insulation and a water resistant barrier. Partly the problems resulting from the complex relation between performance and technical solution will be overcome by the clustering of the demand for performances.

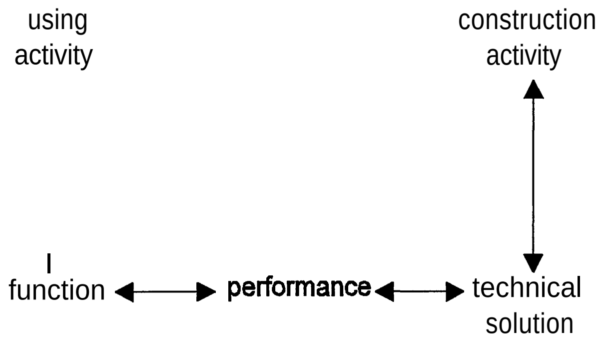

Fig. 8 Performance as measurable decision parameter between demand and supply
--------------------> choice determination process
<--------------------- cost allocation process

12. Clustering of demand in Open Building
Each function has its own demand period, which may result in a large range of demand periods. This may cause problems, because of the connection between performances, when they will be supplied by the same technical solutions. From the practical point of view I may be better to combine adaptation activities to diminish construction costs and the disturbance of he using process. Clustering can be based on the functions which are related to the same type of activity and by fitting the various individual demand periods into less numerous market demand periods.
An extreme example of clustering around activities is the demand definition for a hot house to be used as a laboratory. Since the experiment will last only seven years [27] the demand periods for space and for equipment will all be seven years (fig. 9).
Practice is, that decision makers are not aware of his clustering and as a result choose solutions which can last a much longer period and are bad from the sustainable point of view.

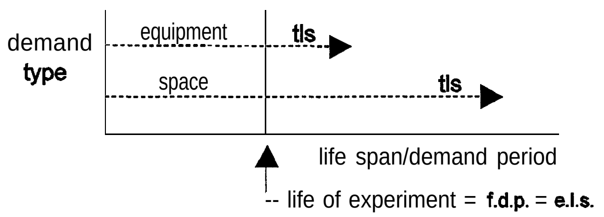

Fig.9 Clustering of demand around one activity (hothouse-laboratory-experiment)

More consequences has the clustering of demand for a bank office building [4]. The demand is split up in four parts: two concerning market demand for space and parcellation and two parts concerning the bank process. The letter two are connected to the technical bank process (safe and internal money transport) which will be defined for fifteen years and the period connected to the character of he interior of the bank (fig. 10). It is especially the last one, which results in high disposal costs over a very short period, of which he decision maker is not aware.

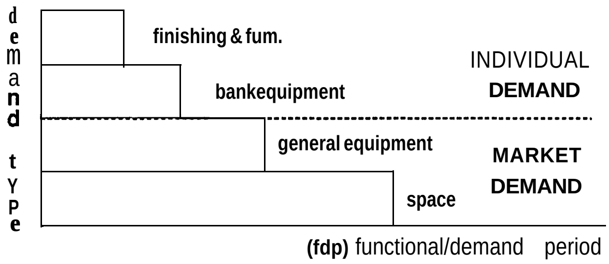

Fig. 10 Bank office building: a split up in individual demand and market demand to limit number of clusters maximise functional (market) demand period

An important consequence of the clustering in only a few demand periods is, that decisions about clusters do not have to be made at the same time and it is clear that only solutions which are related to different demand periods need attention as far as future disconnection is concerned.

13. Inadequate information concerning demand definition

To find technical solutions which will have minimised environmental consequences, we need information about activities and functions related to the primary process and to which are connected demand periods. A second important point is, that information concerning maintenance activities and disposal is lacking. As described in figure 11, most information is still lacking to have a really reliable demand definition and cost information to choose the adequate technical solutions [26].

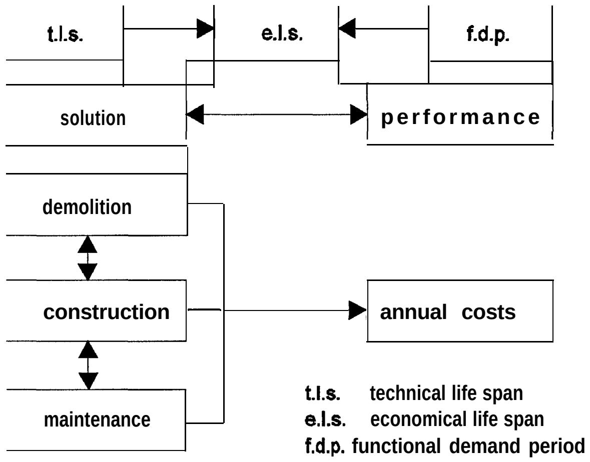

Fig. 11 Black boxes in information about performances and costs

14. Conclusion

In sustainable building focus it still too much on diminishing the consequences at the moment of (new) construction and at the moment of demolition. The period over which the technical solution has to be incorporated in decision making; incorporating the time parameter.

Taking time into account in fact is only possible when demand is defined properly. As a consequence, to maximise sustainability, decisions have to be taken on the basis of annual costs. In these costs all he environmental consequences have o be expressed. Sustainability is not an additional goal, but just economics, in which the environment is one of the cost parameters.
Since the various functions will be needed over different periods, the technical solutions have to be disconnected at different moments in time: Open Building is still actual. Only a disconnection scenario is needed, not a replacement scenario of the building.

An attempt to measure the unsustainability

J. Şuler
National Research Institute on Urban and Regional Planning, Bucharest, Romania

Abstract
As an expression of a legitimate need to become more responsible for the use of our present resources and the quality of our future life, Sustainable Development (SD) was, generally speaking, a favourable received concept. In spite of this it is still a matter in dispute, beginning with its denomination into Romanian and continuing with its definition and practical approach.

Taking into account the present situation of the society, which is faced with a difficult process of restructuring and the fact that there is not yet a global strategy of SD, it seems to be very convenient and useful to know where we are from this point of view. To give an appropriate measure of the development is itself an impressive work, but to measure non-performance or unsustainability could be seen as a venturesome attempt.

The Method of Evaluation the Sustainability Alteration Degree represents a proposed solution for such approach, which relies on a matrix composed by **82** rows (the descriptors of the build environment) and **19** columns (the factors of the natural environment and the social economic environment, including the sustainability criteria).

The main principle is the treating of the built environment both as a generator and a receiver of unsustainability in relationship with the other environmental components.

The paper contains some elements concerning the difficulties to adapt the principles of SD to the national context, some theoretical guides, the content of the method and its methodological aspects, its advantages and disadvantages, the results of two case studies and some conclusions.

The final idea is that the method is feasible and it is worth to improve it.
Keywords: built environment, criteria of sustainability, Romanian context, sustainability alteration, unsustainability evaluation.

1 Introduction

The concept of sustainable development (SD) is very familiar within the scientific community and on the top level of decision making from Romania.

We could also mention some progress recorded during last eight years which succeeded more or less in guiding the society in the right way, such as: the drawing of some global and sectorial strategies; the renewal of the legal system; the promotion of the research in the fields of energy conservation, protection and rehabilitation of the natural and built environment; the functioning of some governmental agencies and non-governmental organisations etc.

Nevertheless there are some factors which act upon the accuracy of SD assimilation.

One of them is the Romanian denomination of the concept ("dezvoltare durabilă") which was translated from French and does not express the strict meaning of the English corresponding.

The second is the ignoring of the possible difficulties to implement SD principle in a society, which experience a profound process of restructuring accompanied by a strong economic recession and very high social costs.

At last, the fact that there is not yet a national strategy of sustainable development generates some confusions and deviations.

In this context, the creation of a realistic basis for a suitable strategy could be seen as a project both necessary and opportune.

The papers summarise the results of such a project developed in the framework of Urbanproiect Institute, since 1996 [1].

2 Some conceptual guides

The research started with a review of the theoretical approaching of the SD in order to use the generally accepted meanings.

For instance, the notion of the built environment, which is frequently considered to be identical with human settlements, is found in the international documents [2] with the following definition:

> "The type which includes all the lands occupied by the houses, roads, mines, quarry, and other facilities together with the additional surfaces of intended use for human activities. Are included also, some types of open spaces which are closely related to these activities such as waste storage, vacant land, parks, urban gardens etc."

CIB-W82 Commission "Future Studies in Construction" [3] adopted the following definition for "sustainable construction":

> "The responsible design of a healthy built environment based a resource efficient use and ecological principles that can be responsibly created, managed, maintained and dismantled."

As concerns the structure of the environment as an entity, it was considered very convenient the global model launched on the occasion of the World Conference on the Environment, which took place in Stockholm, in1972. The issued document [4] presents the environment as a whole which embodies as the main components the natural environment and the anthropic environment. The last one includes the artificial environment and the socio-economic environment.

3 The existing practices

3.1 The external framework

The available references do not contain a model of indicators conceived to describe the unsustainability of the built environment.

However, studying the experience treasured in the other countries, we remarked some practices very interesting from the methodological pint of view, even if they were not suitable to our vision.

Such an example is the method of ecological quality of construction (QEC) from France [5]. It is applied to the new constructions and is based on some principles, which could be extended to the built environment (to save the natural resources; to reduce pollution; to integrate the buildings in the environment in harmonious way; to provide a healthy and comfortable life inside buildings).

The evaluation of the constructions eco-quality method (BREEAM) from Great Britain [6] introduces the idea to assign different scores to the solutions, which meet the high level of quality performances. It is applied to the buildings either new or existing.

Those 120 indicators of sustainable development recent published in Great Britain [7] were conceived in order to evaluate the dynamics of the English society development an to identify the tendencies which have to be adjusted in accordance with the SD exigencies. The indicators were based on the idea that the human activities induce some pressure upon the environment causing some changing with respect to the quality and the stock of natural resources the society in its turn act by policies and measures aiming to reduce this pressure.

In the Netherlands, the delivering of the National Plan for Environmental Policy [8] started with an analysis of the main components of the environment, most of them belonging to the built environment. They attached importance to the factors with a strong impact on the natural environment and the health of population. The specific indicators could be applied to evaluate the situation at one time, but some of them could measure its seriousness.

The model of the urban sustainable development indicators, which come from Norway [9], is interesting for the qualitative elements introduced beside the qualitative ones and also for the ethical signification attached to some indicators.

3.2 The internal framework

Although there are not a direct and unitary approach of the indicators concerning the sustainable development of the build environment, many existing models could be used as sources of useful data.

Thus the data periodically published by the National Commission of Statistics – NCS [10] give some information on the global and regional level, on the economic activities or parts (functions) of the human settlements. This data are more suitable for the qualitative evaluation, the qualitative elements being exceptionally introduced. Anyway those indicators are not intended to offer an integrated vision regarding the built environment state from SD point of view.

Others publications NCS [11] contain in addition some relevant data concerning the built environment (protected areas, the main economic activities with the strong impact on the environment, etc) and also some useful data to set up the comparison terms (e.g. the clearing surface versus afforestation surface which could point out the exceeding of the limits of absorption of negatives effects caused by cutting of).

The same source provides some information related to the environment protection expenditures, very useful for SD approaching.

On the occasion of some studies carried on in the framework of Urban Proiect, were defined and tested some indicators which deserve our attention.

Thus, the housing indicators [12] are interesting as they analyze the renovation and maintaining expenses, the land conversion rate and share of the dwellings of low comfort.

The prosperity indicator [13] on the counties represent an aggregation model of more indicators taking into account the hierarchy corresponding to the specific performances.

At last the quantitative and qualitative indicators aimed to define the sustainable city [14] are interesting as the intention but are disputable as the proposed optimum limits and the compatibility of all kinds of settlements.

4 The method to evaluate the unsustainability of the built environment

4.1 A way of understanding the reality

A holistic approach of the environment, which is counted as a basic principle for the application of SD concept, imposes the taking into account of its all defining components as well as the complex connections between them.

Consequently, the built environment is treated as a part of the whole environment having mutual relations with the other measure parts, i.e. the natural environments and socio-economic environments.

In relationship with them, the built environment works both as a generator and a receiver of the positive or negative effects from the point of view of SD.

In a certain context, sometimes appears more useful to know the weakness of the system then the high level of its records.

Along the same line, the approaching of the different parts of the environment is a conventional operation justified by the methodological reason. In fact they form an organic whole due to the human being - as individual and also as community - who is common factor acting like a blending element between them. That’s why the man must be found either in an explicit or in an implicit way in any evolution of the environment which respects the SD spirit.

This condition is the more so as, the whole society is in a critical state, meaning that the main features of sustainability are strongly altered and the given economic potential is situated under the level of requirements; such a situation imposes as a reasonable way to establish the urgent needs as an elementary stage before the allocation of the limited resources.

This is the situation of Romania, a country where the profound and so imperative process of restructuring and reform of the entire society, might involve some disorders and onerous costs hard to bear by a population which have already experienced a long period of restrictions and frustrations.

In this context, our research aimed to offer an instrument able to give a picture of the existing deviations against certain standards of normality in the sense deduced by the SD principles.

The proposed method was named The Method of Evolution the Sustainability Alteration Degree (MESAD which is MEGAD in Romanian). It was built on the idea that it is more profitable for the action to identify, first of all, the tender spots or vulnerability of the environment and also its proportions.

4.2 Method description

In order to analyse the built environment (BE) as a generator- through the instrumentality of human activity- of potentially negative effects upon the other components of the environment, i.e. man/society and the natural environment, which could be found within its impact field, it has been used as a working scheme a matrix constituted as follows:

* On the first horizontal row are figured the constituent elements of the BE or the factors that generally correspond to the functions by it. They are: achieved land use; dwellings; transports; water supply; sewage; industry; culture; education; health; public institutions and services; trade; tourism; services; parks; waste.

Each of the 15 factors of the environment is detailed by means of several specific indicators selected as function of their capacity to induce effects altering the sustainability of the other components of the environment. These indicators may characterise the size, the structure or the quality of the factors to which they refer. For instance, among the indicators for dwellings are to be found: dwellings in stock, weight of sick dwellings; average number of persons/room. The total number of these indicators is of 82.

* Vertically are introduced the other environment factors located within the impact field of the BE, i.e. : man and/or society, vital resources and the natural environment.

The detailed vital resources are grouped in primary and secondary resources. The first category comprises renewable (solar energy, rain water, wind energy, forests) and non-renewable resources (oil, coal, natural gas, minerals, soil). The second category comprises: energy and building materials with major impact upon the environment (limestone, aggregates, wood, cement, coatings, etc.). The natural environment is described by its factors, i.e. : climate, relief, air, water, soil, vegetation, fauna. The total number of columns is 19.

* The reciprocal causality analysis between the two co-ordinates is achieved by means of auxiliary elements, as for instance the reference terms, with which the performances of each indicator of the BE is compared. Those reference terms generally represent quantitatively expressed levels , but under given circumstances may be expressed as ‘existence’ or ‘non-existence’ of an important characteristic of the BE.

For instance, in the case of bad maintained dwellings, the reference term is of 50% from the total, but for unsafe dwellings, as low as their percentage might be, the situation is estimated as risky and therefore the reference term is the ‘non-existence’.

* Other auxiliary elements are: the list of phenomena liable to induce effects altering the sustainability (climatic changes, landscape modification, reduction of the ozone layer, pressure upon the agricultural land, increase of the transport distance, poverty, dependency, etc.); the list of sustainability characteristics for man and/or society accompanied by importance marks awarded on a scale from 1 to 5 (health/5, comfort/4, tollerance/3, equity/2, altruism/l etc.); the list of sustainabibility characteristics for resources, also accompanied by importance marks (efficient use of non renewable resources/4; rehabilitation of land/3, etc.); the list of sustainability characteristics and of the importance marks for the natural environment (climatic stability/5; bio-diversity/$ aesthetic value/3, etc.).

The four lists are abbreviated named: List A, List B, List C and List D and comprise receptively 32, 24, 11 and 10 positions.

4.3 **Application methodology**

Applying MEGAD presumes going through the following stages:

1. Establishing a comparison base
2. Measuring of the vulnerability indicators (VI)
3. Interpretation of the results

* In fact, the comparison base represents a summation of the effects or indicators liable to alter sustainability characteristics, or of the ‘black points’ dispersed by the action of diverse factors of the BE.

This sum may be calculated in two ways: as a simple summation of the identified effects, or as the weighted summation taking into account the importance marks awarded to the sustainability characteristics.

For instance, the exceeding of a certain limit (reference term) of the urban surface/inhabitant may generate 3 5 alteration effects, that representing a score of 140 points if the importance marks of the affected sustainability characteristics are taken into account.

Under the assumption that all the possible negative effects of all the 82 indicators of the BE occur, a score 1413 will result, respectively 4766 ‘black points’ which constitute the primary elements for characterising each case apart.

The ratio of 3: 1 between the two sums indicates the degree of implication in the alteration process of the primordial sustainability characteristics (bio-diversity, health, efficient use of resources, etc.) which are rated with maximal importance marks (5 or 4).

* The vulnerability indicators are determined as percentage after the identification by means of the same scheme of all the effects altering the sustainability of the analysed system, in the proposed two variants, as against the initially scores.

For the situation in which the BE is considered as the receiver of sustainability altering effects generated by the other components of the environment, the following hypothesis have been chosen: 1) area with increased disaster risk; 2) area with degraded waters; 3) area with forests strongly affected by the drying up phenomenon; 4) geographically, demographically, economically, socially desadvanteged.

Each of the 4 situations corresponds to an increase with 0.5 points of the sustainability alteration indicators multiplication coefficient. So, the ratio between the indicators corresponding to the comparison base, may increase, for example, from 3 to 5.

* The results obtained on base of the analysis scheme proposed by MEGAD contain at each moment useful information for decision makers.

So, the sum of alteration effects in its first variant indicates in fact the number of problems that require solutions in order to stop the sustainability altering phenomenon. The indicators, adjusted by means of importance marks, indicate how serious the situation at a given moment is in what concerns the sustainability of the analysed system.

This information may be useful both for establishing the objectives of SD, and for rating the action priorities.

For instance, if the sustainability of a system is menaced, especially by the action of industrial agents, the aim will be to balance the efforts between the pollution reduction at the source and the rehabilitation of the affected factors.

On the other hand, in case the domestic waste constitutes an obvious pollution source, but on the other side unsafe buildings, endangering the safety of people exist, the efforts for strengthening the latter should not be diminished or neglected, in order to radically solve the problem of domestic waste.

The lower or higher vulnerability of the BE, considered from the point of view of the SD requirements, must be treated as a motivation for action, understood as improvements of the sustainability degree by reducing or eliminating alteration effects and not as elimination of unsustainability sources, which is practically non feasible.

5 Case studies

Till now, the verification of MEGAD has been performed on the example of two towns of the group of major cities (with over 300.000 inhabitants). They are individualised by the following characteristics:

CONSTANTA

- historical town erected on the site of an ancient Greek citadel
- the main harbour at the Black Sea, tax free zone
- surface: 5942 ha
- population density: 5866 inh./km^2

IASI

- ancient historic and cultural centre in the east of the country
- important node for political and economical relations with neighbouring countries in the east
- surface: 3 560 ha

population density: 9675 inh./km^2

The sustainability alteration indicators established by MEGAD have been 690 ‘black points’ for Constanta and 763 for Iasi. After being adjusted with the importance marks, these sums became 2503 and 2955 respectively, which correspond to vulnerability indicators exceeding, as a rule, 50%.

The multiplication coefficients of the alteration degree are 3,6 and 3,8 respectively, which is explained by the high weight of important sustainability characteristics which are already under the impact of different alteration phenomena.

More than that, the two cities display the following characteristics:

CONSTANTA	IASI
• area with a significant disaster risk • area with stream ways affected by pollution and with highly pollution vulnerable ground water	• area with high disaster risk • low quality stream ways (III-rd category) • woods severely affected by drying out phenomenon

Consequently, the multiplication coefficients will increase with 1, respectively 1.5 points, that means they will become equal to 4.6 and 5,3 respectively.

Testing the method on the two specific cases proved to be very useful, because it confirmed its logic and signalled some of its shortcomings in what concerns the way some environment factors are characterised, as well as in what concerns some units and some reference levels used.

It permitted also to draw some conclusions concerning the access to primary data and the possibility of independent (non-assisted) use of the method.

6 **Conclusions**

From the point of view of the SD, the assessment of the BE state is capital for deciding upon the necessary measures and for rating their priorities, especially under the circumstances of limited resources. Such an analysis is very useful for preparing orientation documents for the development, such as:

- long term strategies for the development of the BE, irrespective of its size
- urban and territorial planning development plans

The most important advantages of the MECAD are:

- it addresses the BE as a constituent part of a living whole, who's components are in reciprocal causality relationship
- the BE is treated both as a generator and as a receiver of sustainability alteration effects
- it permits to aggregate very heterogeneous, both by origin as by impact area, elements
- the identification of the most risky unsustainability sources becomes possible by computation of certain vulnerability levels
- the fact that vulnerability is established as compared with sustainability criteria and not related to a specific case permits a more accurate assessment of the existent situation because the idea of competition brings in front more readily the achievements than the failures
- has an open character because it permits the adjustment or replacement of some elements, such as the indicators characterising the BE, the characteristics of sustainability, the sustainability altering phenomena.

As disadvantages are to be quoted:

- the great volume of primary data and the difficulties to obtain them
- the subjective elements it contains (importance marks, sustainability criteria) which might induce a certain caution concerning the exactness of the method

- the need of special skills and competence as multi-criteria1 analysis capacity, method, lack of prejudices
- the great number of required verifications, and, probably the need of adaptation in order to be applied to other categories of towns (medium cities, little towns, villages)

As a final conclusion, MEGAD may be considered as a feasible method which deserves to be developed for the role it may play in promoting the SD in our country, which substantiates the necessity of pursuing the research in **1998.**

Necessity of common understanding of sustainability in construction in Asia

K. Baba
Department of Infrastructure Systems Engineering, Kochi University of Technology, Kochi, Japan

Abstract
From the end of this century to the beginning of next century, a quite big construction boom is expected to occur in Asia for the development of the countries in that region. This boom will be considered so big that major world construction market will be shifted to Asia.

The Third Conference of Parties to the U. N. Framework Convention on Climate Change (Kyoto CP03) was held at Kyoto on December 1997. According to the Kyoto Protocol developing countries are exempt from new commitments to mitigation of global warming. Rapid development together with the conclusion of Kyoto CP03 may have a great influence on the global environment.

One of the key issues to avoid such kind of problem is to let people understood the importance of sustainability for environment who will be involved in execution of the construction projects for development. However, almost all people of developing countries considered that development means industrialization and urban development, which in a sense developed countries experienced during development of their countries. Moreover, the typical examples of Asian developing models are Japanese, Korean and Taiwanese model. Scarcely these model did give careful consideration to the global environment. They only studied local problems of environment.

However, in the discussion of sustainability of construction there is quite big gaps of opinions of the people between developing countries and developed countries. Therefore, establishing clear and common concept of sustainability will be indispensable to maintain good global environment for future generation of the world.
Keywords: Asia, construction management, development, global environment, growth of economy, professionalism, sustainable construction

1 Introduction

Recently many countries in Asia are suffering from financial crisis which originated from Thailand in the middle of 1997. Certainly, this situation will slow down, in some extend, the speed of development of many countries in Asia. However, it does not mean that the world center of development from the end of this century to the beginning of next century is shifted to any other place than Asia.

On the contrary, the fact that the financial crisis of Thailand have a great influence on the world economy shows that the increase of importance of economy of Thailand in the world. Towards 21 century, Asia will become the dominant region of the world economy.

Today, in Kuala Lumpur, Malaysia, there is the new tallest building in the world. Although there is some argument that Sears Tower in Chicago is still the world tallest building, without doubt it is a symbol for the progress made in Asia. This progress and momentum will be remarkable sea changes not only in the economy in Asia but also of the world. In this progress, Asian are going to create their own rule for development.

As a well known sociologist pointed out, "what is happening in Asia is the most important in the world today. Nothing else come close, not only for Asians, but for the entire planet. The modernization of Asia will forever reshape the world as we move toward the next millennium." He also predicted that this modernization will be done not as Westernization but rather Asianization.[1] Therefore, the development in Asia by Asianization will give some impact to the whole world in many aspects in the next century. Among them, the most important issue for future of the world should be the relationship between development in Asia and its influence on the world environment.

Before discussing this relationship, concept of development and its mechanism should be clarified. The definition of previous development should be analyzed to adjust for sustainable development in the future.

Also, civil engineers have taken big roles for these development. Especially the system and methods of "construction management" in civil engineering originated in U. K. and developed in U.S.A. have been and will be used for the execution of many projects for development such as construction of infrastructure. From this point of view, a key to this problem is depending on both how "construction management" is handling the environment of the world and what kind of concept to the world environment civil engineers have in execution of actual projects for development.

In 20^{th} century, there were many wars in the world, through experiences of these wars, people of the world, especially, in Asia consider that most important thing for the people and country should be economy rather than military force of the country. But this concept should be checked from view point of the world environment.

Coming 21^{st} century should be a challenging era fur human being whether new philosophy will be established for maintain the environment level of the world in the level of as it have been.

From this point of view, the result of The Third Conference of Parties to the U. N. Framework Convention on Climate Change (Kyoto CP03) held at Kyoto on December 1997 is quite important as the starting point towards 2 1^{st} century to make a consensus of the people in the world to establish rather new philosophy for world environment.

There is a quite big question in the Kyoto Protocol which exempt developing countries from new commitments to mitigation of global warming.

2 Present mechanism of development

2.1 The meaning and measurement of development

Nowadays, it is a common sense of the people of Asian developing countries that a major goal of poor countries to escape from poverty is economic development or economic growth. This concept is supported by Japan's experience of rapid modemization in previous half century. During the second world war, almost all of Japan's manufacturing base was destroyed by air raid of U.S. air force into ashes. As a result, approximate half of workforce of Japan worked in agricultural sector. At that time Japanese average income was quite small and ranked below those of many developing countries.[2] Much has been changed since then. Japan with small mountainous land without any natural resources has become a highly developed country challenging American leadership in a number of industries. Also, the group of NIEs (South Korea, Taiwan, Hong Kong and Singapore) is showing the most successful economies in the world. These are the typical example of Asian miracle pointed out by world bank report in 1993. Keywords for this progress of these countries are "development" and "growth of the economy".[3]

However, these two terms are not identical in the strict sense of terms. Economic development is linked with economic growth accompanied by some changes in output distribution and economic structure of the country.

Also, measurement of economic development is quite important to know actual state of the country. For this purpose, usually two indices are used. One index shows the rate of development and the other shows the level of development. The rate of development indicates developing speed and it is explained by using growth rate of economy which is computed in the form of annual change of GNP per capita after adjustment by price deflator. On the other hand the level of development is measured by using the figure of annual GNP per capita which usually used for classification of countries. One classification used by World Bank divides all countries into three categories by using GNP per capita. According to this classification, in 1993, three categories were *low-income countries* (less *than* $700), *middle-income* countries ($700 ～12,000), and *high-income* countries (more than $12,000). [3]

Today an increasing number of the high and upper-middle-income countries are non-Western, and fastest-growing countries are among countries in Asia and not necessarily those of with the highest GNP per capita. Usually the countries with higher GNP show the less growth rate of economy.

It is quite natural for developing countries to make their best effort to pull up their rank in the classification by income level.

2.2 Principle and concept of development

It is quite remarkable thing that there are three countries and area in Asia among high - income economies, Japan, Singapore and Hong Kong. Especially Singapore and Hong Kong surpassed or almost surpassed United Kingdom which was their suzerain country. Thus, growth rate of economy of NICs are quite high . This means that developing speed of the countries in NICs is quite high .[3]

This fact produce some expectation to other developing countries in Asia so strongly that for the development of the country industrialization is most effective way and principle and concept of development of the country cannot be discussed without industrialization. Many people in Asia consider that development of the country can be done by economic modernization by industrialization.

2.3 Economic modernization in Eastern world

2.3.1 Capitalism as a key to economic growth in Western world

To begin with, it is necessary to know the origin of the economic growth. What did make sustained economic growth? In the history of Western world capitalism made it. Capitalism is the economic system dominated in Western world since the breakup of feudalism from the fifteenth to the eighteenth centuries. In principle, capitalism is the economic system of relation between private owners and workers. Pieces of land, mines, factories, and other forms of capital as means of production are privately held and workers who were free but without any capital sell their labor to employers.[2]

Capitalism, as an engineer for rapid economic growth, spread beyond Europe to the outposts of Western civilization. And capitalism is most suitable system for industrialization. In Eastern countries there have been some barriers to capitalism not only in traditional societies but also in effect of colonization by Western countries. It is clear that most of Asian countries are lacking the strong capitalists and the effective bureaucratic and political leadership which are essential for rapid economic modernization. [2]

2.3.2 The Japanese developing model

Japan is one of rare exception of the country of modern economic growth in non-Western countries. Japan's economic developing level was much lower than Western countries before the Meiji revolution in 1868. After Meiji revolution Japan's "guided capitalism" to catch up Western civilization by its government initiated large investments in infrastructure which helped domestic industries to export their product overseas and also borrow abroad.[2]

Japan was devastated economically during the second world war. In the late 1940s and beginning of 1950s, technical and economic assistance from U.S. like the Marshal Plan made it possible to reorganize international trade system and financial system as well which provide the basis of creating economic miracle.

It is obvious that the remarkable rapid growth of Japan occurred because technical knowledge and human capital were intact, even in ruins of other capitals by war.[2]

2.3.3 Development of Asian Tigers

The fastest developing countries in the world now are the countries called Asian Tigers. In other words they are called NICs as mentioned before: South Korea, Taiwan, Singapore and Hong Kong which became the part of main land China after middle of 1997.But Singapore and Hong Kong are only small city states doing business mainly in the field of trade and finance. Therefore. rapid development of these city states are associated with development of their neighboring country. For Hong Kong there is developing main land of China. In the case of Singapore there are developing Malaysia and Indonesia. Only Taiwan and South Korea are the countries which experienced quite high rate of growth through the years at the end of this century.

The models of development of these two countries are almost same as that of Japan. Similar to Japan, Their governments systematically intervened to invest to construction of infrastructure for further development of the countries and promote export their products and education for better human capital under the political and economic stability. Also, these two countries like Japan, had a high quality of their own management backed up by ancient Chinese philosophy of Confucianism.[1]

2.3.4. Lessons from non-Western models

Due to the collapse of the Soviet communism only few countries such as North Korea and Cuba stay with the Russian model of economy. For many Asian developing countries including Vietnam after their "doi moi" Japanese, Taiwanese and Korean models are quite attractive for developing their countries because these three countries are not democratic in the Western sense with Eastern tradition which many developing countries have in common. These models were effective at past. However, there is a big possibility that they will bring big problems of global environment in the future.

2.4 Infrastructure for development

2.4.1 Infrastructure as a key to development

As has been mentioned, in the models of fast developed countries in Asia investment to infrastructure is one of the most dominant factor for economic growth. Good infrastructure raises productivity and lowers production cost.

The precise linkages between infrastructure and development are still open to debate. However, infrastructure capacity grows step for step with economic output ; a 1 percent increase in the stock of infrastructure is associated with a I percent of increase in domestic product (GDP) across all countries.[4]

2.4.2 What is infrastructure

Usually infrastructure is divided into three categories by World Bank [4]: public utilities, public works and other transport sectors. Public utilities are consist of power, telecommunication, piped water supply, sanitation and sewerage, solid waste collection and disposal, and piped gas. Public works are including roads and major dam and canal works for irrigation and drainage. Also, other transport sector means urban and interurban railways, urban transport, port and waterways and airport.

Infrastructure is an umbrella term for many activities referred to as “social overhead capital” by many development economist. [4]

2.4.3 Efficiency of Infrastructure

Infrastructure can deliver major benefits in economic growth, but only when it provides services that respond to effective demand and does so efficiently. Service is a goal and the measure of development in infrastructure. Major investments have been made in infrastructure stocks, but in too many developing countries these assets are not generating the quantity or the quality of services demanded. Cost of this waste are high and unacceptable. The causes of past poor performance, and source of improved performance lie in the incentives facing providers.

3 Roles and concept of construction management

3.1 Effective execution of the projects of infrastructure

World bank report [4] says that infrastructure has a high potential payoff in term of economic growth. However, infrastructure alone does not guarantee growth of economy. There are many infrastructure which have smaller return on investment. The disparity in return on investment may be due to the differences in the efficiency of investment across countries.

3.2 Construction management as a tool for effective implementation of projects

As the report of world bank [4] mentioned the efficiency of infrastructure is indispensable. For this purpose, system and methods of "project management" and "construction management " has been developed and used in the execution of actual projects. However, the efficiency of infrastructure mentioned above are efficiency from view point of economy. There is no consideration in construction management on environment. There are so many text books on "construction management" published in U.S.A but there is no indication about global environment in them.[5]

Modem theory of construction management only written on the basis of economic efficiency. Economic efficiency dose not meet with global environment.

3.3 Basic concept of construction management

Modem theory of construction management is aiming the efficiency in economy. Actual approach to this is divided into two aspects; efficiency in performance of project, and efficiency in construction works. Efficiency in performance of project should be checked by the feasibility study of project in planning stage. Efficiency in construction works are analyzed by time, quality and cost. However, only few projects checked by assessment of local environment, but not that of global environment.

4 Paradigm shift required for sustainable development in Asia

4.1 Are economic growth and development worthwhile?

By economic growth the range of choice for human being has been widen in one way. But at the same time, it brings a quite big restraint for the activity of human being by changing environment of the world. Even before environment problems caused by economic growth were pointed, economic development and growth have both costs and benefit. There are many people who considered that the widen range of choice brought by economic development and growth does not link directly to happiness of the people because happiness is depending one the balance between wants and resources. Moreover, the serious cost overlooked before is environment of the world.

4.2 Influence of development on global environment

World bank report [3] shows that energy consumption per capita equivalent to kilograms of oil will increase proportionally to GNP per capita. This mean that rapid development of countries in Asia causes big amount of consumption of oil resulting in emission of green gases discussed on Kyoto conference.

There is well-known theory of relationship between economic index and environment index by Kuznets.[6] In this old theory environment will be improved after the income level reach to certain level. Application of this theory may be limited to environment problems in the country but not for the global level. And also this theory itself has been denied by some people.[7]

4.3 Report from Maldives

Development of countries in Asia will make a big influence to the global environment. But more direct influences on the region of Asia is predicted and discussed on the conference in Maldives in 1997. Among them are diminishing area of tundra in Siberia, drought in Mongol, more smog at big cities in Japan, break out of heat waves and epidemic disease in Thailand, Myanmer Bangladesh, increase of flooded area due to rise of sea water level in South China and Japan, and diminishing of tropical rain forest in Thailand, Laos, Vietnam and Cambodia

4.4 Required changes of concept

4.4.1 Small is beautiful

First of all, it is necessary to consider whether development or growth of economy is important for human being. There have been several people who considered this problem in the deferent way like Mahatma Gandhi, nonviolent politician and leader of nationalist of India. He advocated of small scale of development taking harmony with nature and reduction of materials want. For him, humane means for development were as important as appropriate end. [2]

4.4.2 Development

Gandhi's vision has inspired many people and has been followed by Schumacher, British economist who believed that productive activity should be judged holistically including environment as well as its simple economic ends.[2]

Also, it is easier for Asian people to understand and follow Gandhi's principle. Therefore, the review of the existing concept of development should be done from such kind of view point and establish rather new concept for development..

4.4.3 Construction management

Theory and practice of the "construction management" is only one general and effective method which will solve problems of global environment in construction. Of course, there is some special field to handle environment hazard prevention in civil engineering, but construction management handle projects for development as a whole. Also, projects for development should be reviewed in every stages of execution of projects under the light of global environment. For this purpose, necessary amendment should be done in existing system and methods of "construction management".

5 Effective measure to be taken

5.1 Political aspect

Same as Kyoto conference, some political international conferences are indispensable where total problems of global environment will be discuss to establish legally binding targets for saving global environment. In addition to them, every effort should be done for global environment using other political and economical systems such as OECD ODA and even Technology Transfer.

5.2 Civil Engineers' professionalism

There is well-known official register of the American society of civil engineers which defines and amplified "profession" of civil engineers.[6] In this register, there is no indication about global environment. It might be quite effective if this register will be amended to focus to the problems of global environment.

5.3 Necessary amendment in "construction management"

The time has just come when to avoid possible blaming civil engineers for destroying nature and environment, it is necessary to establish new concept of construction management for saving environment. In that new theory the performance of the projects as a whole should be checked from view points of global environment. After that each stage of project execution checked as well. By this necessary amendment civil engineers become a deity instead of notorious destroyer of the nature.

6 Conclusion

From the end of this century to the beginning of next century, tremendous amount of construction projects of infrastructure will be carried out in the region of Asia. These construction projects will effect so much to the world environment that some counter measure should be needed. There is quite strong linkage of the concept of Asian people among happiness of human being, poverty, development, growth of economy, infrastructure, and construction project. Concept of environment is out of this linkage. This tendency should be changed and common understanding of sustainability in construction will be needed to keep global environment for the coming next generation of human being. For this purpose, system and methods of "construction management" should be reviewed to put concept of environment into its theory as most important principle. Also, professionalism of civil engineers should be also revised in order to put the concept of environment into its fundamental philosophy.

7 Acknowledgement

This study was started at Asian Institute of technology in Bangkok, Thailand from 1995 when the writer was a visiting faculty there. The writer is indebted very much to the faculties of AIT and to the people in Indonesia, Malaysia, Singapore, Thailand, Philippines, Vietnam and Bhutan for their useful information about this subject..

Taking into account environmental values in building construction

J.-A. Kaivonen
Tampere University of Technology, Institute of Construction Economics and Management, Tampere, Finland

Abstract
The article deals with the improvement of environmental management in the building sector looked from the viewpoint of the building market needs. The base for the article is the method for calculating ecological balances of buildings created in the Institute of Construction Economics and Management of Tampere University of Technology. It has been used to assess the impacts of building construction and creating it has brought experiences in the assessment of environmental impacts.

In design, acquisition and use of buildings, understanding of ecological interrelations cannot be expected of the building sector experts and clients. So that the market mechanism on the ecological building market can function, it is important that the ecological quality of a building can be proved reliably to the client. Unambiguous ways to verify the quality levels are therefore needed for the sector. These unambiguous and simply to use indicators should cover a significant part of the environmental impacts of building construction. This will turn out to be to the whole building sector's benefit. The operational implementing organisation gets clear development targets and the clients can buy the quality they want.

The total impact of buildings must be considered in the strategic development work and in the improvement of the lines of action of the market. In that case, the typical environmental loads connected with the construction, maintenance, use and demolition must be understood. The calculation method for ecological balances of buildings used in this study is one way of assessing the impacts of whole buildings. Models like this are based on information collected from production plants and literary sources. The models are well suitable for showing the improvement needs and for supporting development work. Instead of that, it is difficult to verify the quality of a building to be sold with these models. The essential choices to be made in the building design causing environmental impacts can be found by using a total model. It seems probable that the development according to the mere purchase decisions of clients is not enough for reaching the sustainable level of environmental impacts. So to transfer the costs of external impacts to those generating them is an additionally needed way of market control. In that case the non-material inputs which are normally left outside the assessment of environmental impacts are taken rightfully into consideration.
Keywords: Ecological balances, sustainable construction, input-output analysis

1 Introduction

For the time being, the building sector is dealing with the question of how to considerably reduce the environmental impacts associated with the production, maintenance, use and demolition of buildings. Several procedures have been and are being developed this very moment for the assessment and control of impacts.

This article deals with the problem of controlling environmental impacts. The problem is crucially associated with the research where the method for calculating ecological balances has been created. The basis of this research has been the research traditions of the Institute of Construction Economics and Management of Tampere University of Technology (TUT). The TUT has studied extensively the design management of buildings which comes from customer activities and pays attention to customer needs (e.g. [1],[10],[11]). In addition to this, the structure and markets of the building sector and its importance to the Finnish economy have been studied in TUT by using the input-output analysis (e.g. [6]). Also studies on the environmental and energy economics of buildings have been done (e.g. [2],[7], [S]). Environmental impacts of building construction and their reduction have been examined on this basis. This article presents aspects that became known in the research.

2 Consideration of Environmental Values in Building Construction

2.1 Environmental impacts of buildings and building markets

A method for calculating ecological balances of buildings has been created in the Institute of Construction Economics and Management of Tampere University of Technology [3],[4],[5]. It can be used to calculate the natural resources used in buildings and emissions and waste originating from them. In the model, the environmental impacts of building materials production have been calculated with an input-output analysis where the input-output table of the national economy has been completed with information on the production processes of building materials. Building materials used on the site are composed of industrial products and services which are needed for transporting them to the site. Building components and buildings are composed of building materials. The present files in the model enable to estimate the energy amount used for building construction, central emissions causing global warming and acidification as well as waste in construction and industry.

A typical Finnish residential multi-storey building has been analysed with the model. Figure 1 shows some environmental effects from the production and use of this residential building made of concrete elements. Diagrams show that the development of residential buildings should be improvement of both technical and operational factors. With technically better solutions it is possible to have influence on most impacts. It is quite clear, however, that the quantity of dumping waste and energy consumption can be reduced significantly by guiding and facilitating building user functions. It can also clearly be seen that in building design there can be found very important decisions concerning the total amount of environmental impacts and, on the other hand, quite unimportant choices.

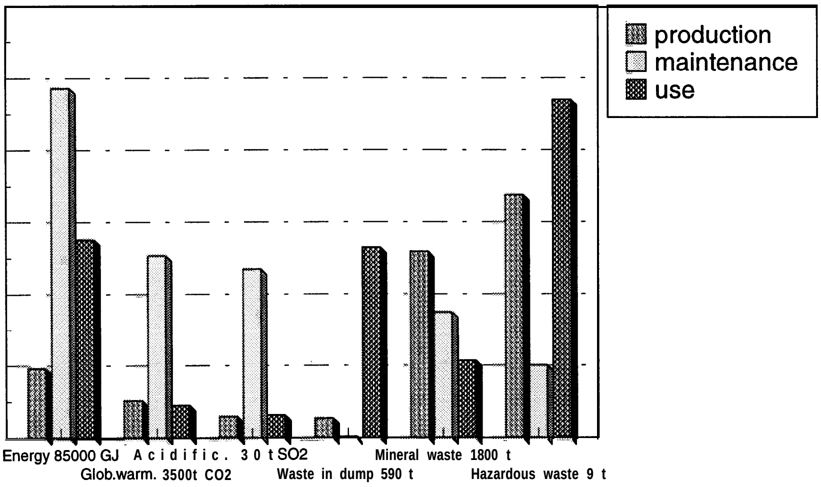

Figure 1. Environmental impacts of a typical Finnish residential building (appr. 4 500 m³) during 50 years of use. Function includes calculation of electricity consumption and waste amount of typical families.

The aim of ecological building construction is to reduce environmental loads. In addition to the environmental impacts shown in Figure 1, several other environmental impacts are related to buildings and their use and should be identified in future. However, identification of environmental impacts is not enough. It is just as important to find the decisions and choices which make it possible to reduce environmental impacts.

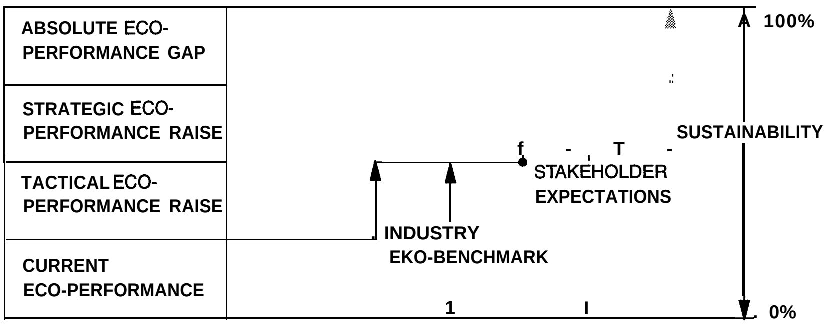

Figure 2. Development of eco-performance in business ([8], converted).

Implementing sustainable development shall for the most part be carried out by the markets. Therefore, decision-making on the market shall be studied in order to find tools for a real reduction in environmental impacts. Figure 2 shows a simple model of the development goals of products on the market. According to it, the tactical rise of eco-performance takes place within operational goals. They are simple target values, e.g. own environmental impacts compared with those of the competitors. In strategic development, one tries to identify customer needs, market development and in general the defects in environmental issues control. On the basis of detected possibilities and threats products are being developed according to needs. Purchase decisions only are not leading the building sector directly towards sustainability so the society should tend to affect with its decisions on the way that the eco-performance gap is as low as possible.

2.2 Operational development

In order to maintain the present competitiveness, the enterprises should try to take care of a sufficient competitiveness compared with that of competitors. Operation can be improved remarkably already with some benchmarks on the level of practical design. Energy consumption can be affected by decisions concerning among other things casing, heating and ventilation of a building. Indoor climate is affected among other things by ventilation and emissions from surface materials into the indoor air. To reach the goals of the operational level can neither require understanding of complex evaluation methods nor complicated calculations. All experts in the building sector cannot be specialists in solving environmental problems. To the operations model of a building project should be added clear operational target values for decisions in which a significant part of the environmental impacts of a building are determined. From the standpoint of a building process, control of environmental impacts should be started in the earliest possible stage. The chance to influence is best in decisions on large entities. The clear operations models of the operational level are important, because on this level the impacts are being determined continuously.

It is very useful to the building construction clients if the decision on the purchase of a house can be based on very simple assessment criteria. In addition to simplicity, the assessment criteria have to be reliable and widely accepted. Building owners need to be able to prove the environmental criteria further to their customers.

2.3 Strategic development

The aim of the strategic development is to create products competitive on the future market. The threats and chances of building construction and possession of buildings can be identified only by studying buildings as operational entities. Then it is possible to notice the most important environmental impacts associated with production, maintenance, use and demolition. Concerning strategic development, all significant environmental impacts are risks to business activities. Rise in productional inputs can be seen directly in production costs. Customers are interested in how they can meet future challenges in their buildings. If customer needs during using time have not been taken into account, the attraction of buildings will become weaker.

The results of strategic development shall be transferred to a part of the practical construction. As we stated earlier, development in the implementing organisation can be carried out only based on simple lines of action. Therefore we have to identify the design decisions in which the coming environmental impacts are really being affected. Impacts need to be interfered in the earliest possible design stage. Even a good building shall be sold to the customer. Reducing environmental impacts is not that kind of quality customers could identify directly in the end product. It is very difficult for a single enterprise to create a generally accepted model for assessing the environmental quality of products. The procedures applicable to the assessment can be worked out best in collaboration inside the building and real estate sectors.

2.4 Development of market procedures

It is very important to the building sector market that supply and demand meet. The building sector has to produce such buildings the real estate sector and building users need. The real estate sector and the users have to be able to identify the quality of buildings. Rules of the game for the building sector can be worked out by the building and real estate sectors themselves. Society can control the markets wider e.g. by directing the costs of harmful impacts to those generating them. In some cases also restrictions and prohibitions are well-grounded.

Understanding the economic decisions on the market is a prerequisite when influencing market operation. At the same time it is easier to understand the importance of different measures. In Figure 3, this basis of decision-making has been examined a little closer. Many people are ready to give up something of their financial well-being if they can affect the state of the environment. Consumers acquire those commodities which, examined in the decision-making, bring the biggest benefit compared to used inputs. If consumers regard environmental or social values as important in the short or long term, they tend to take them into account as much as possible when making choices. In principle, natural resources conservation and restriction of emissions could stay on a level consumers on the average want. In practice, markets alone do not deliver sustainable solutions. Consumers' will to give up something of personal comfort for the nature and coming generations does not correspond to the level required by the nature. On the other hand, market activities are restricted by several factors like incomplete competition, insufficient knowledge of products and their impacts, externalities as well as insufficiently specified ownership. These factors cause that even those who really want to influence cannot become convinced of the significance of their decisions. Building sector customers do not know all incompletenesses of the markets in the decision-making phase and cannot obtain and understand all the information necessary for the consideration of environmental values. So, if the additional value includes a cost, a significant uncertainty connected with the additional value may in practice prevent the customer from making a choice. There have been presented so many environmental arguments of different types on the market that customer scepticism is well grounded.

If the building sector wants to create markets that take the environmental values of buildings into account, it has to remove the barriers to decision-making stated above. A so simple and unambiguous model needs to be created for the markets so that customers do not feel uncertain when making purchase decisions. In that case it is possible to reach the development level in full customers are ready for. Still, end users' will is hardly enough to respond to those pressures directed also towards the building and real estate sectors e.g. because of international agreements. The building stock is growing fast. Green house emissions must be reduced already from the present level. If the necessary reductions of environmental impacts will be realised, in addition to the influence of the customers' purchase decisions, costs of externalities need to be directed towards those causing them or more strict regulations are needed

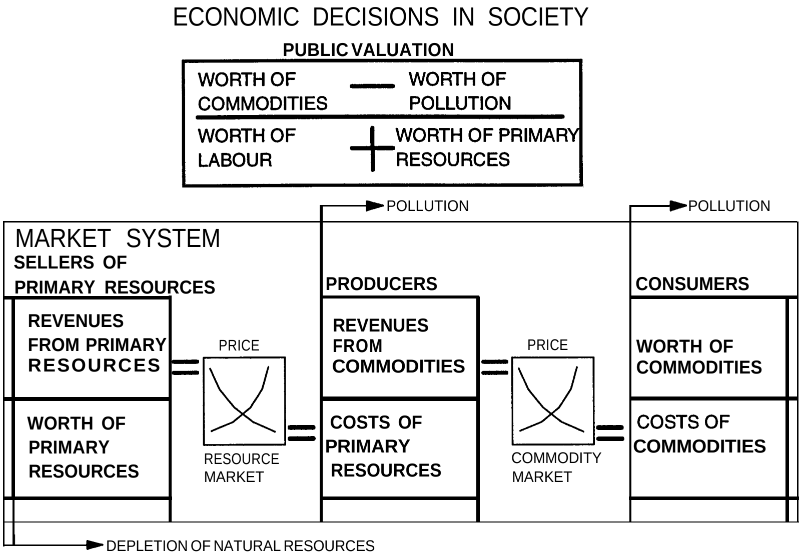

Figure 3. *Decision-making concerning exchange of commodities between economic units [11].*

2.5 Assessment of the environmental impacts of buildings

The central goals in the assessment of the environmental impacts of buildings are identification of improvement needs and comparison of development alternatives. On this basis it is possible to set operational development targets and to direct product development towards essential factors. Assessment of the environmental impacts of buildings is always a difficult and comprehensive task. The results are affected by many factors. Scoping of analyses have a significant influence. The results depend on whether average data or data from a specific production plant are used. It is also difficult to update the vast store of data required. Environmental impacts calculations of a building cannot be entirely unambiguous. Therefore buildingwise calculations do not well apply to an unambiguous verification of these issues. It is safer to verify the environmental quality of buildings by using indicators well applicable to the most important impacts.

This study has not utilised the common life cycle assessment (LCA) but the combination of the input-output analysis and LCA. In practice, the input-output table was specified and extended with information from single production processes. The input-output analysis is at its best when wide entities are being studied.

In addition to materials and work contribution necessary for the production of commodities, also machines, industrial and office spaces, means of transport as well as storage and commercial spaces and maintenance of them are needed. By utilising the input-output analysis it has been discovered that in the analysing of the environmental impacts of built spaces also the effects of capital and service inputs have influence on the environmental impacts originating in the construction industry. Energy consumption concerning several products in the building material production is quite small. In building construction, the quantities are large. Furthermore, the production includes several phases all using services, built spaces and machines. When considering for example the production of facade elements, the significance of capital formation, capital maintenance as well as leasing and commercial services makes a little more than 10 % of the energy amount used in production. In practice, precise control of these factors in the calculation is almost impossible. If the prices of used inputs include the costs of externalities, these factors will be taken automatically into account but concerning capital consumption only in the long term.

In this study, the input-output table was complemented with a quite small amount of emissions and natural resources. In future, it would be useful to add a wider amount of emissions to the model and, if needed, to allow lower detail accuracy. Then it would be possible to estimate roughly the significance of the building sector as generator of a larger number of emissions.

3 Conclusions

Environmental impacts of building construction and facility management need to be reduced. Some building sector customers want to have influence on the state of the environment with their purchase decisions. Environmentally friendly buildings can be attractive if the customers can assure themselves that their purchase decision is good. All customers in the building sector do not, however, find environmental values especially important. It is presumable that the goals to reduce emissions cannot be reached only by voluntary actions. In future it may be possible that the companies and their clients shall pay costs corresponding to the real environmental harms when using natural resources and generating emissions. In order to utilise the demand for environmental values, building construction and real estate branches have to create a simple and reliable way for the definition of environmental impacts of different buildings. Environmental impacts of production, maintenance, user activities and demolition need to be considered in development. In this way the central development targets shall be found which can used for design control of buildings. Furthermore, the enterprises in the construction and real estate sector shall in their strategic development work be prepared for the fact that the cost of causing all the most central environmental impacts will rise. Transferring the costs of externalities to those causing them also means that the non-material inputs which are usually left outside when assessing environmental impacts, are taken rightfully into consideration.

Cultural Change in Construction: Generic Or Gendered?

C. Greed
Faculty of the Built Environment, University of West of England, Bristol, UK.

Abstract:

This paper discusses interim findings from a pilot research project, funded by ESRC for one year in 1997, which investigates the changing composition and culture of the construction industry. Emphasis was put upon the under-representation of women, and other minorities at the professional level, with particular reference to the specialisms of civil engineering, construction management and building surveying, which represent three key aspects of the construction professions, namely design, management and technology. Acceptance of minority individuals by the dominant group is seen as essential for them to progress and thus change the culture. The use of qualitative methodology is discussed in identifying key themes with a view to undertaking a more focused second stage study, after this initial stocktaking phase. An ethnographic approach is seen as essential to get beneath the surface - post-Latham Working Group 8's report on 'women and men in construction'. Latham has provided a 'script' for everyone to repeat, but, it is argued, little has changed, yet. Firstly internal subcultural factors which prove problematic for minority groups are identified. Emphasis is putting upon 'making the familiar strange' and describing the construction industry, 'as others see us'. Secondly, external regulatory, funding, organisational and cultural change agents are identified. There have been a range of educational initiatives and programmes, and attempts at 'changing the culture' of construction from a variety of perspectives in recent years. Key change agents are identified, both inside and outside the industry. These include a range of community and minority organisations, which have grown up around the construction industry (such as the Society of Black Architects). Governmental bodies which influence over the industry are also contributing to change, especially those with funding powers. For example the Millenium Programme requires a higher level of equal opportunities policy compliance in funded building schemes, both in terms of the composition of the workforce and in the design of buildings. There is clearly a need to change the culture and image of the industry.
Keywords: Access, change, culture, disability, ethnicity, ethnography, professions, women.

Cultural Change in Construction: Gendered or Generic?

1 Changing cultures

1.1 Research basis

This research builds on previous studies of women in surveying [1] and town planning [2], and seeks to investigate the more site-related end of the built environment professional spectrum, emphasising construction management, civil engineering, and building surveying; whilst considering architecture and housing for comparison. This research utilises qualitative, ethnographic methods [3], with some quantitative contextualisation (Table 1). Ethnography is a means of getting below the surface of 'words' and 'fronts'. The method is based on observing the culture of the various construction 'tribes', and seeking to understand their perception of 'reality', not least how they see 'others' who are unlike themselves. From this research a series of key ethnographic themes, that frequently manifest themselves in the course of contacts with organisations and conversations with individuals in the world of construction, have been developed upon which this paper draws [4], [5]. The second part of this paper is illustrated by comments from respondents relating to these themes (shown *'in italics'*). The research is topical because minorities, including women, ethnic minorities and the disabled are demanding both better design and accessibility in the built environment, and more opportunities to enter the construction professions themselves. These two factors are undoubtedly linked. Professional decision-making is not entirely socially-neutral but is influenced by an individual's perception of 'reality' as to how he (and its usually 'he' in the world of construction) sees the world, and imagines society to be. The need for the identification with the values of the construction subculture would seem to block out the entrance of both people and alternative ideas that are seen as 'different' or 'unsettling', but which may be more reflective of the needs and composition of wider society. 'Subculture' is taken to mean the cultural traits, beliefs, and lifestyle peculiar to the construction tribe [6]. One of the most important factors seems to be the need for a person to fit in to the subculture in order to succeed and progress.

1.2 Generic Considerations

There are demands for change within the industry from a range of mainstream and minority sources. Government initiatives such as the Foresight programme (Department of Trade and Industry) and Partners in Technology (Department of Environment); working groups including CISC [6], and Latham [7]; and a range of research projects have all highlighted the need for cultural change within construction. Reasons for change variously include 'the business case' ; increased efficency of industrial processes within the industry; health and safety considerations; greater competitiveness; recruitment crises; down-sizing; multi-tasking; greater flexibility; environmental, economic and social sustainability; improved human resource management, and the need for creating a climate of technological innovation and progress. The UK construction industry is often characterised as being conflict-ridden, fragmented yet feudal, dangerous and dirty, unattractive to young people, obsessed with professional status, and less productive than in other comparable European countries [S].

1.3 Gender Considerations

Many of the above initiatives adopt a generic approach, not 'disaggregating' the needs of different groups within the construction workforce upon the basis of gender, race, age or other social differences. But, many researchers would argue that the question of gender imbalance has to be taken on board, as a symptom of deeper problems, in an industry characterised by less than 5 % female employment, which is meant to be serving a society which is 52 % female, [9], [10], [11]. The Construction industry employs around 1.3 million people at present, a drop of half a million from the end of the 1980s. In spite of this state of decline, it still responsible for around 10% of the Gross National Product, employing 7% of the total male workforce, yet only 2 % of manual trade workers [12], and less than 6% of professionals in construction are women, the bulk of women in construction being employed in administrative, service, clerical, and personnel roles [13]. Arguably gender may be seen as a barometer by which to measure the overall wellbeing of an industry. In these days of manpower shortages, it is in the interests of the industry to attract, train, and retain more women and other minorities. The construction industry is not a separate planet, it does not exist in a technological vacuum separate from the wider society. Indeed its economic future depends upon being in tune with society's needs and demands. Thus the Latham Report, Working Group 8 [7] on women and men in construction is to be welcomed.

2 Changing attitudes

2.1 A new script?

It was found from the research that a Latham 'script' now exists which construction professionals can confidently recite on the topic of 'women' and 'equal opportunities': the topic has been 'done'. One gets the same sound bites again and again when seeking to elicit construction professionals' views on the position of women and other minorities in the industry [14]. A reading of Latham's 'proposals' as 'actions' imminently to be implemented can bolster this optimism [15]. The Latham-phenomenon has led to what ethnographers call 'reactivity' a feed-back loop has been created. Some might say the subject has been done to death, everyone is bored with hearing about gender, but few seem to understand what the implications are for the industry. But the fact that the right 'words' now exist, does not, necessarily, mean that the situation has changed, in terms of implementation, and 'actions'.

An element of 'secretiveness' within the construction culture was encountered, making it difficult to get a straight answer when seeking figures and 'facts', possibly because of fears of litigation, taxation and increased regulation, but this is particularly in respect of gender statistics. Also there is often a lack of clear written criteria in evidence on matters such as recruitment, promotion, career development, and qualification, and much of the system still seems to run on the 'he's a good *chap, I knew his father'* principle, with informal social and sporting networks playing a key role in the management of the industry, and the chances of work, at all levels. It would seem that relatively little has changed in the mainstream, but that nowadays, 'equal opportunities' has been taken on board as a separate minority topic, which is seen as *'adding costs'* rather than as contributing to overall economic growth, and as a valuable investment for people within the industry.

2.2 New practices?

The building site is still used as the great excuse as to why women cannot go into construction. In conversations the emphasis on the 'hardness' and 'dirtiness' of the work increases proportionately to respondents embarrassment about women' s exclusion. It seems it is not the physical site that is the real problem but rather the nature of social relations on site, in particular the ethos of pressure, and bullying, which many have commented upon [16]. The construction industry is not only highly gendered it is also strongly classed [4], quite feudal, and military in structure. Admittedly some aspects of professional work in construction are likely to result in somewhat flexible and discontinuous employment patterns, because the workforce fluctuates as new sites and projects are developed *'as the circus moves on'*. Also the whole industry is subject to 'boom and bust', and 'stop go' cycles within the economy as a whole, but, women appear to have greater difficulty maintaining employment mobility and continuity than male counterparts. Women in construction are increasingly likely to work in smaller firms or as self-employed professionals, many preferring off-site consultancy work, to predominantly on-site roles. The 'big boys' in the 'big firms' are only the tip of the iceberg, as the majority of all firms in construction are small, even though greater attention is often given to the large 'big name' contractors in Britain [17].

Subtle vertical divisions between different skills, and levels of responsibility in which every man knows his place, are reflected, in the 'map' of the construction industry produced by CISC for qualifications policy development purposes [7]. Women may feel there is no place for them in a world divided between 'officers and men' (cf Building, 14.10.94 pp 2 10-3). Black (especially afro-Caribbean) women professionals may feel even more out of place, particularly in sectors of the industry where colonial and 'ex-pat' attitudes prevail. Asian women may be the subject of racial stereotyping that typifies them as *'businesslike, obedient, and hardworking'*, especially the Chinese.

Relatively few women are to be found in senior posts (New Builder 24.3.95 'top posts still elude women'). However there are now more young professional women in construction (Table 1), and some large firms have positive recruitment programmes. But my attempts to track individual women down often resulted in my being informed, *'oh there was* one, *but she left'*: the *'there was* one' phenomenon proved common. Many have argued that attracting more women would lead to more humane forms of management which would result in greater productivity and less of a confrontational, conflict-ridden, ' macho pack culture' (compare Construction Manager October 1996, pp.5), resulting in more efficency and cost-effectiveness. Indeed it is often argued that *'what is good for women is good* for *the industry* as a *whole'*. But, one of the obstacles, it seems, is the unwillingness of managers and professionals to admit the need for drastic change, plus fear among manual trades workers of being seen as less than 'real men' in admitting dissatisfaction. The entrance of a greater range of types of people into the industry will bring new perspectives and objectives.

3 Agents of change

3.1 Alternative perspectives

In this section the situation will be considered from the 'other' side, in relation to external change agents which might transform the construction culture. These include ‘bottom up’ and ‘top down’ initiatives, that is, respectively, those deriving from community and minority groups, and those from governmental levels. In ‘the middle’ within the industry, the influence of both these forces needs to be translated into changes in educational and professional practice.

3 .2 Educational access

Many women, ethnic minorities and disabled people (not mutually exclusive categories) are interested in the built environment, because of concerns about community issues, especially the impractical and inappropriate nature of the design of many buildings. This concern may translate into a desire to enter the construction industry at some level in order to change the situation, particularly among mature women students who already have some idea about how the system works. Unfortunately the ‘windows of opportunity’ for training and advancement are still geared to the younger, rather than mature candidate [18] and the construction press seems obsessed with the lack of younger 16-17 year old manual workers (Construction News, 6.2.97 pp 2) especially the shortage of steel erectors, crane drivers and welders, which, in comparison are growth areas for women in the USA [19]. Generally one finds that women seem to be more concerned about the caring, environmental and design aspects of the built environment (but this does not preclude a parallel enthusiasm for technological and scientific aspects too). One does not see these interests fully reflected in the publicity material for careers in construction, or integrated within course subject-matter.

More women have been entering professionally-exempting built environment courses since the mid 1980s [1], [2], but there has been a gradual decline in recent years, especially in surveying, as if women have ‘tried’ the construction professions, not thought much of them, and moved on to other areas, especially law, accountancy, media studies, and environmental courses. Even on courses where there has been a substantial number of women and commendable completion rates, some of those who qualify may subsequently ‘vanish’ (compare the ‘*there was* one’ factor discussed earlier). Some are taking a temporary career break to rear children but others are not ‘dropping out’ but positively going into other more interesting fields. Among these are women who are still very interested in built environment and building design issues, but who channel their energies into the voluntary sector.

For young women, and men, the changeable and uncertain nature of the industry may discourage them from investigating it as a career choice. *'It's* a *rubbish industry, there 's no future in it '*. But potentially women’ s need for career breaks and maternity leave would fit in well to the industry’s project-driven employment patterns and need for flexible workforces. There are more students studying leisure, sport and recreation degrees than the total on all built environment courses, and four times the number of students on hairdressing courses than on construction courses at the technical college level. There are now small cohorts of women on most courses (7% on average, with considerable variation between courses), but this is hardly a growth area. But, initial access is now easier, because of the expansion of higher education. In comparison architecture continues to attract by far the greater number of women, and men, with 30% women being common on courses. The emphasis in architecture upon ‘design’ and ‘environment’ and ‘changing things’ and ‘working for the community’ are key incentives for women. Construction courses are struggling for students, yet much of their course material activities are not that different from architecture [20].

Many students, both male and female, become disillusioned or chose alternative career paths having entered architecture, as only 25 % of those who enrol ever become architects [21] and a similar figure applies to civil engineering. Women are likely to drop out early on, or continue doggedly to the end. One problem is the question of ‘fitting in’ to the respective subcultural image of each profession, none of which were designed with women or non-white groups in mind. Women may be confused by the multiplicity of different professional bodies and demarcations [22]. Educational initiatives such as the Construction Careers Forum are seeking to create a better, less fragmented ‘image’, so recruits are clearer as to which specialism might suit them best.

3.3 Minority organisations

A range of women, ethnic minority and disabled construction professionals, who have given up on the mainstream, are to be found in community, charity and campaigning groups. Far from altering the culture of construction, a series of new satellites are now circling ‘Planet Construction’ with their own subcultures and organisational structures. Significant groups include the Centre for Accessible Environments; Planning Aid for London; London Women and the Manual Trades; the Society of Black Architects, and Women’s Design Service.

Those actively involved are admittedly quite small in number but they may be seen as a force for change in that they form part of a powerful network of alternative groups, they are often highly productive in publication, research and campaigning. Also the organisations they run offer a model of alternative mangement structures, which are often based on a more co-operative, inclusive attitude towards employees at all levels, and a greater level of the communication with ‘society’ particularly when their ‘client’ is the community, or a disadvantaged or under-represented minority group. Whilst it may be argued these organisations are not commercial enterprises and therefore irrelevant as models for the construction industry, yet their ability to achieve a great deal with limited resources shows they have a respect for the ‘cost factor’ and for efficency, economy, and flat management structures, which might be emulated. For example, one often finds among women’s groups a complete lack of the social division between manual trades and professional levels found in the mainstream industry, with everyone seeking to integrate childcare considerations into the working day. Many women take a more holistic viewpoint towards the construction process, seeking to incorporate environmental and sustainability priorities. In contrast some young people seem perceive construction and environmentalism to be quite incompatible, particularly in respect of road building, the eco-warrior Swampy epitomising this trend.

3.4 Governmental bodies

Central government ministries responsible for industry and the environment are ‘over and above’ the industry and can be instrumental in generating change, and if necessary, enforcing it. Also some ad hoc governmental funding bodies, for example, those responsible for the Lottery, Millenium, Sports Council, and Arts Council all have higher equality opportunities requirements and accessibility design standards than are found under ‘normal’ legislation, and can insist upon higher levels of ‘contract compliance’ in new construction above current Building Regulation and employment legislation in respect of ‘what’ is built, and ‘who’ is building it [23]. Voluntary, community and minority groups are likely to be among the beneficiaries of such grants, thus enabling them to produce exemplar schemes in terms of both design and employment practice. But, black groups may still feel excluded even when other community groups are getting recognition, particularly when it comes to 'competitions' for new schemes. Many are critical of the perceived racism of some such organisations and also housing associations who put black women professionals on their management committee, 'because *it looks good'*, but never actually use black professionals or contractors in construction projects [24].

Local government bodies are also able to play a role in improving standards in the construction industry, for example by co-ordinating Local Labour in Construction Schemes, such as GLLiC in Greenwich [25], in association with major developments in the area, and in liaison with training schemes and local small business initiatives. Also, many London borough town planning departments make it a requirement of any major planning permission that certain equal opportunities measures and design features should be integrated in the development [26].

4 Future cultural change

4.1 Conclusion

The combination of pressures to change the culture from within, the activities of satellite pressure groups, and the power of governmental regulation may with time ameliorate the nature of the construction culture - and then women and other under-represented groups will enter freely, enthusiastically and in greater numbers. But, there is also fear of a backlash as some male construction professionals appear quite defensive when they realise that equal opportunities policy does not just affect women but may mean mainstream changes in <u>their</u> own lives and careers too.

Whilst it should not automatically be assumed that 'more means better' in respect of increased minority participation within the industry, it is likely that women in particular will bring a wider and innovative perspective, particularly a more 'sustainable' approach. Sustainability originally [27], incorporated three components of: - economic viability, social equality and environmental balance, but ironically in Britain, unlike Sweden, the latter has often been stressed at the expense of social equality. The way forward is to pursue all three, for the good of the industry, the economy, the whole of society . . . and the planet.

Environmental Book of Specifications and Qualitative Assessment Method for Green Secondary Schools

S. Nibel, Ph. Duchêne-Marullaz
Scientific and Technical Centre of Buildings (CSTB), Champs-sur-Marne, France
G. Olive
Consultant (GOIC), Paris, France

Abstract

In France, the Region of Ile-de-France now integrates an Environmental Quality approach into its projects of new secondary schools. A first green secondary school has just been built according to this approach.

The CSTB and GOIC assisted the Region Ile-de-France in designing, among other things, an environmental book of specifications, and a simplified qualitative method, both adapted to the projects of green secondary schools in Ile-de-France.

The environmental book of specifications is a document which completes the functional brief of the Building Owner. In the framework of the competitions launched by the Region, this book of specifications is part of the calls for tender.

The book of specifications is structured in 14 environmental quality targets, themselves divided in sub-targets. It comprises, for each target, a definition, environmental requirements to be respected, recommendations for guiding the designers, and information asked to the Design Team at different stages of the design process. The answers to the questions relating to the pre-design stage form the input data of the qualitative assessment method.

Consequently, candidates to the competition are made sensitive to the environment from the beginning, can integrate early in their design the requirements and take into account recommendations. Furthermore, they know the points on which their project will be assessed.

The qualitative assessment method is used at the competition stage and allows the Building Owner to assess the technical and architectural solutions of the different projects submitted, in terms of improvement of the environmental quality. In coherence with the book of specifications, the method is structured in 14 targets. The assessment is made according to expert opinion, associating objective assessment and actors' points of view. For each elementary target, an assessment scale is defined. The Building Owner may define, *a* priori, a « theoretical objective level » on these scales. The assessment is translated into elementary marks, weighted within each target. The result is presented as a profile of 14 assessments, which may be if necessary aggregated according to certain rules.

Key words : assessment method, book of specifications, competition, environmental quality targets, qualitative, secondary school.

1. Introduction

Public Building Owners presently need help from environment specialists in order to implement in a concrete way their environment protection policy.

This paper presents an upstream environmental action that CSTB and GOIC carried out for the Region of Ile-de-France.

Among the numerous actions the Regional Council of Ile-de-France has undertaken regarding sustainable development, one of them consists in integrating « Environmental Quality » into its buildings. The Regional Council has chosen the reconstruction of the Maximilien Perret technical secondary school near Paris, to implement this new approach and to make an experiment. In France, the Regions are the public building owners of secondary schools.

In 1994, the Regional Council of Ile-de-France defined a programme for the reconstruction of this school, and launched a competition between five architect-contractor consortiums.

In order to integrate environmental concerns into the project, the Regional Council needed to add an environmental book of specifications to the functional brief and to define a tool for the assessment of the proposals.

A team formed by CSTB and private consultants helped the Region of Ile-de-France in this task. The first version of this set of tools was implemented for the Maximilien Perret secondary school. What is presented hereafter is the second version of this set of tools (book of specifications : completed, assessment method : under final phase).

2. Environmental Book of Specifications

2.1. Context

The environmental book of specifications [1] takes place at the brief phase. It is a document which completes the functional brief of the Building Owner. It is *in fine* targeted to the Design Team, but before, it can help the Building Owner in fixing his environmental objectives.

In the framework of the competitions launched by the Region, this book of specifications is part of the calls for tender. It is important to have this upstream action. Particularly, the architect has to integrate correctly the approach in his sketch and pre-design project.

2.2. Objectives and general features

This book of specifications has several objectives :

- to develop awareness on environment and explain the stakes
- to be associated with or integrated into the functional brief (programme)
- to provide environmental requirements to be respected
- to guide the design phases, by recommendations
- to explain and prepare the « environmental management » of the project
- to ask the Design Team for information, in order to :
    - prepare the qualitative assessment (preliminary design, competition stage)
    - prepare the detailed design

Through this book of specifications, the Building Owner is free to express his requirements. Namely, he can select his priorities, he can reinforce the requirements in changing the reference values.

The book of specifications is structured in 14 environmental quality targets, themselves divided in sub-targets.

2.3. Presentation of the 14 environmental quality targets

The notion of « environmental quality target » is a pragmatic one, mixing on one hand requirements of environment protection and creation of a comfortable and healthy medium for users, and on the other hand families of action means belonging to the building sector.

Four families of targets have been defined :

- Eco-construction
- Eco-management
- Comfort
- Health

The table 1 details the structure of EQ targets and sub-targets.

ECO - CONSTRUCTION
1. Relation of the buildings with their immediate surroundings (Use of the opportunities offered by the neighbourhood and the site / Management of the advantages and drawbacks of the plot of land / Organisation of the plot for creating a pleasant quality of life / Reduction of the risks of nuisances between the building, its neighbourhood and its site)
2. Choice of construction products and processes (Adaptability and durability of buildings / Choice of construction processes / Choice of construction products)
3. Green building site (Reduction, sorting and management of the construction wastes / Reduction of the noise on the building site / Reduction of the pollution on the plot and the neighbourhood / Management of the other nuisances of the building site)
ECO – MANAGEMENT
4. Energy management (Reinforced reduction of energy needs / Reinforced use of environmentally-friendly energies / Reinforced efficiency of energy equipment / Use of low-emission generators when combustion boilers are used)
5. Water management (Management of potable water / Use of non potable water / Certainty of the sewerage of used water / Aid to the management of rain water)
6. Activity waste management (Design of activity waste collection premises adapted to present and probable collecting systems / Sorting and management of activity wastes, adapted to the present collecting system)
7. Maintenance (Optimisation of maintenance needs / Implementation of efficient processes of technical management and maintenance / Reduction of environmental effects due to maintenance processes)
COMFORT
8. Hygro-thermal comfort (Permanence of hygrothermal comfort conditions / Homogeneity of hygrothermal ambiences / Hygrothermal zoning)
9. Acoustic comfort (Acoustic correction / Acoustic insulation / Low-transmission of impact and equipment noise / Acoustic zoning)
10. Visual comfort (Satisfying visual relationship with outdoor spaces / Optimal daylighting in terms of visual comfort and energy expenses / Satisfying artificial lighting and in complement of daylighting)
11. Olfactory comfort (Reduction of unpleasant odour sources / Ventilation allowing the exhaust of unpleasant odours)

HEALTH
12. Sanitary conditions (Creation of non-air features of satisfying indoor ambiences / Creation of hygienic conditions / Easiness of cleaning and evacuation of activity wastes / Easiness of health cares / Creation of convenience for disable people)
13. Indoor air quality (Management of pollution risks by construction products / Management of pollution risks by equipment / Management of pollution risks by maintenance or improvement / Management of pollution risks by radon / Management of risk of polluted fresh air / Ventilation for indoor air quality)
14. Water quality (Protection of collective distribution network of potable water / Keeping of potable water quality in buildings / Possible improvement of potable water quality / Possible treatment of non potable water used / Management of the risks linked to non potable water networks)

Table 1 : list of environmental quality targets and sub-targets

This list of EQ targets has been used in several green building projects in France, and has been recently discussed in the framework of an association gathering the main French actors involved in environmental quality of buildings [2].

2.4. Structure for each environmental quality target

An environmental quality target is in fact a set of elementary targets. At a whole, there are more than 50 elementary targets, called sub-targets.

Each EQ target is divided in four parts : the first one gives the definition of the target, the second one lists the requirements to be respected by the Design Team, the third one presents some useful recommendations in order to improve the result, the last one details the questions asked to the Design Team. These questions concern different points of view : architectural, technical, economical, and linked to environmental management. Furthermore, these questions are adapted to different stages in the design and planning phases : pre-design (competition), detailed project, final contracts, and construction.

2.5. Advantages

Consequently, candidates to the competition are made sensitive to the environment from the beginning, can integrate early in their design the requirements and take into account recommendations. Furthermore, they know the points on which their project will be assessed.

3. Qualitative assessment method

The qualitative assessment method is used at the competition stage in order to allow the building owner to assess the technical and architectural solutions of the different projects submitted, in terms of improvement of the environmental quality.

The assessment is made according to expert opinion, associating objective assessment and actors' points of view.

3.1. Methodology

3.1.1. Inputs

The answers to the questions relating to the pre-design stage form the input data of the qualitative assessment method. There are 27 questions to be answered at the competition stage, certain of them gathering two sub-targets at a time.

3.1.2. Organization

In coherence with the book of specifications, the method is structured in 14 targets.

3.1.3. Main steps of the method, for each sub-target

For each sub-target, an assessment scale is defined, between 0% and 100%. The method in itself proposes a description of what is level 0 and what is level 100, and also defines the intermediate levels of performance (25%; SO%, 75%). So we get a 5-level assessment scale.

In the method are defined the weightings within the set of sub-targets, allowing to pass from the sub-target assessment to the target assessment.

The method also proposes, but it must be validated or modified by the Building Owner, an “objective level” for each sub-target. It is the performance expected by the Building Owner for this sub-target. So we obtain a set of Building Owner “benchmarks”.

The assessment is divided in two parts, reflecting an environmental assessment and a valuation according to more general quality criteria.

The first part of the assessment consists in giving, by expert opinion, and most of time qualitatively, a mark (from 0 to 100%) for the proposed solution with respect to the sub-target, on the basis of the answer given by the Design Team for this sub-target. This rating is completed by a comment, justifying the assessment.

The other part of the assessment consists in giving, always by expert opinion and qualitatively, warnings or credits on other quality criteria. These other criteria are the following : “Technical”, “Human”, “Ecological”, “Investment Cost”, and “Running Cost”. The valuation scale is : + +, +, 0, -, - -, according as the proposed solution has a positive or negative influence on the considered criterion. In the case the expert has not information enough to valuate, the result is “?”. Here, there is also a comment to be added for interpretation.

The figure 1 shows the two parts of the assessment for one given sub-target.

3.1.4. Towards an environmental profile

After rating the different sub-targets, a process of weighting and aggregation allows to get one rating by EQ target.

The result is presented as a profile of 14 assessments, pinpointing both the performance of one project for each target, and the Building Owner “benchmarks”. It is possible to build comparative graphs for the different projects in competition.

If necessary, but it is only optional, the environmental profile may be aggregated according to certain rules. It could be the case if the Building Owner wants to arrange the different projects in competition, according to actors’ viewpoints. But if the Building Owner wants to communicate about the projects, it is important he keeps all the substance of the detailed results. These phases are shown on figure 2.

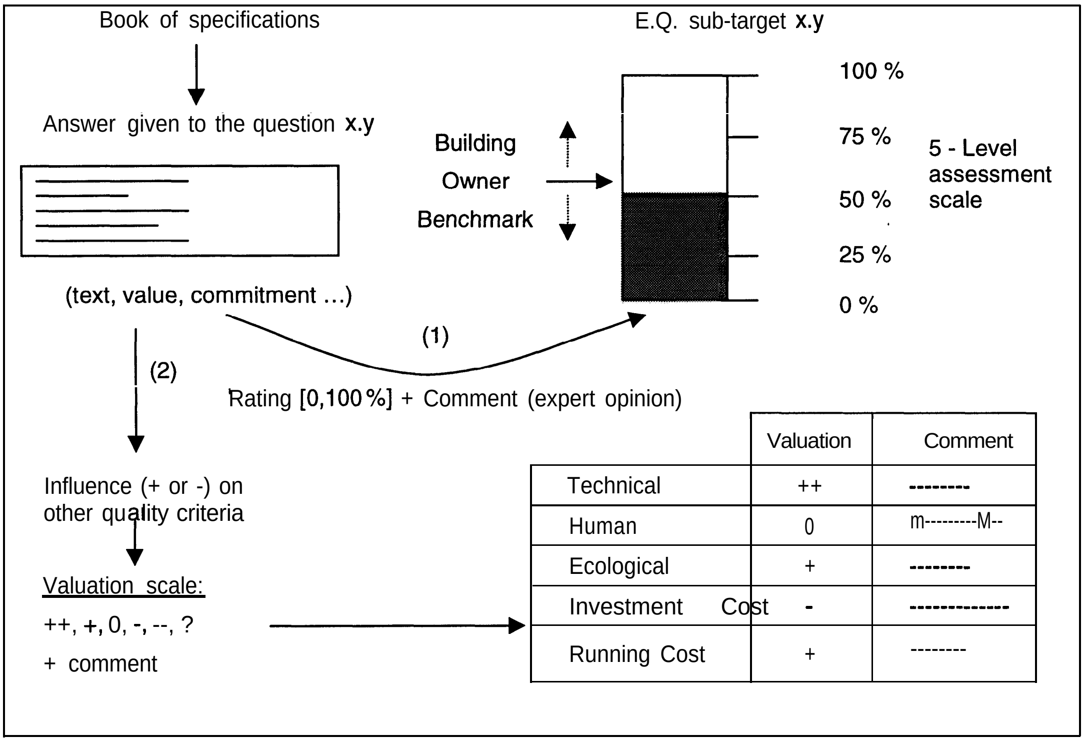

Figure 1 – Principle of the assessment method for one sub-target

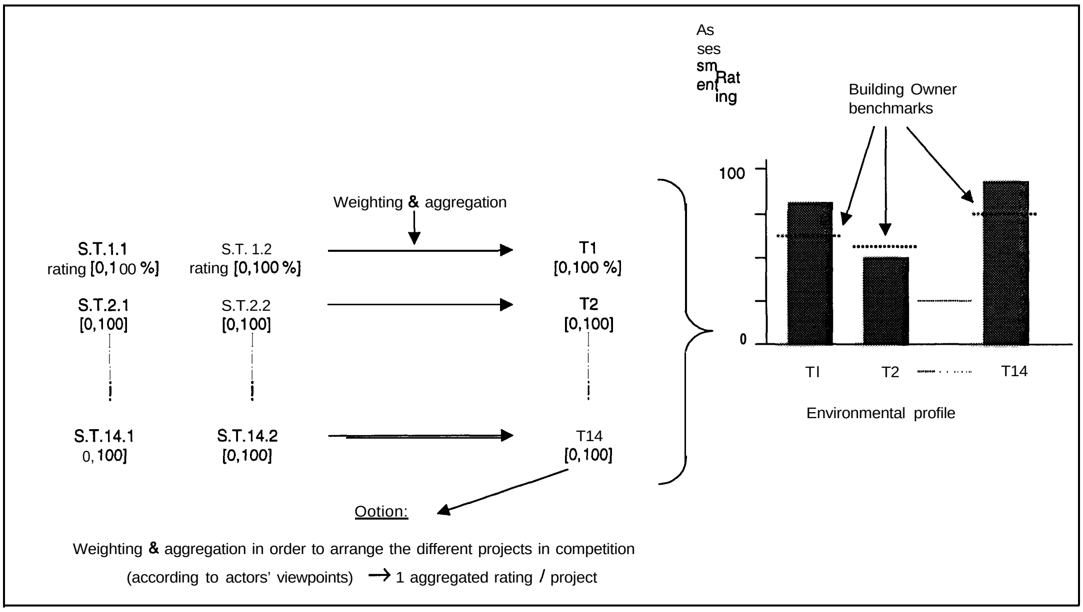

Figure 2 – Rating the environmental quality targets

3.1.5. Aggregation of results on the other quality criteria

The results of the valuation according to the other quality criteria are presented in a table crossing the criteria and the sub-targets. Then, there is an aggregation process which avoids compensation between the (+) and the (-). To each valuation is associated a weight, positive, negative or zero. A sum is performed, leading to 5 double-valuation by project, one by criteria. It is possible to aggregate more, but it is not recommended. Anyway, the aggregated results must not hide the detailed results. Figure 3 shows the way of presenting and aggregating the results on the general quality criteria.

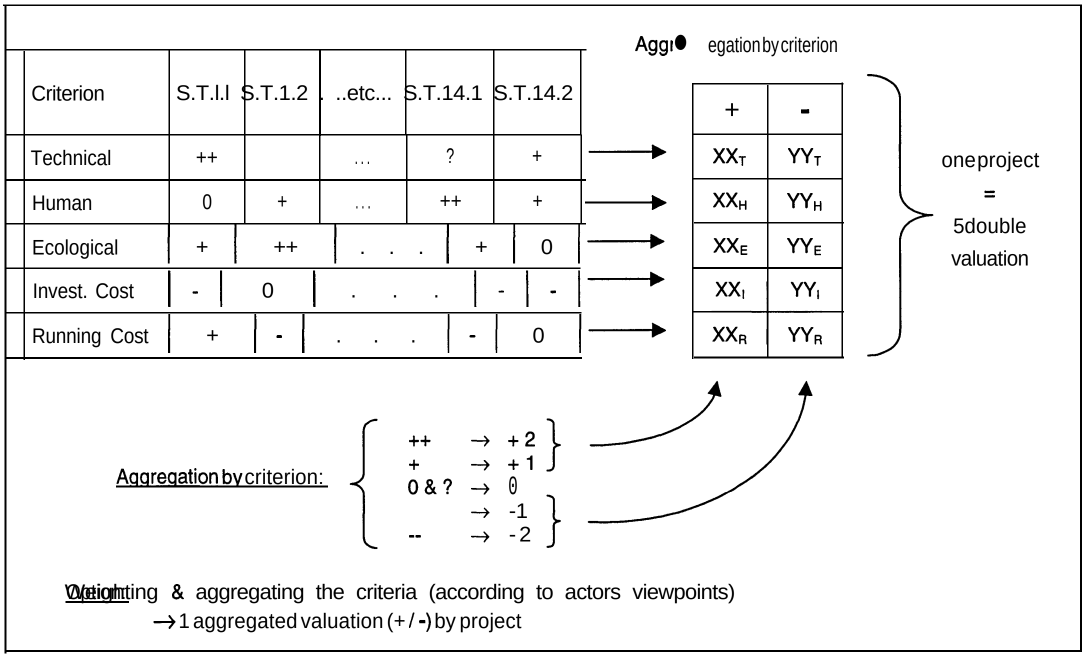

Figure 3 – Aggregating the valuation according to the other quality criteria

3.2. Results and discussion

As a summary, the qualitative assessment method leads to the following results :

- one mark by EQ target, after weighting the sub-targets
- presentation by an environmental profile (14 values)
- aggregation of results on the other quality criteria
- comparative graphs for the different projects in competition
- option for more aggregation, for a final arrangement
- possibility to go upstream in the detailed results

Through the book of specifications, the Building Owner may promote its environmental policy in fixing benchmarks. With the assessment method, he can see in what extent the candidates reach the objectives he has fixed.

The economical aspect is probably not enough developed in the book of specifications and in the method, particularly in the questions asked to the Design Team. It is a point to be improved in the future.

The assessment may be seen as a subjective one, but in fact, given the assessment scales are clearly described, the difference between two expert assessments is small.

In most of the environmental assessment methods, it is assessed (sometimes with an illusory precision) in what extent the solutions included in the project lead to reduce environmental impacts, and that's all. In our opinion, this is not sufficient.

One original feature of our method is that it does not assess the solutions only from an environmental point of view, but also according to more general quality criteria. This is essential, because environmental quality must not be disconnected from global quality of building.

Put together, the two kinds of assessment included in the method are complementary, and form a good information basis for the choice of the winner project, and for the communication about the project. It is also a good work foundation for the following phases of the design. In particular, the information contained in the assessment allows the Design Team to improve his project on various criteria.

4. Conclusion

The described set of tools allows three axis to be connected (see figure 4) :

- the environmental brief, by the book of specifications
- the assessment of the submitted projects, by the qualitative method used at the competition stage
- the environmental management of the project [3], by the recommendations included in the book of specifications (not detailed in this paper).

Technologies of family house construction

Petrovic J.
Vidakovic D., Dolacek Z.
Faculty of Civil Engineering, Osijek, Croatia

INTRODUCTION

Richness of some country can be measured via development of means of labour and technologies it utilizes. At the same time capability of new technology adoption is in accordance with standard increase. The worst obstacle to new technology development are people favouring tradition, afraid of new and reluctant to learn. Another problem is the fact that today's new technologies demand higher initial investments, developed marketing and higher mobility of labour force.The result of this is that the well-growns develop faster than those which are more in need of innovations and higher standard. This rule is valid for all economy branches including construction.

Construction, apart from food preparation, has the longest tradition in human life which necessary implies development slowness. On the other hand need for housing quality improvement requires new demands. Minimum conditions of heat and acoustic insulation, earthquake safety, energy consumption, permitted limits of different radiations and chemical influences as well as ecological conditions have already been defined in the regulations of many countries.

The above mentioned problems at development due to which less developing countries are in difficult position may be sometimes avoided.Introduction of new technologies may be considerably intensified at big projects running such as : new settlements construction or with mega projects like renewal of the complete areas after war destructions, severe earthquakes, floods etc. Croatia suffered from such tragic experience. Thus, the investigation on advantages of new technologies was started here. Partial results are presented by this paper.

PROBLEM

This is the time when materials and semiproducts with some emphasized properties ocurr i.e. when the most required criteria can be met by combination of such materials. On the other hand standard requirements, recently unpredicted climate, earthquakes, ecology etc. caused concern on approximately 3 0 different criteria while constructing family houses. These investigations present those criteria as subcriteria classified into three main criteria :

A-criterion pertaining to construction of facilities
B-criterion pertaining to expenses of facilities maintaining and use
C-criterion pertaining to housing comfort

Criterion A includes the following subcriteria in this study : Kfl-construction -- costs, Kf2 - construction time, Kf3 - mechanical equipment and Kf4 - skills. Criterion B consists of subcriterion Km1 - house damaging, Km2 -fire danger, Km3 -surface schock-resistance, Km4 - heating costs, Km5 -house maintenance costs and Km6 - house duration. Criterion C comprises the following subcriteria: Kc 1 - sound protection in the room, Kc2 - thermal radiation, Kc3 - chemical effect of the building parts, Kc4 - Influence of other radiations, Kc5 - possibility of hanging on the walls, Kc6 -possibility of wall i.e. rooms arrangement change and Kc7 - walls quality and their contact. Only a part of today’s relevant subcriteria which are used at total building evaluation was analyzed.

Subcriteria are so different that comparison can be partially carried out after determination evaluation (calculations, gantograms.. .thermal radiation.. .) and partially after evaluation i.e. stohistically. This investigation was also treated in that way.

“Method of analysis of applicable value” enables us to combine both procedures. Apart from the comparison of complete technologies, combination of some segments (the best ones) from each technology can be carried out by the same method and then compared.The above mentioned helped in analyzing i.e. comparing technologies in different phases of a family house construction.Also everything was compared with the type and technology of the facility accepted by The Ministry as an investor, for example houses without facade, final floors, paintings etc.

Conditions of construction had to be equalized at investigation of variables i.e. technologies to ensure the most reliable results. It was obtained in the way that calculation took into account as all technologies were applied for construction :

- facility of the same size occupying 57 m^2 netto of the ground floor or 1 14m^2 netto with a storey
- the same number of employees work in the same transport conditions
- purchasing prices of materials, semiproducts and the same products are equal
- facility is in III climatic zone
- equal roof loads and soil bearing power.

Comparable properties have been searched for 9 technology types. Apart from mutual comparison , all technologies were additionally compared with the type chosen by the Ministry of reconstruction. The analyzed types were as follows :

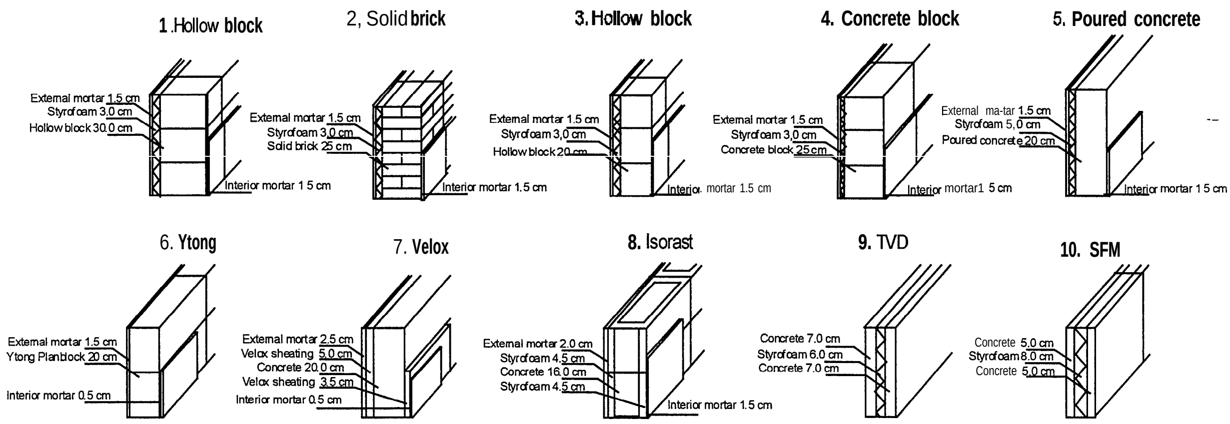

Figure 1 : Representation of the chosen technologies

Here it should be mentioned that technologies 3,4 and 5 have been mostly abandoned in Croatia whereas 1 and 2 are in fact the same ones. The only difference is that type 1 i.e. the one of the Ministry has walls of 30 cm but without vertical ties. This type has been mostly used today. Other types have only started to appear.

RESULTS OF THE INVESTIGATION

Technological innovations at family houses construction are firstly applied with walls of storey construction and overhead slabs. Stability of the house and the facility physics are the main requirements which should be met prior to any investigation. Walls per dimensions and sandwich structure can be seen from the following Table.

ordinal number	Technologies	Statistics requirements		Physics requirements		thickness of supporting wall part (cm)	thickness of thermal wall part (cm)	total wall thickness (cm)
		Minimal thickness (cm)	next standard thickness (cm)	primary material (cm)	next standard thickness (cm)			
1	2	3	4	5	6	7	8	9
1.	HOLLOW BLOCK - M	13,88	19	56,3	20	30	5,3	35,3
2.	SOLID BLOCK	14,86	25	62,8	64	25	6,3	31,3
3.	HOLLOW BLOCK	12,395	19	56,3	59	20	6,3	26,3
4.	CONCRETE BLOCK	13,67	19	53	57	25	6,3	31,3
5.	POURED CONCRETE	10	-	221		20	8,3	28,3
6.	YTONG	8,02	20	18,4	20	20	2,3	22,3
7.	VELOX	10	22	221	20	20	11,X	31,8
8.	ISORAST	10	16	221	16	16	13,1	29,1
9.	TVD	10		221		14	6	20
10.	SFM	10		221		10	8	18

Figure 2 : Table of equivalent thicknesses

Chosen walls thickness (columns 7,8 and 9) meet the needs of house statistics and physics accomplishing approximatelly equal housing conditions. Unit prices of wall m^2 of each technology were calculated by means of market standardized prices.The results can be seen from Figure 3.

Prices ($/m2)	Hollow block	Solid brick	Hollow block	Concrete block	Poured concrete	Ytong	Velox	Isorast	TVD	SFM
1	2	3	4	5	6	7	8	9	10	11
$	65.38	69.90	52.62	53.55	45.96	48.58	66.95	69.29	60.10	45.65

Figure 3 : Unit prices of wall m^2 per technologies

Prices of product units (m) neither take into account different conditions under which a building is constructed nor relation of the wall m^2 toward other building parts. Data on it can be only obtained if technologies comparison is carried out in the building construction phases. In that way dominance of some technology in different phases can be seen which is obvious from Figure 5.

Apart from the walls, the technologies are also applied at overhead slabs. Different overhead slabs were investigated relative to range change.The cheapest type of the slab was searched in various technologies. Line of the total (U) costs depending on the range change was demanded for each slab type. The line was obtained by the formula

U =F+Vxc where : F = total of the fixed costs
V = total of variable costs
C = price of m^2 of prefabricated slab

Points of intersection of minimum costs line al =a min are at the places where U1 and U2 are equal. Minimum point for the lines nl and n2 is

Unl=....

Points a2, a2, a3.....costing minimum were obtained by this procedure which can be seen from the following diagram :

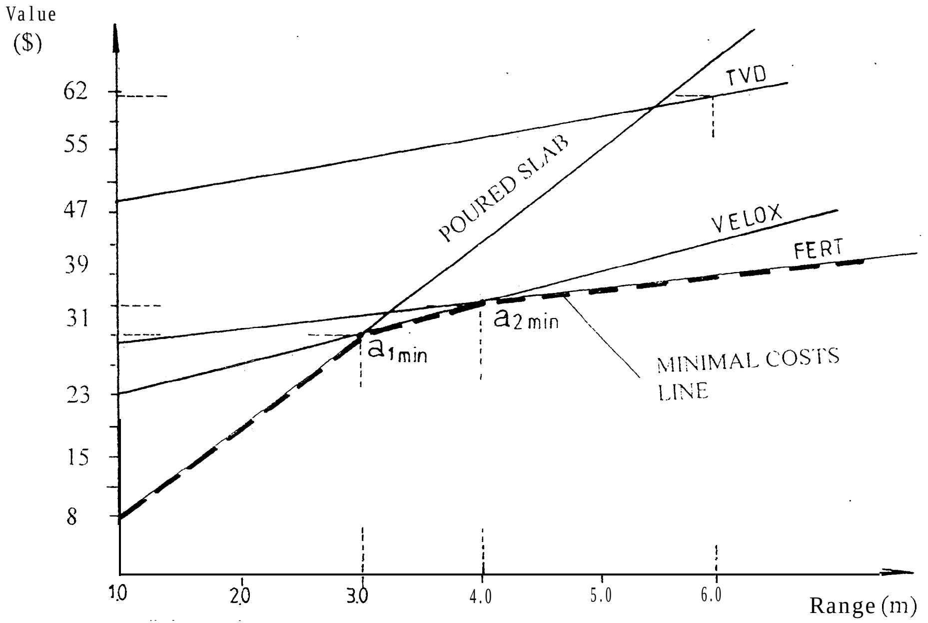

Figure 4 : Diagram of minimal costs of overhead slabs

“Fert” type of the overhead slabs is the cheapest one for ranges appearing at facility of the same type.Thus, it was mostly used for the investigation. Apart from Fert Velox and TVD slabs were also analyzed with belonging technology. Third changeable dimension is of foundations which change depending on load intensity and supporting wall dimension. Six types of foundations and three of slabs were considered at investigation of the best combination of

foundation and overhead slab with individual technology. The two most important subcriteria i.e. construction costs and duration were taken into account at choice of the most favourable combination. Once arranged buildings in each technology could be compared per various criteria and subcriteria.
Criterion A denoting favourable conditions at building construction is the most significant of the given three important criteria A,B and C. The subcriterion Kg 1" Costs of building construction" is the most important within criterion A .This subcriterion has been analyzed by calculation i.e. determination. Result for all variants (technologies) can be seen from the -- following table. The phase - finished house with facade and partial internal arrangement according to the Ministry standard (column 6) is observed in the further procedure whose determination size of coefficient Kg1 is given in column 7.

Ordinal number	Type	Storey	wall dimension (cm)	k1	total costs ($)	
1	2	3	4	5	6	7
1.	Hollow block	Ground floor	30	1,00	37092,6	1,00
2.	Solid block	Ground floor	25	0,98	37735,1	1,02
3.	Hollow block	Ground floor	20	1,05	35334,1	0,95
4.	Concrete block	Ground floor	20	1,08	34557,5	0,93
5.	Poured concrete	Ground floor	16	0,83	44339,5	1,20
6.	Ytong	Ground floor	20	1,12	32928,7	0,89
7.	(Velox	Ground floor	16	1,06	34952,6	0,94
8.	Isorast	Ground floor	20	1,10	33893,7	0,91
9.	TVD	Ground floor	14	1,09	33993,1	0,92
10.	SFM	Ground floor	10	1,20	30910,5	0,83

Figure 5 : Prices of house per construction phases

The next significant subcriterion following costs, within A criterion, is subcriterion Kf2 "Duration of a house construction". This calculation is also carried out by determination using network plans. Gantogram which can be seen in this Figure is derivative of these plans.

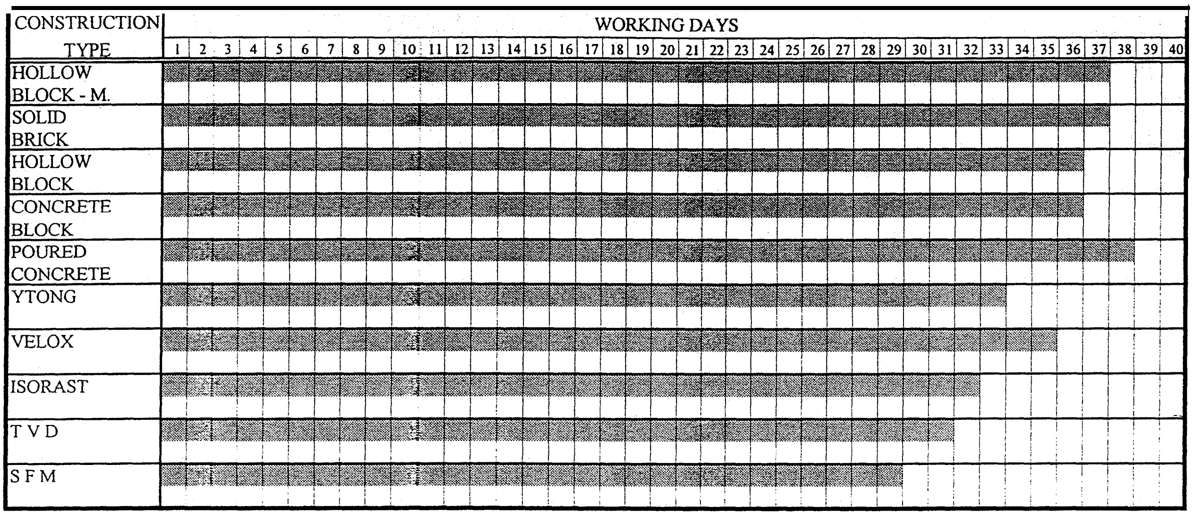

Fig.6. Total construction period

Due to limited space results of other determination calculations for subriteria Kf3 “ Mechanical equipment of a construction site” and Kf4 “Labour force skill” in criterion A as well as subcriteria Km1 “Maintenance costs”, Km2 “Heating costs”, Km3” Fire resistance” in criterion B - as well as others are not presented here.

Defined relation between technologies according to costs construction subcriterion (Kfl) was accomplished by the Table from Fig.5. Relations between technologies obtained according to construction time period criterion (Kf2) can be seen in a gantogram from Fig.6. Interrelations per technologies are obtained for all subcriteria which are investigated by determination. Since second and third criteria Ko and Ku “Housing comfort”, some subcriteria for example Ku5 “Possibility of hanging on the walls” or Ku7 “Quality and walls contact” etc. can not be measured directly thus stohastic method by dominance matrix-table is used for their comparison. Such table for subcoefficient Ku2 can be seen from Figure 7.

If variable :

V1 is larger than V2 it is marked by 1

V1 is the same as V2 it is marked by 0,5

V1 is less than V2 it is marked by 0

Criteria Kc2 : Fire resistance

	V1	V2	V3	V4	V5	V6	V7	V8	V9	V10	total
V1	0	0	1	0	0	1	1	1	1	1	6
v 2	1	0	1	1	0,5	1	1	1	1	1	8,5
v 3	0	0	0	0	0	1	1	1	1	1	5
v 4	1	0	1	0	1	1	0	1	1	1	7
v 5	1	0,5	1	1	0	1	1	1	1	1	8,5
V6	0	0	0	0	0	0	0	1	1	1	3
v 7	0	0	0	0	0	1	0	1	1	1	4
V8	0	0	0	0	0	0	0	0	0	0	0
v 9	0	0	0	0	0	0	0	1	0	0,5	1,5
V10	0	0	0	0	0	0	0	1	0,5	0	1,5

Figure 7 : Table of dominance for subcoefficient Kc2

The table i.e matrix was set up by the principle of mutual comparison of variables i.e. technologies according to some subcriterion evaluating 1, 0.5 and 0. Rank position of variables i.e technologies was given on the right.
Also at criterion Km “Costs of house maintenance and use” a part of subcriterion was evalued by determination and the other one stohastically. Analysis of applicable value allows comparison of both evaluation types to be in the same dominance matrix.
Obtained position of technologies per subcriteria are a base for further evaluation.The next step is subcriteria comparison i.e. their role in total technologies evaluation. Subcriteria were firstly compared for each criterion separately in this investigation. For example criterion Km “Costs of house maintenance and use” can be used to see table-matrix of contribution for all subcriteria Km 1.. . Km6 and technologies being variants here from V1 to V1 0. Weight of each subcriterion has been defined by a weight table G. Multiplication result of the sizes in these two tables results in table-matrix of the values according to criterion Km.

Contribution	kl	k2	k3	k4	k5	k6	k7
V1	1	4	9	0	0	0	0
v 2	2	7	7	0	0	0	0

V10	9	5,6	3	0	0	0	0	17,6

Figure 8 : Table of contribution, weight and value

Order and values of technologies according to criterion Km is obtained by addition of values from matrix right side.
Tables from Figure 8 are performed for all three main criteria Kf, Km and Kc.
Finally, we are interested in the order among technologies when all three criteria are compared with all subcriteria within criteria. This can be found out if all three criteria are put into contribution matrix. Now weight of each criterion from Table G is determined in order to reach values table order.

Final technologies order is obtained in the table right from value matrix.

CONCLUSION

The main aim of this investigation was to set up such method which enables simple comparison of different technologies (or other values). At the same time adoption degrees of some technology are chosen in the phase of construction and effects testing of each technology in further building use. Such stratified choice is required since not the same technology effects are demanded in all countries.
Hundreds of different tables were used , many measurements were carried out and standards were checked during the investigation.
Original standards of building-into were set up for new technologies having no standards. Technology of "Small format prefabricated modules" has not been completely investigated, thus some data are omitted.
The investigation helped us to find out the role and technology effects in construction phases as follows: rough in a storey, more stories, storeys with foundations and roof, then only internal walls and a part of equipment in fine processing, internal walls with a part of equipment and external facade and finally complete equipment with external facade. Such precise investigation was necessary since ,due to high costs, investors prefere partly finished building and immediate use. Ministry also partially finish buildings. In that way established method of technologies comparison is tested.
On the other hand table of G weights, which can be changed, is used with subcriteria and criteria ranking. Various G sizes occur due to different understanding of priorities in some countries. We can claim that for e.g. comfort criterion in richer countries is more important than maintenance criterion which will be expressed by higher G for comfort etc.
Obtained order is the result of priorities understanding in Croatia today. The order shows that technologies with higher degree of "dry construction" i.e. semi-finished products are preferable. Thermal protection demands, for most standard technologies, facade lined by insulating layers (styrofoam, tervol, porofen, etc.) which makes facade very expensive. Technologies which solved it in a different way, TVD and SFM, are therefore more favourable.

TVD PROCESS-a high quality building process

Abstract:
Fast and economical, TVD &Transformable Variable Design") system is a simple and performing high quality building process, which can suit any architectural shapes and standards of buildings, from social housing to luxurious habitations, with the same high quality work, especially with regards to finishing, thermal and sound insulation.

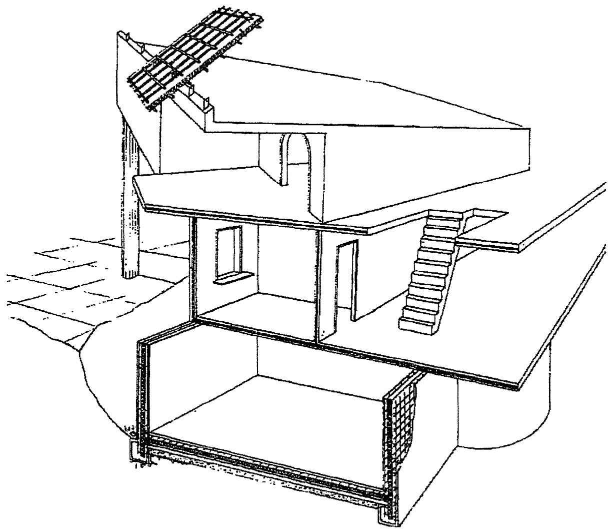

Fig. I TVD building envelope

The TVD System has been developed for any types of constructions with all the characteristics of the ones made in the traditional way. It unites planning and building in full compliance with end-user's wishes at minimal cost and in the shortest delays. The concept is simple: the available building materials are so modified that several building phases are integrated, without the use of sophisticated machines nor qualified workers.

The basis of TVD System are „Thermo- Panels", building elements that enable quick structural erection and satisfy structural, physical and ecological requirements. They consist of a prefabricated electrowelded steel frame and thermal insulation, dry-set and completed „in-situ" with a spray concrete. The panels serve as forms for vertical (flat or bent) bracing walls made out of spray concrete. Industrial production of panels, combined with the use of the typified connections and specially developed tools enable precise and quick building completion according to the project. Buildings constructed in TVD System are low energy houses, nature friendly and ecological. The TVD process as the complete building process been patented.

Keywords: TVD process, building process, technology, low cost, low cost, speed

TVD PROCESS

TVD process utilizes modern materials and methods, coupled with mechanization and rationalization of building in all its phases, from planing and design to site preparation and structural erection.

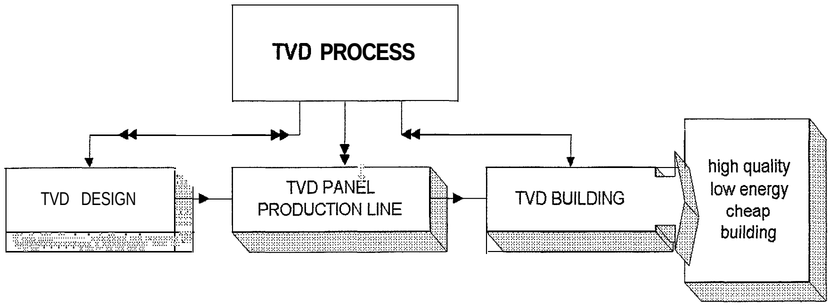

Fig. 2 An outline of the TVD process

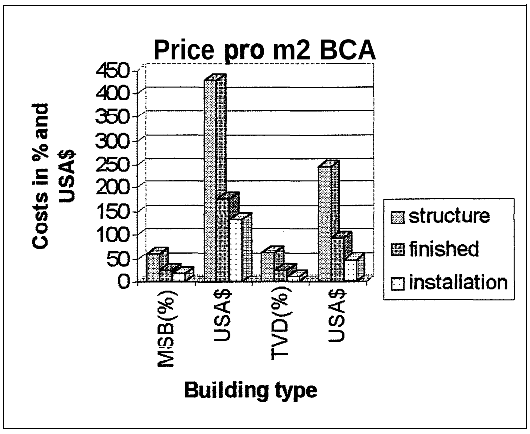
Building costs are successively monitored from the beginning to the end, which contributes to a cost reduction and a system optimization.
This closed management system with its fully integrated specific software leads to:
* increasing productivity and progressive shortening of erection time;
* lowering non-productive work (form and shuttering works);
* suppressing heavy machines on site;
* diminishing need for qualified workers;
* enhancing high building quality with respect to its structure and finishing works;
* gaining usable area (reducing thickness of walls implies a better coefficient of brut/net area);



Maintenance
*maintenance is limited and easy;
*energy costs for heating and cooling are reduced (TVD=low energy houses);
*together with low pollution (lower CO2 emission-TVD=environment friendly houses).

Fig. 3 Comparison of the costs pro m2 for many story dwellings house

TVD design

TVD is based on modular co-ordination of measures. The basic module is 30 centimeters, the structural module is 3 or 6 meters. A great structural flexibility is assured by using various structural systems:

-wall-sandwich panels in both directions;
-wall-frame structures with openings;
-skeleton structures;
-infill elements for other structural systems (lattice work, skeleton structures, etc.).
All structural systems have a stiff slab structure for force transfer in horizontal direction.

Standardized vertical and horizontal connections of the panels are specifically &signed to enable force transfer in both directions and prevent cold bridges (direct contact between outer and inner wall sides).

These combined elements form an efficient soundproof envelope offering an excellent protection against climatic conditions, a good resistance to fire and earthquakes.

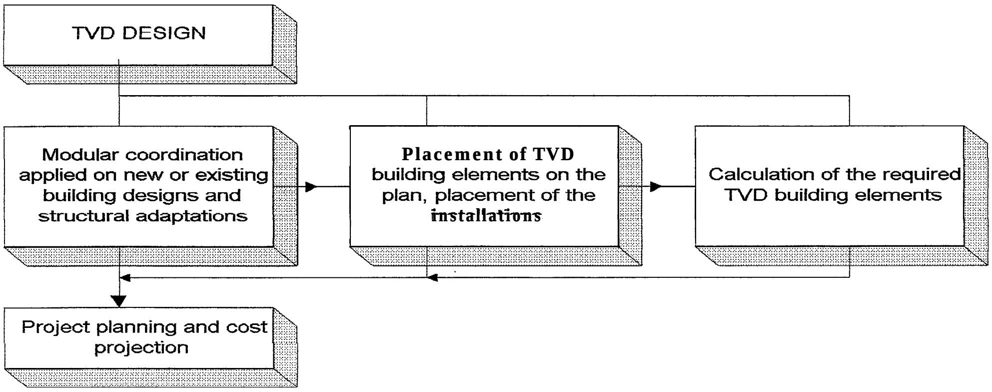


Fig. 4 An outline of the TVD design

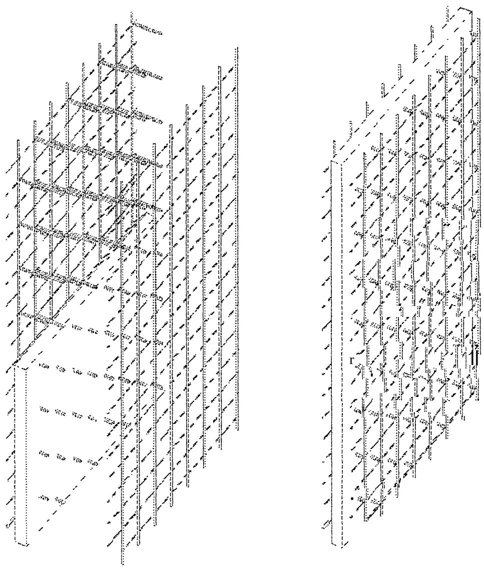
By coordinating design, flexibility of the system and freedom in the choice of finishing elements, building is fully optimized.

TVD building elements

The basic building elements are „TVD thermo- panels" which consist of prefabricated steel frame (made out of two spaced inter-connected reinforcement meshes) and the insulation in-between (which during the concrete spraying serves as a caisson), dry-set and completed „in-situ" with spraying of concrete; thus forming a purely monolithic structure with uniformed concrete walls and slabs.

Thermo-panels consist of two spaced reinforcement meshes adequately connected and enclosing insulating foam. Their construction is simple and does not require high energy consumption. The components are usually available on the market as building material.

Welded wires (reinforcement mesh) are standardized web-reinforcing wires. Panel-connections and additional reinforcement bars are made of deformed stainless steel reinforcement bars.



Connections (steel and polyethylene tiles) unite steel-mesh and thermal insulation forming a space truss system for one panel. Polyethylene disk and distance holders hold steel link bars in place and guarantee stability and distance between meshes and thermal element. Thermal element, held in place with the space truss, serves as a caisson for spraying of concrete and eliminates the need of formworks.

Thermal insulation gives its physical characteristics to the panel and stiffness it in its erection phase. This foam structure (a) stiffens the lattice and (b) serves as a horizontal or vertical support for spraying of concrete.

Fig. 5 TVD thermo-panels

Concrete is at the last stage the load bearing part of the “sandwich” panel wall and has minimal cubic strength of 25 MPa. It is sprayed on the panels in two layers.

There are different thickness of panels for the walls, slabs and base plate, each corresponding to a specific use. Panels are 0.60 to 1.20 meter wide and 2.60 to 6 meters high. The biggest building element does not weigh more than 35 kg and can easily be handled by one single person. The panels are very easy to use and any architectural shapes can be designed and further realized. The four types of panel elements serve as follows i.e.:

-bearing panels for facades and load bearing interior walls to guarantee a static, dynamic stable and resistant structure;

-non-bearing panels for partition and decorative walls;

-slab elements for floors and ceilings;

-base plate elements for foundations.

Industrial production of panels, standardized connections, adapted tools, together with a computerized control of the whole building process enable a quick and precise completion of any building, up to *8* stories high, with very little manual work.

TVD building process

1.The panels are industrially produced while the excavations are made. Their quantity and size are fixed according to the project. Once on site, the panels are directly assembled with high precision. Through unification, work is simple, repetitive and quick, including spraying of concrete. Final phases, usually done after completion of rough works (plumbing, insulating, electrical installations, plaster, rendering works, doors and windows) are already provided.

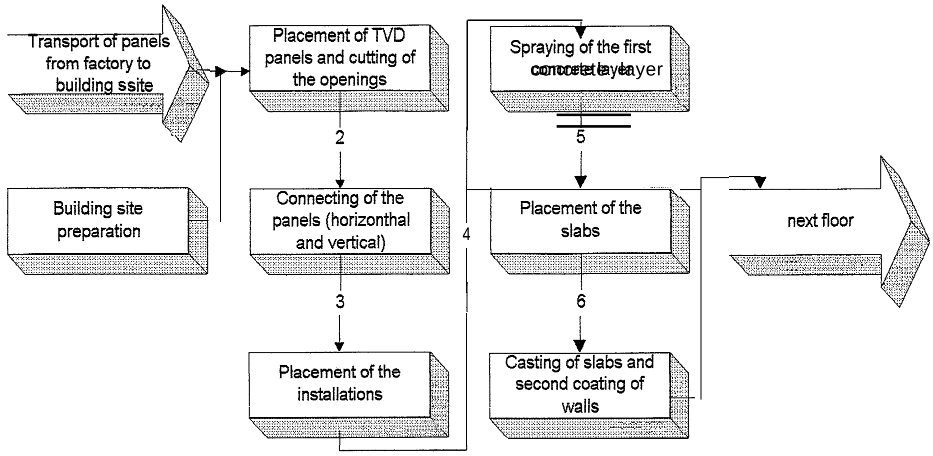


***Fig. 6 An outline of the** TVD construction process*

The use of special equipment for erection and classified connections reduces in-situ works are reduced and room for improvisation -and failure- is thereby limited.

2.**Openings** for windows and doors are precisely cut out before the erection of panels. Around the openings reinforcement is added (when needed). Special forms are placed in the openings and connected to the mesh reinforcement to keep the openings during the spraying of concrete. As an alternative, windows and doors are fixed in advance and directly connected to the meshes.

3.**Panels** are connected to the foundations with anchor bars and in-between with special links which enable unified work of panels in the wall. Additional wall reinforcement (if required by the structural analysis) and splice bars for slabs/walls connections can easily be added at this phase and connected to the mesh reinforcement. Various panel/panel and panel/slab joints (structural and non-structural) are standardized so that the whole procedure is unified and therefore simplified.
So the floor built with the panels is stable enough to serve as a caisson for the spraying of concrete. Shuttering and strutting are not necessary.

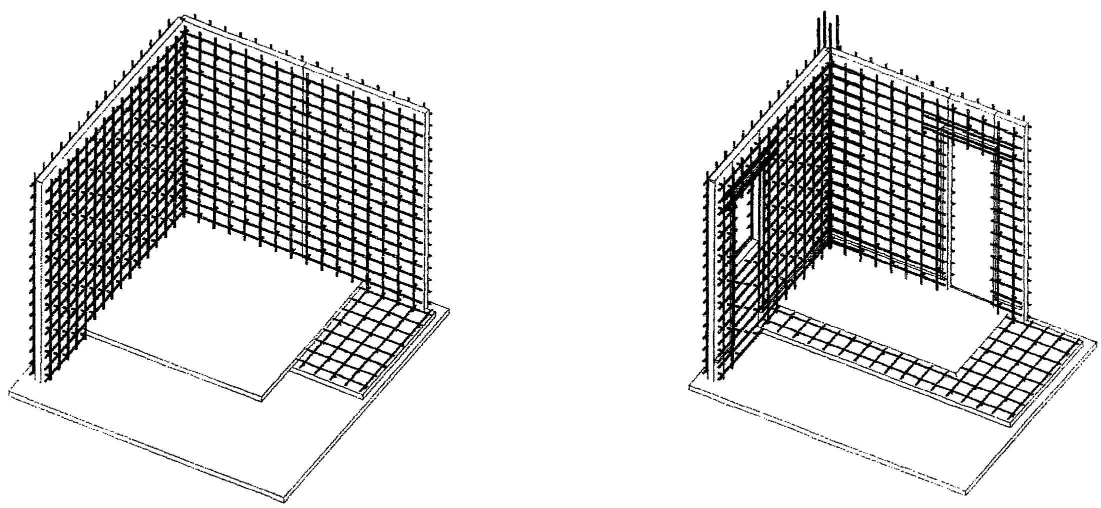

***Fig. 7** First phases **in** TVD **building** process*

4.Plumbing and electrical installations, together with related boxes, are fixed to the meshes. Insulation already exists.

5.First coating with concrete is done with aggregate mixture (0-6m.m) with rough finishing for the better adhesion of the next coating.

6.Placement of ceiling slab structure and equipment for slab finishing. Joint starter and splice bars (slab/wall and wall/wall) are added. In these phases slab strutting is needed.

7.Casting of intrados and extrados of floors and upper beams.

8.Second coating is to be carefully carried out in order to have a uniform finished surface and the required wall thickness.

For the next floor phases **2** to 8 are repeated.

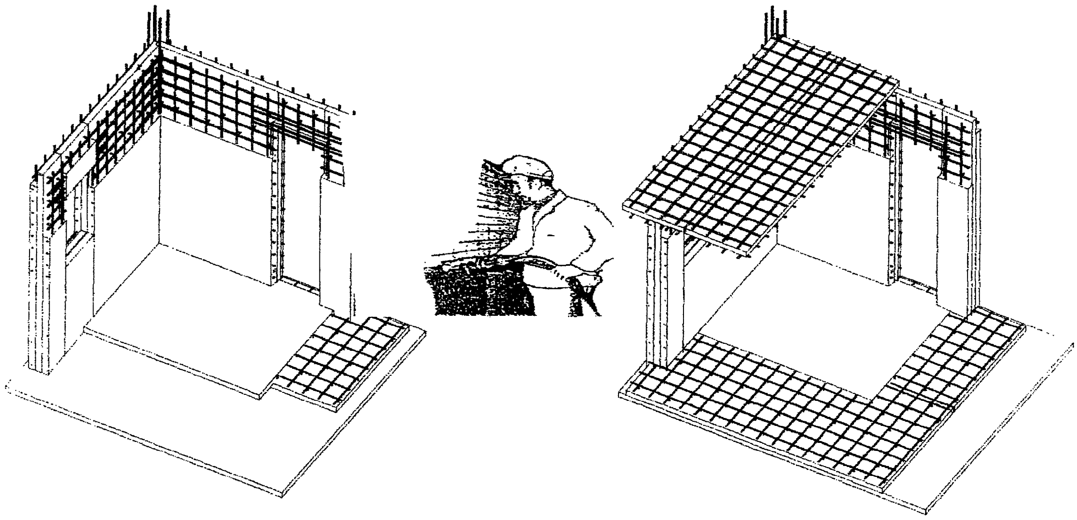

Fig. 8 Last phases of the TVD building process for one floor

Inner and outer finishing of the walls as flagging, painting and wallpapering works are the same as for traditional buildings.

Sustainable Building Maintenance

M.H. Hermans
Damen Consultants Rotterdam, The Netherlands

Abstract

As a part of the Sustainable Building concept, the attention for sustainable building maintenance is increasing. Unfortunately, knowledge development has focussed on new building. The available information to support and steer decisions on the existing stock from the viewpoint of durability, is therefore relatively poor.

The maintenance and refurbishment market, however, equals the new building sector in production size. This legitimates specific attention to environmental issues in this particular section of the market.

Sustainable building management is now a firm part of the Dutch governmental environmental policy. It is one of the focal points in the recent "Plans of Actions" designed by the Ministry of Housing to steer developments towards a more sustainable built environment. In recent years, several projects have been carried out, investigating the durability of maintenance activities and aiming to improve building practice.

This paper utilizes the results of these projects. It describes options for the parties involved in the building process to consider sustainability in respect to maintenance. In the design stage, the future maintenance expenditures are determined to a large extent. A well-considered selection of materials and careful detailing, helps to control the expected maintenance activities.

Principals, building owners and managers play an important role in establishing a sustainable maintenance policy, containing environmental requirements for maintenance activities. Developments towards performance contracts will affect the maintenance industry. Those contracts would then contain an agreement on the qualitative and quantitative maintenance levels to be preserved over a period of time.

Sustainability may be one of the requirements requested by the customer or even by changed building regulations. This will further increase the building team's responsibilities regarding sustainable aspects.

Keywords: Building maintenance, building process, durability, life spans, management and organisation of maintenance, sustainability

1. Introduction: the history of sustainable building

The attention for sustainable building started to grow about 20 years ago, mainly due to the increasing need to save energy. The oil crisis in the beginning of the seventies was an important turning point. From that moment onwards, governments started to be actively involved in energy saving. In a later stage, the increasing environmental awareness lead to durable building projects and legislation.

In the Dutch building regulations environmental aspects, such as the prescription of sound insulation, thermal insulation, and ventilation, and the prohibition of applying hazardous materials are covered. At this moment, more performance requirements in relation to sustainable building are added.

In the Netherlands, National Environmental Policy Plans have been made since 1989. Low energy building is widely applied. The number of refurbished dwellings with energy saving measures has increased rapidly. Research gradually supplies index numbers to compare alternative building designs on durability aspects. All parties involved in the building process are convinced of the importance of sustainable building and are prepared to support further developments. They are, for instance, entering into "Durable Building" agreements. In the housing sector, measures are incorporated in large-scale projects. In the Environmental Council for the Construction Industry parties involved in building are in continuous debate on possibilities to improve the sustainability of the building sector.

Up to a few years ago, the programmes mainly aimed at new building, and less at the existing stock or civil structures. Now, we see that urban aspects acquire more attention and building management becomes a separate object of research. Sustainable maintenance and refurbishment is gaining more awareness, specifically in the social housing sector. Many housing associations are drawing up environmental policy plans, of which maintenance and refurbishment form part. Installing double glazing, replacement of local heating systems by improved or high performance systems are normal activities for most corporations. Some of them even use listings of preferred materials.

To be able to pay attention to the sustainability of the existing stock, parties involved will need adequate information on the durability aspects of their decisions. This paper gives an overview of those aspects.

2. The maintenance and refurbishment market

In Europe the maintenance and refurbishment sector account for a building production equal to that in the new construction market. For the Netherlands, the current size of the market is over 29 billion guilders. An overview is given in figure 1 [1]. The maintenance sector increases with 1,5% per year due to an ageing building stock. The size and growth of the existing market justifies more attention for maintenance and refurbishment issues.

The building industry is responsible for a considerable share in the total waste production. For 1993, the Dutch Institute for Public Health and Environmental Protection calculated the amount of building and demolition waste to be 12,8 Mton [2]. The maintenance and refurbishment sector creates an important part of this waste, due to the small scale and labour intensiveness of the activities. Reuse and recycling possibilities are therefore important issues. This gives another reason to pay more attention to refurbishment and maintenance from an environmental point of view.

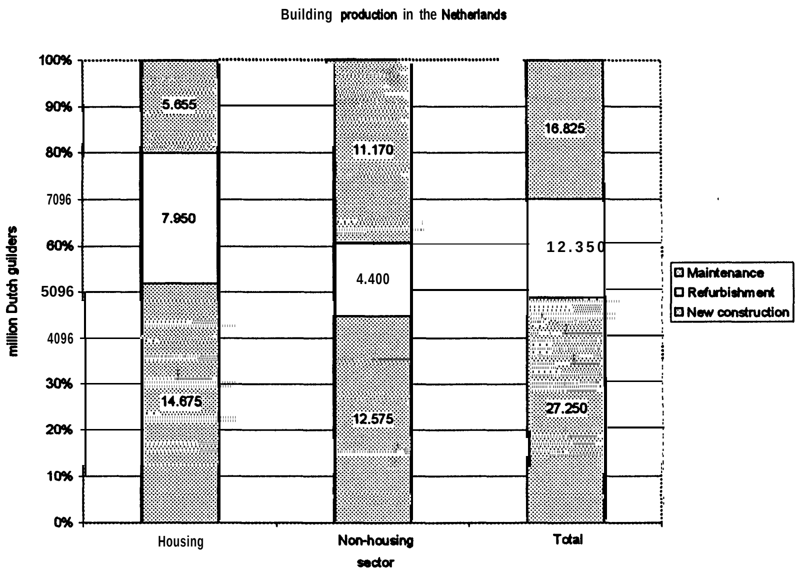

Figure 1 Buildingproduction in the Netherlands

3. Sustainable maintenance

The Dutch Environmental Policy Plans define sustainable development as "a development which fulfils the needs of the current generation without endangering the possibilities of future generations to fulfil their needs as well". Sustainable building, in line with this definition, is: building in a way that supports a sustainable development. Two types of measures can be applied to obtain a sustainable development. The first type contains measures aimed at reducing harmful effects. The second and most preferred one relates to measures for treatment at source. Those include:

- an integrated life cycle approach;
- the reduction of energy consumption;
- the improvement of the quality of products and services.

Maintenance can be described as: all "activities aiming to upkeep the performance supplied". Maintenance fits the definition of each of the sustainable measures. By extending a product's life span, maintenance reduces the demand for base materials for the production process of new components or buildings (integrated life cycle approach). Reducing the demand for a product also implies a reduction of the energy needed for production (reduction of energy consumption). And, finally, upkeeping a product's performance fits the theme "quality improvement" [3].

At the same time, however, maintenance activities themselves require material and energy. The reduction of the environmental impact, accomplished by prolonging the life span of components, should therefore be weighed against the impact imposed by the maintenance activities themselves.

3.1 Maintenance and integrated life cycle approach

The urgency to prolong a building component's life span from an environmental point of view, depends on its environmental impact during its life cycle. Data on this environmental impact are presented in so called Life Cycle Analyses. LCAs structure the environmental effects of products or activities in the different stages of their life cycle.

At this moment, no universal LCA-method exists, although several parties (for instance ISO) are working to establish such method. This obstructs the comparison of product alternatives. Therefore, a comparison presently is often based on qualitative judgements and rules of thumb. The lack of a reliable life span forecast in LCAs, vital to make a realistic estimate of the environmental impact, is another problem to be solved.

Maintenance activities have to be reviewed for their environmental implications as well, and LCAs should be developed for those activities. The impacts of a specific activity can then be compared to the impact of alternative actions. The main aspects in the evaluation of maintenance from this point of view are:

- the maintenance cycle: the more often an activity should be repeated, the larger the impact;
- the impact of the activity: for instance the amount of energy needed, pollutants released (such as dust or hazardous emissions), hazardousness of its waste (such as asbestos), and the annoyance to the building users (such as noise), indicate this impact;
- the environmental impact of the products used for maintenance (for instance solvents released in painting or glueing).

In the Netherlands, the Netherlands Steering Committee for Experiments in Housing (SEV), the Netherlands Agency for Energy and Environment (NOVEM) and the Dutch Foundation for Building Research (SBR) have published manuals with sustainable building activities for housing. These manuals also cover the refurbishment and maintenance sector [4,5,6]. Similar manuals are currently being developed for the utility sector.

3.2 Sustainable maintenance and the reduction of energy consumption

Most measures relating to energy conservation do not fit the definition of maintenance, as they imply improving the energy performance, rather than upkeeping the "old" performance. Insulation measures are, however, often applied when a component is to be replaced for technical reasons anyhow. As such, they can be incorporated in the planned maintenance policy. For instance: if a roof cover is in a bad condition, the extra costs of replacing the cover by an insulated one are relatively low, compared to adding insulation during the component's life span.

If a component is replaced before the end of its life span to install a more energy efficient component, the extra waste, material and energy use caused by this untimely replacement should be considered and weighed against the benefits of this replacement in terms of energy saving.

To reduce the energy consumption of actions, both the efficiency and effectiveness of maintenance measures should be considered. Reducing the amount of an activity is important too. The amount of building "skin" (external surface) appears to be indicative. The maintenance need of a design can be estimated beforehand, to anticipate and facilitate design revisions.

3.3 Durable maintenance and improving quality

Maintenance is only useful if a building component will remain in use for sometime afterwards. This may sound logical, but in many cases, the maintenance planning is not adapted to the owner's future plans with his building stock. The horizon of a maintenance planning can be as far as 25 years ahead. If the owner considers a major refurbishment, selling or even demolition of the building, maintenance should be adapted accordingly. Re-use and waste reduction measures should be considered.

The "repairability" of a building component is another aspect of improving quality. In relation to sustainability, there will be a strong preference for repairing components rather than replacing them. This repairability has proven to be a problem in realising a long life span for a number of so-called "low-maintenance" products. Those products indeed have a low maintenance need during the life span, but if a failure occurs by accident, this defect often can not, or only at a very high price, be repaired. A minor defect can thus result in full replacement or demolition and wastage of high quality products. Paying timely attention to repair possibilities would have prolonged the component's life span. Accessibility of components for maintenance activities should be considered in this respect as well.

Improving the quality of maintenance can also affect the choice of the activity itself. The nature of maintenance and refurbishment activities often complicates attunement between parties involved in a project. Examples of inefficient building processes are abundant. Paying more attention to the logistics of maintenance processes would favour sustainability.

4. Relationship between durability and life span

Durability in daily life is used in its meaning of "long lasting". However, from an environmental point of view, durability has many more aspects than this technical life span only; a product can only be considered durable if there is an actual need or, in market terminology: demand, for that product [7]. Nowadays, instead of the word "durable" the word "sustainable" is used.

The life span of a product should be attuned to the demand. If the demand ceases to exist, the product should either be completely disintegrated and cause as little waste as possible, or it should be re-usable (demountable and re-usable) or fit to be recycled.

For maintenance activities this implies that no maintenance activity should prolong the life span of the component longer than the required period, and that no materials should be applied lasting longer than the component's life span, unless recycling is possible. The concept of flexible, open building plays an important role in solving this problem [8].

Life span information is essential in determining the sustainability of any solution. Products with minor environmental effects, but a very short life span, can have the same environmental impact as a product with more effects but a very long life span, due to the necessary continuous replacements of the short-lived component.

At this moment, reliable life span information on buildings and their components is still missing. There is no universal, objective and internationally accepted standard method to determine the life spans of components yet, although several committees and groups, both within and outside CIB, have been addressing this problem.

5. Sustainable maintenance strategy

In recent years, the Dutch organisations SEV and NOVEM have supported projects and experiments in the area of energy reduction and sustainable refurbishment. In the DUWON-project, a methodology and manual were developed for durable maintenance in housing [5]. The manual requires housing owners to evaluate their maintenance policy from the combined viewpoint of maintenance, environment, market strategy and economics.

In the realising a more sustainable built environment, the client, whether consumer, building owner, investor or building manager has a major responsibility in requiring sustainability in the early stages of any building process, whether new building, maintenance or refurbishment.

Maintenance is a part of real estate management. As such, decisions relating to maintenance should involve more than just technical matters. Changing consumer requirements in relation to the building market as well as financial and legal matters can set preconditions and objectives for maintenance activities. These preconditions and objectives should be considered if evaluating sustainability aspects of maintenance as well. Focussing on maintenance only, may lead to suboptimisation. All phases in the building process should be considered to allow the most sustainable solution to be found.

This most sustainable solution may not always be feasible. Reasons may be the limited availability of a material or high costs or less explicit matters, such as lack of experience, implying higher application risks. Unfortunately, new products, which have not yet been tested thoroughly in practice, are often not guaranteed [9].

6. Organisation of sustainable maintenance

Sustainable maintenance involves the reduction of unnecessary maintenance. Unnecessary maintenance can be prevented by carefully planning activities on the basis of the actual building condition. Careful planning allows activities to be executed at the right moment in time, in combination with other activities, and in line with the objectives the organisation has for its real estate. This allows equipment and actions to be attuned.

In condition based maintenance, activities are based on the defects found in a building inspection. These inspections determine the performance supplied by a building. This performance will be compared to the performance required by the building owner or user. This allows actions to be exactly fitted to the requirements of a specific building. In a European research project titled “Condition Assessment and Maintenance Strategies for Buildings and Building Components”, the possibilities for implementing condition based maintenance were investigated for several European countries [10].

Duijvestein and van Hal [11] have introduced a stepwise procedure to reduce the environmental effects of building activities. The procedures review both the input and the output flow of each activity. Applied to maintenance their procedure leads to considerations as described in table 1.

Input	Output
Prevent unnecessary use Is maintenance really necessary? Can the amount be reduced? Can more efficient measures be taken, in terms of performance, life spans, environmental impact, maintenance cycle? Does maintenance solve the existing problems? How should the maintenance activity be executed to decrease the amount of future maintenance? Does maintenance have adverse consequences for surrounding components, diminishing their life spans or endangering their performance?	**Prevent waste** Is it possible to reuse existing materials? Is it possible to diminish the amount of waste due to material processing? Can the amount of packaging be reduced? Are the newly installed materials and components reusable, maintainable and repairable? Is it possible to apply used products or recycled materials? Is it possible to apply materials with a take-back-guarantee of the manufacturer?
Use infinite resources Are the materials used for maintenance renewable? Does maintenance affect the possibilities for reusing the components treated? Is it possible to use sustainable energy sources for maintenance activities requiring electricity? Is it possible to use human power in stead of machine power?	**Reuse waste** Is it possible to disassemble components in such way that they are fit for high quality reuse or recycling? Recycle waste wisely, using clean technology and ensuring possibilities for future use Can the building waste be subdivided in separate fractions? Is it possible to store the second hand goods for future use? Can activities be executed in such a way that recycling is easy in future?
Use limited resources wisely (clean technology and high return) Is it possible to execute activities in an efficient way in order to use less energy (logistics, attunement of activities)? Is it possible to use equipment, which needs less energy? Is it possible to use less material without losing quality?	

Table 1. Sustainability considerations relating to maintenance input and output

7. Performance contracts

Relatively new are the developments towards performance contracts, for instance discussed in the conference of CIB W60 in December 1996 in Tel Aviv. Next to contracts on the performance of new buildings, parties are now discussing possibilities for maintenance contracts as well.

In maintenance contracts, parties agree upon the performance level to be maintained by a supplier, usually the maintenance contractor. The customer is usually the building owner or manager. Another form, not yet applied but expected in future, is a contract between the building owner and user, expressing the performance level to be maintained by the owner and the user and the obligations and rights of each of them. Next to the technical and functional performance, such contracts could contain requirements on the sustainability of the maintenance activities as well.

8. Conclusions on future actions required

A method for evaluating the sustainability of maintenance plans should now be implemented on a large scale in the building industry and translated to fit all building types. Incorporating sustainability in the building regulations will be an important step forward and it will force building owners and' users, specifically in the private and commercial sector, to reconsider their policy.

Further research is required into the life spans of building components. Parties involved in the building process should agree on an acceptable methodology for the determination of life spans. A plan should be made to expand this methodology to obtain real life data and a forecasting model to estimate life spans of new materials and products.

Parties should also agree on a standardised LCA-method. This method should also be used to determine the environmental effects of maintenance activities. Both the effects of the activities themselves, as well as the consequences of activities for the life spans and possibilities for reuse of the components maintained, should be taken into account. By classifying activities on their environmental impact a well considered selection becomes possible. CIB could take a leading role in establishing an international task group in this area.

The South African Public Sector, Proposed Legislation and Sustainability in the Construction Industry

R D. Hindle
African Centre for Strategic Studies in Construction
Department of Construction Economics and Management
University of Cape Town
South Africa

Abstract
South African legislation is presently undergoing dramatic change, as the government of National Unity works to eradicate apartheid laws and introduce laws that do not discriminate Three of the proposed areas of new legislation are concerned with the built environment and development of those industries that serve it This paper offers a review of them, with particular reference to the application of sustainability, which is one of the cornerstones of government policy Providing an interesting insight into ways that sustainability can be used to develop people, and the construction industry, using it as a vehicle for the delivery of sustainable development

The paper first reviews several attempts at defining sustainable development or sustainable construction before adopting one which is used to compare the proposed legislation against

It provides details of proposed legislation intended to change the way that the government and industry interact, how the industry performs and is governed and the innovative ways that sustainability can be applied to communities

It concludes that sustainability is not defined in the proposed legislation but that it is being applied across four categories of sustainability goals Offering the idea that a precise definition is less important than a 'sustainability mindset' when formulating policy Whilst, recommending that a definition be provided for use by those who are expected to implement the policy

Key Words: Sustainability, sustainable construction, public sector, procurement reform, affirmative action, Construction industry development, socio-economic development

1 Introduction

South Africa is classified as a ‘developing’ country yet it has infrastructure that compares well with that of most ‘developed’ countries. Unlike most of its neighbouring countries, it has a world class construction industry, developed, largely as a result of the infrastructure and building programme. This development programme took place during the period of apartheid and because of the pariah status of the system foreign competitors were reluctant to participate, hence, it developed the necessary skills and expertise needed to construct modern high-rise buildings, roads, bridges and dams without their intervention. However, the ownership and management of these construction consultants and contracting firms was vested in the ‘white’ population group, whilst other racial groups were prevented from participating.

With the expulsion of apartheid in 1994 and the formation of the Government of National Unity, a great deal of emphasis was placed upon the development of people who were disadvantaged by the apartheid system. It has spurred innovation, in ways to speed the development of people who were previously disadvantaged. People development is a national priority that was encapsulated in a government priority . programme, named ‘The Reconstruction and Development Programme’ (RDP). [1]

The RDP document describes the need for socio-political development as well as economic development and the construction industry was seen to have a major role to play. Essentially, through housing, another national priority. It was envisaged that by motivating a housing programme, thousands of jobs would be created, training programs implemented, leaving local communities with homes and a set of sustainable skills.

2 Sustainability and Government policy formulation in South Africa

With the advent of the Government of National Unity in April 1 994, South Africa’s first democratic government was given a mandate to implement the Reconstruction and Development Programme. Consensus was secured among stakeholders, from across the political spectrum, on the centrality of RDP objectives to post-apartheid society. The six basic principles of the RDP are:

* An integrated and **sustainable** programme
* Link reconstruction and development
* Peace and security for all
* Nation-building
* A people driven process
* Democratisation

These broad principles are central to most of the legislation that has been promulgated since then, or that which is in the development phase. However, a full definition of the policy makers understanding of this term is lacking and we are forced to look elsewhere for this. This compares with Hoole and Milne’s [2] findings:

> *Whilst sustainable development has been widely embraced as a goal, it is still largely defined at the level of rhetoric and broad policy definition. The concept remains difficult to apply in practice.*

This appears to be true in South Africa but it would seem to be appropriate at broad policy level given Dovers assertion [3], that, sustainability could only mean something useful for policy formulation once a specific context had been identified, in terms of ‘goal’, ‘time’ and ‘space’. This should be the case when broad policy is applied to specific areas of policy implementation, such as that which concerns the construction sector.

The search for a more detailed definition in the literature shows that the concept is still being developed and further defined.

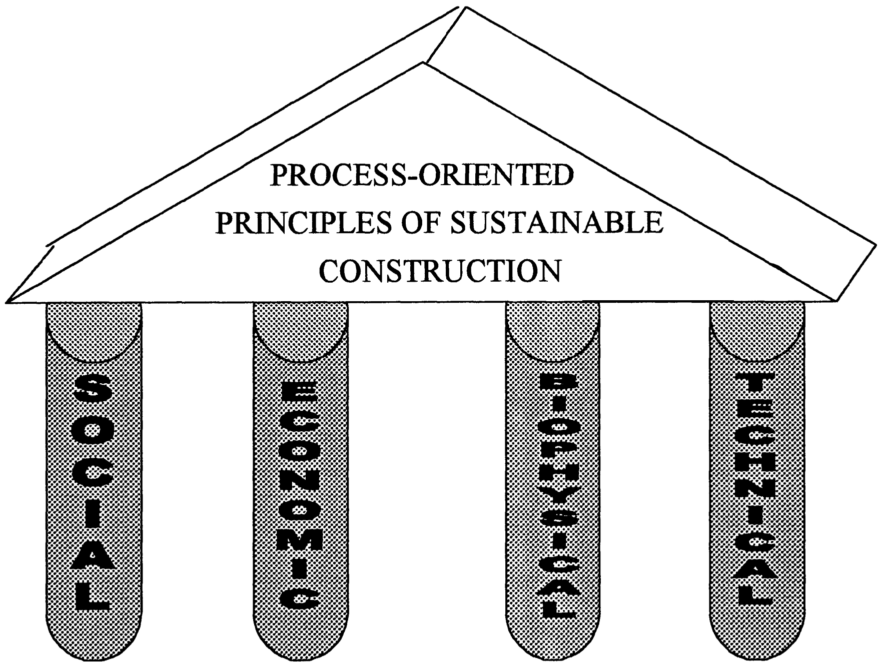

Figure 1 Principles of sustainable construction - Adapted from Hill & Bowen [6]

The World Commission on Environment and Development [4] put forward the view that the Environment and development are inseparable and intertwined. Its definition of sustainable development was, that which:

> *... meets the needs of the present generation without compromising the ability of future generations to meet their own needs.*

This early definition is now thought to be over-simplified and Barbier [5], offered a model which included three components, which together, could be described as sustainable economic development. The components being; Social system goals; Economic system goals and Biological system goals. A fourth component was added by Hill and Bowen [6], who advanced the concept of ‘sustainable construction’ whilst offering the theory that it is founded on four pillars. Supported upon which, are a number of overarching principles. The model is shown in **Fig 1**.

3 Public sector application of sustainability in construction

The Government of National Unity has embarked upon a major programme of policy development and renewal and amongst that which is still in the formulation stage are three proposals which will impact upon construction. These are:

1. Public sector procurement reform. A discussion document prepared by the procurement task team. [7]
2. Restructuring the Department of Public Works and the policies which will govern its procedures. [8]
3. Proposed legislation concerned with the creation of stability, improved delivery and value for money in construction whilst ensuring participation by previously disadvantaged persons. [9]

Each of these represents the attempts of various Government Departments, to translate the objectives of the RDP, including sustainability, into policy. In the following section, an attempt is made to show how sustainability appears to have been applied to each of them:

3.1 Public Sector Procurement Reform

This draft proposal is at the 'first draft' or 'Green Paper' stage, awaiting response from interested parties prior to being put to parliament in its next draft stage, (White Paper). The Department of Public Works (PWD) objectives are described thus:

> *The Government's aim is to transform the public procurement process in order to achieve its socio-economic objectives within the ambit of good governance.* [7]

In doing so the Green Paper recognises that the organs of state have enormous collective buying power and that public sector procurement can be used as a tool, to achieve economic ideals, including socio-economic objectives. In essence, it aims to stimulate economic growth by economically empowering, previously marginalised, sectors of society and is, clearly, more concerned with job creation and affirmative action issues than with economic of other sustainability issues. Indeed, there has been much criticism about the potential poor economic effects, in terms of the overall cost to the taxpayers who are the source of funding for infrastructure development. [10]

In order to achieve the socio-economic objectives the proposed procurement procedures must be applied in a transparent, visible and measurable manner, without compromising principles such as fairness, competition, cost efficiency and inclusion. The system is to contain the following key components:

- Removal of barriers to entry by improving access to tendering information and simplification of documents and procedures
- Breakout procurement (unbundling large projects into smaller packages) and structured joint ventures.
- Creating accelerated opportunities for target groups (weighting in favour of targeted groups)
- Small Medium and Micro Enterprise (SMME) promotion and support
- Promotion of employment-intensive practices
- Affirming marginalised sectors of society in construction projects

Many of these components have formed part of construction procurement practice, on an experimental basis since mid 1995 and, whilst there have been some problems it appears that the measures have been accepted by the industry and that the governments objectives are being achieved, at least in the short term.

In order to asses how sustainability is achieved, the following example is provided. Most of South Africa's poorest people live in rural and areas, though some urban suburbs were neglected and have similar problems. As a result, most of the present Public sector spending on infrastructure development is undertaken in these areas. In addition to the potential that the finished products offer, in terms of economic development, government policy requires that the local populace be 'developed' in the process. They are targeted and benefit in a number of ways:

- Breakout procurement will allow SMME's in the area to tender for the whole or a part of a larger project
- Joint ventures between emerging contractors and established ones are encouraged
- Contractors are required to demonstrate that they intend to employ people in the area of the project and to train them. Employment intensive practices are demanded on certain types of project, together with training.

In these ways, projects that are undertaken in rural or urban areas offer employment opportunities, training and skills development, that could be said to be sustainable. Joint ventures and other opportunities for SMME's will help them to develop skills that would improve their capacity to contract in future. Labour will earn wages that are retained in the rural community, helping it to gain momentum as an on-going economic unit. Building skills learned can be used for maintenance and construction of new buildings in that area, or in others, should the persons decide to 'follow a trade' wherever opportunities exist.

It would seem that social and economic sustainability are being addressed here.

3.2 Restructuring the Department of Public Works

In this proposal, which is at 'White Paper' stage, the Department of Public Works (PWD) describes how it proposes to change the way that it operates its portfolio of functions. It this regard it describes its aim thus: To provide and manage accommodation for line function departments; to assist other line departments in the development of policy and programmes for infrastructure delivery; and to lead the transformation of the construction industry in line with the National Public Works Programme principles. Its key functions are: property advisory services; property development; property management and the national public works programme.

It represents a dramatic change in the way that the PWD intends to operate in three functional divisions: Property investment; Property and facilities management and Project management. As it contributes to South Africa's transformation using the following strategies:

- Property investment
  - Incorporation of social objectives into property investment decisions
  - Use of investment analysis, life cycle costing and value engineering
  - Public/private partnerships in the acquisition and disposal of fixed property
  - Innovation and best practice including international benchmarking
  - Establishing a property investment policy for the entire government

  - Orientating to clients and consulting stakeholders
- Property and Facilities Management
  - Commercialisation (privatisation) of certain property services such as cleaning, security and maintenance.
  - Public/private sector partnerships whilst applying affirmative action criteria
  - Innovation and international best practice
- Project Management (the way in which it intends to manage Public Works projects)
  - Achieving socio-economic objectives through the PWD programmes
  - Influencing the construction industry
  - Improved intra-governmental relations
  - Diverse delivery models
  - International benchmarking
  - Client education
  - Adopting an appropriate organisation structure
  - Human resource development

It can be seen that the socio-economic objectives of the RDP are the basis for new this proposed policy that is to be delivered via the public works programme. All of the measures described in the procurement White Paper are applied and enhanced in this document. With regard to the property portfolio and management of those properties, it is clear that this will be used to increase private sector participation, whilst benefiting **SMME's**. Whilst much of that which is proposed is intended to replace archaic departmental practices and to 'fit-it-out' with state of the art systems and procedures that will lead to client satisfaction and good governance. With regard to existing and new buildings, structures and services, mention is made (section 5.3.1.8) of their intention to become leaders in the field of environmental management and sustainable energy utilisation.

Once again the emphasis is on social and economic sustainability with an apparent technical sustainable intentions and just an inkling of biophysical sustainability.

3.3 Proposed legislation - the creation of stability, improved delivery and value for money in construction

The title provides a clear indication of the purpose of this Green Paper, 'Creating an Enabling Environment for Reconstruction, Growth and Development in the Construction Industry'. It clearly indicates a continuation of the theme that is central to the other two but this is possibly the most far-reaching of them, in terms of its potential impact on the governance and procedures within the construction industry. The other two would affect only those firms that chose to contract with the PWD but this offers to affect all, regardless of the market chosen. Through its primary vehicle of delivery, a Construction Industry Development Board (CIDB). Its prime motivation for this and other interventions is it's assumption that the construction industry is in a crisis situation, thought to have been brought about by the impact of several deep economic recession periods. Its strategic aim is to establish an enabling environment in which the objectives of reconstruction, development and growth are realised in the construction industry.

The vision is one which *sees; a construction industry policy and strategy that promotes stability, fosters economic growth and international competitiveness, creates sustainable employment and which addresses historic imbalances as it generates new industry capacity.* It presupposes a growing and active industry, supported by an effective institutional framework representative of all parties who embrace this vision. It is premised on the ability of government to exert its influence, to foster operating practices conducive to an enabling environment. The following strategies have been proposed:

- Developing a stable environment
  - Counteracting demand volatility
  - Creation of a stable environment by addressing employment issues
- Enhancing industry performance
  - Work process transformation (partnering; Participative management; ADR; Quality and productivity improvement programmes; Health and safety; Environmental protection; Integration of design and construction)
  - Procurement practices to encourage best practice (best practice incentives; contractor accreditation; a register of contractors; monitoring of performance standards)
- Enabling strategy of human resource development
  - Establishing a new education framework
  - Towards appropriate governance of training
  - Appropriate skilling of built environment consultants
- Promoting new industry capacity and the emerging sector
  - Simplification of documentation
  - Access to improved market information
  - Access to finance
  - Payment and surety arrangements
  - Skills formation and access to training
  - Monitoring performance
- Developing the capacity and role of the public sector
  - Delivery to target the marginalised
  - Overcoming regulatory impediments to industry performance
  - Improving public sector capacity to manage delivery
- Institutional arrangements
  - A construction industry development board
  - Emerging contractor development programme
  - Monitoring and evaluation system

This piece of proposed legislation depicts a diverse array of interventions. Most of which repeat the theme set by the two draft Papers reviewed above. Clearly the primary emphasis is towards *social and economic sustainability.* However, there are also indications of *biophysical sustainability,* in terms of maximising resource usage and minimising damage to the environment, whilst *Technical sustainability* is also suggested in the pursuit of quality and other measures to improve the industries' performance.

4 Conclusions

Whilst the term 'sustainable' is used in two of the three documents no definition is provided. Each refers to the application of sustainability but it does not appear to have been applied or considered in a methodological way. It would appear to be a popular 'buzz-word' and part of the necessary jargon in South Africa at present. But there is no doubt that its component parts have been built-in to the proposed legislation that will have an effect on the construction industries.

Measured against Hill and Bowen's model of sustainable construction it would appear that there are components that could be described as fitting all four pillars of sustainability, though social and economic sustainability have received priority. Whilst there is little evidence to show that the authors of these policy documents applied a systematic approach to sustainability a number of Hill and Bowen's 'over arching principles' have been applied.

It would seem that the implementation of sustainable development policies is less dependent upon finite definitions than it is upon a culture of acceptance of its importance and a 'sustainability mindset'. However, the process could be improved, were the policy makers to adopt a model which would help those who are asked to implement the policies.

Sustainable development: a challenge to the construction industry

G. Ashworth
Research Professor, Urban Environmental Studies, University of Salford, UK
Chairman and Chief Executive, Going for Green, UK

Abstract

Sensible environmental policies are an ethical imperative for us all, including those involved in the Construction Industry. All future industrial business (including construction) should have regard to the four 'system conditions' of the Swedish Natural Step 'Institute as a way of embracing the notion of Sustainable Development. The Construction Industry should look to lifecycle analysis as a way of addressing how sustainable its activities are in relation to Place, Process and Product. They must recognise that stakeholders (financiers and insurers; customers; employees; suppliers) will increasingly constrain its activities if they are perceived to be environmentally suspect. The Industry will need to demonstrate good (best) practice in relation to waste reduction, resource management, transport, pollution and environmental enhancement. The Industry must accept a role as advocates of Sustainable Development by developing partnerships and a Sustainable Development Code for all those in or linked to the Industry.

Introduction

This keynote lecture is to do with innovation in the way we think, the way we approach manufacturing and building processes or practices, the way we approach life itself It will begin in abstract philosophy but end in practical ideas that I hope will be of interest and help to those who both build and manage!

I will seek to address the legitimate concerns of those who suspect that the strident demands of the environmentalists are more to do with hidden political goals than with genuine concerns about global survival and hope to demonstrate that many of us who campaign on these issues do so out of a desire to secure a better quality of life for everybody and a belief that is entirely compatible with the notion of growth and development, including the physical development of land.

Environmental issues

So let me begin with the claim that a concern for environmental issues whether in the business, working or private aspects of our lives is not an optional extra. It as central as breathing or eating. Increasingly people in every walk of life and particularly in business are recognising that a carefully modelled environmental policy makes good sense economically and delivers many marketing and management benefits (and I will return to that later). There are many whose environmental urgency is born of nothing other than the fear of annihilation globally and personally and I do not wish to pretend that that is not a matter that interests us all. But there is another reason why we must take the issue seriously. There is a moral imperative also.

Without being unduly pious about it we must recognise that there are in life a range of actions that are unlawful. I do not mean illegal, but unlawful, that is against natural laws. (In the sense that Gravity is a natural law the violation of which results in something very unpleasant and probably fatal.) There are the laws of Thermodynamics (that we ignore at our peril). One of the most interesting innovations of recent years has been the campaign, known under the title The Natural Step, and developed here in Sweden.

The Natural Step

The Natural Step is an Institute offering training to businesses on changes needed to their business management, policies and practices to move to more sustainable methods.

The Institute was established in 1989 by Professor Karl-Henrik Robert who aimed to achieve consensus amongst the Swedish scientific community over the environmental problems being faced globally and nationally. From the consensus document and related discussions there emerged a definition and framework for sustainability based on resource theory. Professor Robert presented his model for sustainability and offered it as a tool for businesses to determine their priority actions for achieving sustainable business practices.

The theory is based on the laws of Thermodynamics I mentioned earlier. The first law and the principle of matter conservation is that matter and energy cannot be created or destroyed. In practice this means mining no faster than the slow geological cycles of nature and not harvesting or manipulating eco-systems in such a way that productive capacity and diversity diminish. This gives rise to the Natural Step's first and third system conditions.

According to the second law of thermo dynamics, matter and energy tend to disperse. This means that all matter introduced into society will tend to be released into natural systems and thus Natural Step advocates that persistent artificial compounds should be phased out, giving rise to their second system condition.

Natural Step's four 'system conditions' defining sustainability (all of which have profound significance for the Construction Industry) are:

- Nature cannot withstand a systematic build up of dispersed matter mined from the earth's crust.

- Nature cannot withstand a systematic build up of persistent compounds made by human beings.
- Nature cannot take a systematic deterioration of its capacity for renewal.
- Therefore if we want life to continue, we must be more efficient in our use of resources and promote their fair distribution.

The Natural Step teaches sustainable development based on these principles and the concept that this provides is agreed by all Swedish Scientists and thus can be relied upon as a secure basis for decision making for their society and, in time, others. It is a concept we should embrace in the Construction Industry as well as in manufacturing.

Sustainable development

Embracing the ideas encapsulated in The Natural Step may be the simplest way for business and industry to embrace the notion of Sustainable Development. But it is a concept that will have to be adopted by the whole of society - a process which will, in turn, exercise a profound influence on industry, including the Construction Industry. As individuals we must be concerned and as individuals in the construction business we need to be especially alert .

I have frequently heard Sustainable Development described as a phrase that is incomprehensible. I believe that is a cop-out. Perhaps the confusion, if there is confusion, is due to our putting together in an unfamiliar way two words that we normally use separately: sustainable and development. So, if we look at the words individually it might help us.

Sustainable: We use that word quite simply in the sense of something being acceptable. We might have neighbours whose teenage children have a life -style that is. When my daughters lived at home we had to have serious discussions about what sort of holidays we could afford, i.e. were sustainable! Sustainable may also be used in the same way we use the word insupportable, as in ‘that argument is insupportable’. So I think we <u>do</u> understand the word Sustainable.

Development: Coming from a background in Architecture and Planning I naturally used to think that development was only related to building. Of course it is not. It is as much about growth or change. Made as we are, we will always be pushing at the frontiers of knowledge and understanding and there is nothing wrong with that. Every time I visit the Dentist I am delighted that there has been development in the Dental Profession! We are meant to explore and progress (even at the expense of failure sometimes) to participate in the ongoing process of Creation. But we must do so in such a way as not to jeopardise all that has gone before or what may yet be possible for ourselves, our children and our world. Whilst I recognise that development means more than just urbanisation we cannot ignore how big a part physical development plays in the wider picture.

So we are talking about engaging in <u>development</u>, but in such a way that we do not harm irreparably the environment nor close down choices for future generations. Sustainable Development is not the same as Sustainability, nor is it about the return to some bygone age or rural economy. It is about being innovative in the way we use resources and skills, about creating new and better lifestyles (including better environments) for all - now and in the future. It is also, obviously, about taking care to ensure that in our management of the environment we take proper account of the impacts we are having on the natural and cultural world around us. In common parlance we must take account of the 'environmental destruction' we perpetrate. I want to challenge the common parlance, however.

Terminology

If we environmental campaigners (and I accept my place among them) are to be taken seriously we must begin to refine our terminology. Very briefly let me illustrate this:

'Environmental destruction' should describe any activity that will result in a situation that is genuinely irretrievable, no matter what money or technology is thrown at it. The cessation of all life in the North Sea as a consequence of the disposal of chemical waste would come into that sort of category.

'Environmental damage' should describe the sort of activity which may be unsightly or give rise to abnormal temporary levels of atmospheric pollution but which can be restored by the application of technology and/or money. Opencast mining might be included in that category.

'Environmental disbenefit' should describe activities that might lead to a change in the local or even national environment but which, compared to the social benefits that are enjoyed by everybody, are deemed to be acceptable. The addition of fluoride to drinking water might fall into that category.

These are the sorts of terms that should be used precisely when we analyse our actions throughout our construction and management techniques. That analysis has to be comprehensive over time and a range of activities. Again the common parlance is 'cradle to grave'.

Cradle to grave assessment

Another name for this is, of course, Life Cycle Analysis (LCA) and we must increasingly ensure that this is applied to our management systems so that it becomes as much a part of our business techniques as investment forecasting, output measurement, or staff motivation.

Properly conducted, LCA will address a wide range of issues that enable a company or organisation to demonstrate its environmental credentials under three headings, detailing what is made, how it is made and where it is made. Thus a complete LCA will provide information on Product, Process and Place. Questions will be asked about the environmental impact of the product. (In recent years the environmental downside of CFC's was exposed and in time its unsustainability led to their abandonment.) Inquiries will be made about the environmental consequences of making the product in a particular way. (An example is the amount of water or energy used in the production of paper.) Finally, and this is often not investigated with enough vigour, assessments will be required which show that a particular location where the product is made is on all counts the right one. (A company making refrigerators with inoffensive refrigerants and a process that maximises the reuse of materials and is energy-efficient but is located so close to a housing development that the noise levels from the factory create serious disturbance to the residents illustrates this kind of environmental impact).

Let me take a few minutes to address this idea of **LCA** in relation to the Construction Industry For convenience let me alter the sequence of consideration and refer to Place, Process and Product, because in the construction business location can **often** be the biggest single factor on physical development being **environmentally** acceptable.

First, then, the question of Place: Whether the construction is for housing, industrial or commercial purposes location is crucial. In the UK, and elsewhere **I** understand, there is a genuine current debate about development in the 'greenbelt' (those rural areas immediately adjacent to towns) and how much should be accommodated on 'brownfield' sites. Often lost in **this oversimplistic** argument are questions of integrating business and housing development together: housing on brownfield sites is not just about 'housing' but the range of 'social' services, like education, that can be provided.

But the 'place' issue is about much more than the urbanisation of hitherto green sites. There are questions of surface water run off from hard surfaces, the adequacy of water supply and the capacity to treat sewerage. There are other **major** questions about the energy use that the development will incur, whether in terms of transmission lines or transportation costs. Land take for access roads, the convenience of journey times, the creation of air and water pollution and access to open space are all extremely potent issues that are primarily created by location.

Next there is the question of 'how' the construction is managed, i.e. what is the 'process' involved. Among the questions that will be urgently addressed are: is the construction process water and energy efficient; are the construction materials appropriate to the locality; are they local materials or do they involve massive transportation costs? Are there just-in-time delivery systems to avoid damage and deterioration of materials stored on site? What environmental protection measures are in place during construction (e.g. noise and dust creation). **Is** the site managed efficiently to reduce pollution (including the escape of packaging materials) in the surrounding areas.

Finally, what about the 'product' (the construction itself!). Will the building be energy efficient, does it minimise water consumption by reusing s-u&ace water. What are the arrangements for good waste management, are there **composting** facilities, is good microclimate created, are there well-designed open spaces, i.e. is there real local environmental quality?

Increasingly there will be those looking for, even demanding, evidence that industry in general, including the construction industry faces up to these issues.

It should be added at this point that the same sorts of demands will be made **upon the** service sector too, whether that is the transport industry, the leisure business and the service industries producing energy, water or telecommunications. But the demand will not only or necessarily be in the form of **statutory** requirements.

Stakeholders

Companies who are already engaged in the development of sensitive environmental practices have identified at least four stakeholders whose environmental interests they have to reflect in addition to the financial interests of their shareholders (who may also, of course, have environmental interests). These are - Financiers and Insurers, Customers, Employees, Suppliers.

For the last decade or so, particularly in the USA, banks and insurers have been asking those to whom they are lending money or for whom they are providing cover, to demonstrate their environmental probity. It has largely come about as a result of them finding themselves associated with environmental offenders in legal judgements handed down by the courts. That will undoubtedly increase over there and there will be a knock-on effect here. I am told that of the claims to Lloyds of London that had such a devastating effect on the 'names', over 20 % were related to environmental disasters.

Likewise there is an increasing interest by consumers or customers in the environmental friendliness of the products they purchase and the companies which produce them Despite the disillusionment of many members of the general public about the credibility of 'green claims' put on consumer products a few years ago there remains a considerable interest in green consumerism and the work of the Eco-labelling board will stimulate this further. This is likely to produce demands for evidence that product, process and place of manufacture are sustainable. (And in a related field I suspect concern about developments in Bio-Technology will produce even more strident demands for openness and reassurance.)

The next two categories of stakeholder (employees and suppliers) are rather less predictable in that they may feel somewhat more inhibited in making their demands on business. In times of high unemployment employees are careful not to make demands that might jeopardise not only their individual jobs but cause the closure of the entire business. Similarly, materials or service suppliers are not usually so altruistic as to refuse to supply to companies whose environmental record is not good. But that will change as the general concern about environmental issues increases. There is the other side of the coin, of course, in that responsible manufacturers can bring influence to bear on their suppliers.

Single-issue groups

These four stakeholders seem to me to be entirely legitimate influencers of the corporate response to environmental concerns. There are others that seem much less legitimate. So it is perhaps appropriate at this point to address the issue of the pressure brought by single issue groups. The strength of such groups is, of course, that they are, by definition, able to focus their energies on a particular problem or even to concentrate on one side of an argument and deliberately refuse to acknowledge that there may be an alternative interpretation or judgement. In some ways that can be a very effective way of highlighting an issue and we can be grateful for it. The danger is that if those views are allowed to carry the day then any sense of balance in the environmental debate is frequently lost.

So in our careful appraisal of environmental issues and the quite proper concern to afford them their correct weight alongside other criteria we must not allow the balancing of the various arguments to be sabotaged by the blinkered concerns of single issue campaigning. Equally we dare not, for all the reasons I have outlined earlier, continue to pretend that a proper concern for environmental matters need not affect the way we conduct our business or manage our lives at the practical day-to-day level. And it is to that I now want to turn.

Practical outcome

Going for Green in the UK, which I have the privilege to chair and manage, is a public **education** campaign designed to persuade everyone to make significant changes in their lifestyles to ensure that the future is characterised by more sustainable development programmes. It is not addressed only or even primarily at business but at every individual. However, it recognises that some individuals exercise much greater influence than others so those in business and particularly in the construction business or other large institutions are a natural target. GfG's message is simple and concerns those practical day-to-day measures to which I have just referred and which, whether **applied** to personal or corporate activities will make significant changes to the way we impact the environment. So it has developed a five-point Green Code, **applicable to the** ordinary individual or to the corporate entity:

- Cut down on waste
- Reduce the use of non-renewable resources like energy from fossil fuels and water
- Travel sensibly
- Avoid pollution
- Enhance local environments

Above all it is designed to encourage people to get involved!

Waste

Badly managed, both solid waste and effluent in large quantities are bad news for the environment. In recent years increasing numbers of companies have found that a review of their waste management strategy has resulted in their being able to savagely reduce the type and tonnage of material going to landfill and use it in a combined materials recovery and recycling programme. In the UK the bottom-line benefit of this will of course be significantly increased with the advent of the Landfill Tax which as from October 1st 1995 is charged at the rate of between £2 and £7 per tonne (payable to HM Customs and Excise) on all materials that go to holes in the ground! One of the UK's retain chains, Safeway, have amassed half a million tonnes of cardboard for recycling in the last five years meaning that 100,000 refuse vehicles did **not have to visit landfill** sites - that will result in cost savings under the new Tax.

Resources

Whilst the warnings of the sixties that we would by now have run out of many vital non-renewable natural resources proved to be inaccurate and alarmist, the fact remains that these resources <u>are finite</u> and we continue to plunder then endlessly. And, of course, their availability is unevenly spread. <u>We</u> in Europe might have coal resources for 300 years: others have little or none. Already countries in the Far East, assessing their own slim hydro carbon resources are now refusing to sell them to others. We face the serious possibility of a resource war in the future. Nations have fought over other riches and this is a real threat to world peace. If you think I exaggerate ask yourself if the USA would be involved in Iraq, Iran or the Gulf States if it were energy self-sufficient itself

So on the political as well as ecological front, there is sense in being economical with what we have. Furthermore, we need to be much more sensitive about our use of renewables! Thirty years ago a lecture like this in the UK would not have said much about water. Now it is a different matter. Likewise the sensible management of forestry (both hardwoods and softwood) is imperative if we are to continue to enjoy the balanced lifestyle the planet has taken for granted up until now.

The call too has to be for less energy consumption. We must use less electricity wherever we can, if it is generated using fossil fuels and continue to press for alternative sources (wind, solar and nuclear). The use of fossil fuels for mobility too needs checking, as we will see in a moment.

Examples of the sorts of savings people have made are very impressive. **For** example, Alida Recycling Ltd., part of British Polythene Industries **PLC** has developed the technology to produce polythene bags from post-use polythene waste. The bags produced from <u>virgin</u> material require three times as much energy, generate over twice as much carbon dioxide, use eight times as much water, produce three times as much sulphur dioxide and give off double the volume of nitrous oxide.. . . and use **1.8 tonnes of** oil ! The challenge is to do more. Perhaps the Construction Industry can be the trigger for further work in this area.

Of course, for some companies, it means rethinking their very existence. The challenge of Sustainable Development is very different for the Construction Industry than it is for a petroleum company, where the very business **itself (not the way it is** done) may be perceived as unsustainable.

Travelling sensibly

In many first world countries the profligate use of resources over the last **20** years in the development of a heavily subsidised road based transportation system has to be regretted. A more balanced, integrated system for the future is essential, even if the capital investment needed is terrifying. Now let us be clear about one thing. Rail., even if it were sensibly developed cannot deal with <u>all</u> the goods and people needing (or thinking they need) to be moved about. But a more intelligent location of transport distribution centres, a different settlement pattern and constraints on the mobility of goods and labour would have dramatic environmental benefits in a number of fairly obvious ways:-

- the reduction of resource depletion
- the reduction in land take for roads
- the reduction in pollution from conventional engines

Vehicles stocked with wooden pallets carry **40%** more product than similar vehicles using roll cages. An audience like this probably needs no introduction to the merits of 'just-in-time' management, with the reduction in empty-running vehicles, waste and warehousing. A major UK retailer estimates that as many as 135,000 vehicle movements were saved in a single year. But this not just for big business. In Northern England the Aire and Calder waste minimisation scheme in West Yorkshire (1992-1995) involved 11 Small and Medium sized businesses undertaking reduction of waste and emissions in their production processes and within a year 75% had seen a reduction in operating costs.

Interestingly, health concerns deriving from the pollution is likely to produce support for unpopular measures like a Carbon Tax and the progressive development of efficient environmentally friendly engines. But the other two concerns need addressing also. We should be looking for the introduction of policies throughout the world that would constrain out-of-town shopping centres and encourage more sensible rural development.

There is no future in pretending that people will settle for the total denial of the personal mobility we have all come to enjoy. But we will have to settle for it being in differently fuelled vehicles and on networks that allow everyone some movement. Electric and gas powered vehicles are beginning to appear and 'smart card' technology that will manage traffic are already being used in some parts of the world. Total mobility for all is a myth as those who live and work in Los Angeles have known for two generations.

Avoiding pollution

I have already mentioned the idea of a Carbon Tax. Governments will be reluctant to introduce it, but the general public will in the years that lie ahead, tolerate less and less pollution from all sources. According to Dutch and USA studies between 2-10,000 people could be dying early in Britain every year as a result of particulate pollution. The 'polluter pays' principle is here to stay - even if we all know that the cost will be passed on to the end consumer. But the incentive to develop cleaner technologies that produce savings and give a competitive edge will provide an incentive to those in the business world. Cheap raw materials and labour will not, in future be the only keys to the production of goods at customer-winning prices.

Many companies are now producing very impressive figures showing a serious commitment to pollution reduction. For example Norsk Hydro UK in its latest report shows discharges of Nitrous Oxide and Carbon Dioxide down by fifth and a third respectively and it has eliminated Sulphur Dioxide discharges altogether.

IBM has this progress to report:

- At year end 1995 IBM's US 33/50 chemical releases and transfers were reduced 84% from 1988 levels, exceeding US EPA goal.
- Hazardous waste generation was reduced 71% world-wide from 1987-1995. Of the waste generated in 1995, 84% was recycled.
- Worldwide plants, laboratories and administrative facilities recycled 65% of non-hazardous waste in 1995.
- Energy conservation efforts saved $15.1 million (approximately £10 million), 226 million kWhr in electricity and 2.15 million gallons of fuel oil in 1995.

What the Chemical and Computer Industries can do should be echoed in the Construction Industry.

Environmental enhancement

It is important to emphasise that Sustainable Development is not just about prevention or reduction, about the need to do less harmful things. It is also about the positive. Many companies have made heavy capital investments to ensure that the surroundings of their buildings are as attractive as possible. You cannot sell even quality goods out of a dirty shop window. There really is no excuse for business premises, whatever the product or the service, to be anything other than elegant. In the Construction Industry which can do so much to ensure high quality environments, providing 'delight' as an outcome of the construction process should be a cardinal element in corporate programmes.

Going for Green

I have already mentioned GfG and outlined its Green Code. It is being tested in pilot sustainable communities in six local authorities, one business and I hope to see another in a major educational institution shortly. To help measure performance we have developed a single unit of measurement so that different environmentally-friendly activities can be measured against each other. The calibration is difficult but we have got there. For the moment it is called an 'eco-calorie'.

What GfG will do, if it succeeds, is change the pattern of consumer values and spending and alter public perceptions about what is desirable and possible. Those alive to the growth of a powerful voice in civil society (quite different from the single issue voices of the past) will soon recognise the necessity to be innovative in product process and place! But help is available in many different ways. Let me cite just one example in the UK - if only because my own university is involved.

The business ecology unit and other services

The four Universities here in Manchester have combined together to respond to the call from the Co-op Bank to provide an environmental service to its customers and anyone else for that matter. I can tell you getting four universities to work together is really innovative! Increasingly the new-style Chambers of Commerce and Tecs are looking to assist businesses who are seeking guidance about good environmental practice. It is all very encouraging. But it needs a major shift in the thinking of many more people, yet.

Conclusion

I am delighted to have had this opportunity to share with you something of what is happening innovatively in the field of good environmental management. But even more pleased to be able to encourage you to consider what, or what more, you can do.

I believe there is a special role for the Construction Industry. It is ambassadorial! You can help to bring about this revolution in thinking; securing a commitment to Sustainable Development. First you can do it when your clients who should have the environmental and social consequences of their buildings spelt out to them. Secondly, you can be tough on materials suppliers, making it clear that you will not consider them if they cannot demonstrate the environmental probity of their materials and thirdly, you can do much to ensure that the end users of your buildings (who may not be the commissioning clients) understand what qualities they should be demanding. In this latter case it will be necessary to develop a partnership with realtors, building federations and the like so that certificates can be issued which provide guarantees on many of these issues. (In the UK we shall be exploring the development of the Eco Cal for housebuilders). There is a genuine need for a Construction Industry 'Green' partnership to develop a Sustainable Development Code for the industry.

The great Liverpool football club manager, Bill Shankly, was once asked if something to do with the club was a life or death issue. His response: 'it's more important than that!' Well, the proper management of the environment is a life and death issue but, more importantly, is a moral issue. How we handle it is a real reflection of our humanity and says all there is to say about where we think we've come from and why we fare here. It is a challenge to the Construction Industry no less than to the rest of us!

The Energy Barometer - A new system for monitoring energy use in the housing stock.

K-E Westergren[1], H. Högberg[2], U.Norlén[3]
[1]University College of Gävle-Sandviken, Gävle, Sweden.

Abstract

A new system for monitoring energy use in the housing stock is presented. With this system, which we call the Energy Barometer, statistics on building energy use can be obtained and analyzed at short time intervals. The principal objectives of the Energy Barometer are (i) to determine levels and (ii) to detect changes of trends in energy use for heating in the single-family housing stock.

In the paper we describe how new measurement technology, Internet-based communication techniques and computer intensive statistical methods are combined into a system to continuously monitor and report changes in actual and predicted building energy use. From each house in the sample data from a number of sensors are pre-processed and communicated via Internet. Measured energy use is standardized by statistically regressing energy data against climate data and using climate data for a 'normal' year for determination of average annual energy use for each investigated building. The results are generalized to apply for the studied building stock by using a weighting procedure based on statistical sampling theory. A comparison of results obtained from a pilot study shows that static and dynamic models give similar results although estimates based on dynamic models have smaller standard errors. Comparisons with actual total energy consumption show that the system can give useful results provided that the estimation period contains enough variations in climate.

Keywords: building energy end-use, monitoring, static energy models, dynamic energy models, rotating panel design, climate standardization, Internet-communication techniques

1 Introduction

The need of monitoring building energy end-use

One important use of energy is for the heating of houses and other buildings during the winter. Space heating is a necessity, and it is also a very large item in the overall energy budget in many countries. Of all the energy consumed in e.g. Sweden about 30% is used for this purpose. Although space heating does not require any sophisticated technology, it is an area in which there are real possibilities for alleviating the energy problem through changes in technology. It is also an area in which individual citizens, with their hands on the nation's thermostats and the choices they make in buying, constructing and renovating houses, can significantly contribute towards using energy more efficiently. A large number of energy efficiency improvement measures have also been implemented over the past decades. These measures have reduced the average heating demand per dwelling. In Sweden, for example, total energy use within the building sector is of the same magnitude today as it was 25 years ago although the heated space has increased by 45 % [1].

The energy situation in Sweden is changing with the continued de-regulation of energy markets. In addition national energy programs for re-renewable energies and decisions about energy taxes are to be implemented as a consequence of the Parliament decision to phase out nuclear power and to encourage the introduction of sustainable alternatives. Changes in the general level of energy prices, the prices of particular energy sources and the relation of different energy prices to each other (relative prices) are to be expected. In a free integrated European market for electrical energy, Sweden may export electricity and "import" a high price of electricity from the European continent.

Several other factors e.g. environmental and health concerns together with the technical and economic development will add to the difficulties of predicting and of distinguishing changes in current trends in building energy use. At the same time the economic consequences of these changes are considerable. The present official energy statistics in Sweden provide only crude and partly out-of-date information based on postal questionnaires about building energy end-use and hence methods of monitoring building energy use in order to detect current trends are needed.

The Energy Barometer idea

The Energy Barometer idea concerns monitoring the development of building energy use via continuous energy and climatic measurements in a random sample of houses and reporting changes of building energy use in a short time span. The word 'barometer' is intended to allude to measuring the pressure on the energy market.

The Energy Barometer may be used to determine whether building energy use follows a path desirable for society and building owners or if remedial measures should be undertaken. The construction of the Energy Barometer is based on a combination of modern electronic measurement instruments, data communication and computer intensive statistical methods made possible by the recent technical and scientific developments.

2 Technical Solution

Data handling system

The suggested system for data communication is shown in Figure 1 below. From each selected house the measurements are communicated either by modem and telephone (plain old or GSM) via Internet to the centrally placed Internet service provider (ISP). A new communication device ('Gateway') constructed by Ericsson Radio Systems [2] has been used in a small scale version of the Energy Barometer in 1998. The software for handling the raw data from the sensors are installed in the Gateway which then is connected to Internet via GSM or the telephone net.

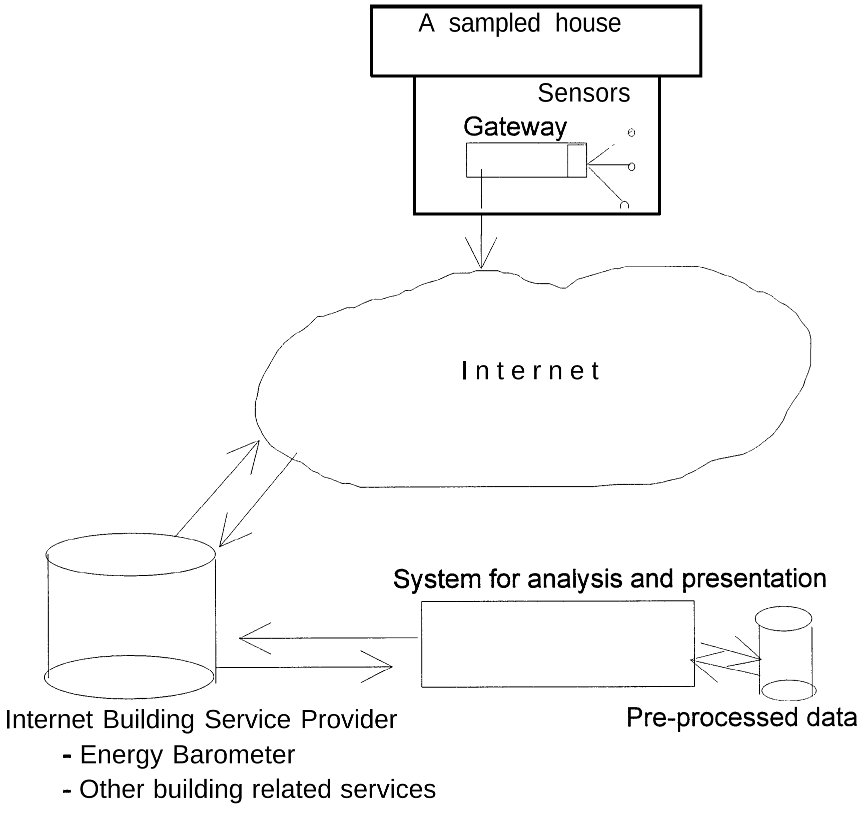

Figure 1. *The data handling and communication system of the Energy Barometer.*

Data needs and measurement design

The Energy Barometer aims at meeting the demands for both accurate and general results by continuously monitoring the following three variables in a reasonably large random sample of houses:

- electrical energy use for household appliances
- energy use for heating, including heating of tap water
- indoor temperature

The main purpose of the Energy Barometer is to give good estimates of total current levels of energy use for heating and changes therein. Therefore the main requirement is that the methods and instruments used give unbiased results with reasonably accuracy.

Table 1. Requirements on measured accuracy.

Variable	Unit	Accuracy	Sensors and additional units
Energy:			
electricity,(electric heating, water borne heating, heat pump)	kWh	± 2 %	kWh-meter with output of pulses
district heating	kWh	± 2 %	integration meter vith output of pulses
oil burner	l	± 5 %	flow meter with output of pulses
Running time: oil	% / h	1% / h	sensor or electromagnetic sond
Temperature: indoor/outdoor	°C	± 0.3 °C	temperature sensor

Basic technical data are collected for each investigated house e.g., number of persons in the household, type of energy source for heating (i.e. electricity, oil and gas, district heating, wood and other bio fuels), heated area, building construction data, electric appliances. Data are recorded on a simple standardized inspection protocol based on interviews and on site inspections [3]. These inspections are performed in connection with installation of the energy and indoor temperature meters.

The measurement designs in the houses differ depending on type of energy source for heating and how the heat is distributed in the house. When e.g., measuring the energy supplied by an oil burner an indirect method is used (see Figure 2). The measured burning time is estimated by dividing the electrical energy used by the burner with its rated power. Then this value is multiplied by the oil flow and the energy content of the oil. The estimated error by this method is approximately +- 6% [4].

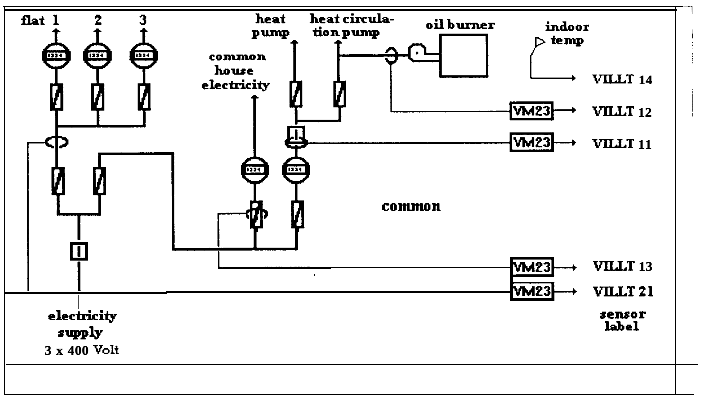

Figure 2. Measurement design in a house with heat exchange pump and oil burner

Weather data are needed in the form of outdoor temperatures and solar irradiation for the measurement periods. These data will be collected from the nearest official meteorological station. Measured energy use is reported in standardized form to apply for a whole year with an "average climate". To this end outdoor climate data are also needed for an "average year" or a so called "normal year" for the different areas where the investigated buildings are located.

3 Statistical Methods

Selection of houses

The initial sample of single family houses is to be selected randomly in three stages. First a stratified sample of some 60 of the 288 Swedish municipalities is selected by probabilities proportional to size. Stratification variables are degree of urbanization and a variable describing geographical location. Then, using the Swedish Property Assessment Register, a stratified sample of single-family real estate properties is selected in each selected municipality. Stratification variable is year of construction. Finally one single-family house is selected randomly from each real estate property.

The whole sample will be selected during the first year. In the following years, one fifth of the sample is replaced annually - a so-called rotating panel design.

The proposed minimum sample size is 700 single family houses. This sample size makes it possible to detect a statistical significant change in energy use from year to year if it is 5% or higher (at 5% level of significance). But for drawing conclusions about changes in sub groups a larger sample and/or additional data are needed.

The results obtained for investigated buildings are generalized to apply for the studied building stock by using a weighting procedure based on statistical sampling theory [5]. Each investigated building is given a weight, which is equal to the number of buildings this particular building represents in the whole housing stock.

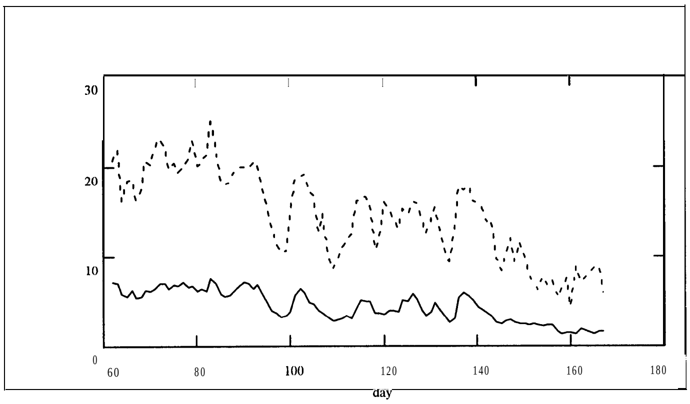

Figure 3. *Energy use for heating (kWh/day; solid line) and indoor-outdoor temperature difference (^oC; dashed line) for a single family house (February-June 1996, Gävle, Sweden)*

Determination of building energy use

The annual energy use is composed of two parts: energy for heating during winter and for heating during summer. The latter consists only of energy for heating tap water.The former depends mainly on the indoor -outdoor temperature difference as displayed in Figure 3 above. Other factors might however also be significant, such as solar radiation, wind and occupancy behavior. Measured energy consumption is standardized to "normal year" conditions by using a sinusoidal approximations of annual daily mean temperature and solar irradiation [6].

The annual energy use for heating W [kWh] in a house during a "normal" year can be calculated as:

$$W = cT + bQ + fI + dP$$

where

c = The 'winter factor' which is the average hourly energy use independent of outdoor temperature and solar irradiation factor [kW]

b = The 'heat loss factor' expressing how well the building stands the outdoor climate [kW/^{o}C]

f = The solar aperture or 'window factor' [m^2]

d = The average hourly energy use for tap water heating during the period when the house is not heated [kW]

T = The length of the heating period (hours)

P = The length of the period when the house is not heated (hours)

I = The solar irradiation during the heating period measured as the global radiation on a horizontal surface [kWh/m^2]

Q = The number of degree hours calculated as T times the average indoor-outdoor temperature difference during the heating season [^{o}Ch]

The energy parameters c, b, f and d have specific values for each house and can be estimated from the measurements using system identification methods. Both static and dynamic models can be used for this estimation see e.g. [7],[8] and [9]. For static models data intervals should be long enough for the heat stored in the building to be very small compared to the total energy supplied (i.e. 24 hours or more). Dynamic models on the other hand can utilize the information embedded in the 'thermal' response of the house to changes in the outdoor climate (e.g. hourly data).

4 Results

The presented technical solution was tested in the first half of 1998 [2] whereas the results presented in this paper are based on a pilot study [3] performed in 1966. The observation period of the pilot study was March - May 1996. Energy use and indoor temperature were observed in four occupied houses. The first half of the period was characterized by relatively cold weather with an indoor - outdoor temperature difference of about 20 ^{o}C and a moderate solar irradiation. At the start of the second half of the period the dynamics of the climate increased with big variations in solar irradiation and a change to higher outdoor temperature. The influence of the varying climate on the standardized estimates was therefore possible to study.

Estimates of similar size were obtained with the simple and more complex static models for both weekly and daily data, but somewhat different estimates were obtained from the first and second halves of the observation period. CusumQ -plots indicated a possible model change for two of the houses both when daily and weekly data are used.

Table 2. *Estimated energy use (MWh) by static and dynamic models in four single family houses (B, F, T and .Y) during the heating period compared to billed average energy consumption.*

	Static model (weekly data)	Dynamic model (hourly data)	Billed average consumption (* estimated)
House B (10 weeks)			
winter heating (MWh)	34.4	35.8	35.0
standard error	12 .	04 .	
adjusted R^2	0.95		
House F (9 weeks)			
winter heating (MWh)	63.4	57.7	60.0*
standard error	2.9	1.7	
adjusted R^2	0.75		
House T (10 weeks)			
winter heating (MWh)	28.5	29.5	30**
standard error	11 .	02 .	
adjusted R^2	0.93		
House Y (53 days ***)			
winter heating (MWh)	20.3	19.1	21.3”
standard error	2.4	0.8	
adjusted R^2	0.78		

** Heated by a combined heat pump and oil burner system (see fig 2) with an estimated total efficiency of about 2.8. 25.3 MWh was supplied to the heat pump and 9.0 MWh in oil to the oil burner. A comparable estimate was obtained as (25.3*3 + 9*0.95)/2.8.
*** static model results based on daily data due to gaps in the data series

The static and dynamic models gave similar estimates of total energy consumption for heating (see table 2). Smaller standard deviations were obtained with the dynamic model. This was expected since more of the information in the data is utilized. One implication is that observation periods can be made shorter when using dynamic models. The results are tentative since we have monitored only four houses for a limited period of time (9-10 weeks).

Models with time varying parameters might perform better than the models with constant parameter systems tested so far. Preliminary results from the analysis of energy data for a longer period of measurement indicate a possible seasonal varying effect.

The estimates agree well with actual total consumption figures. Had we based our estimates on either of the two halves of the observation period this would not have been the case. Therefore, while the search for an improved model goes on, the above methods can be used provided the observation period is long enough to contain representative variations in climate.

Acknowledgments

The results are based on the Pilot study performed in 1996 at the Center for Built Environment, Royal Institute of Technology (KTH). The work was commissioned and financed by The Swedish Consumer Agency and the University College Gavle-Sandviken.

Open Building: balancing stability and change

Stephen H Kendall, PhD, AIA, CIB
Marymount University, Arlington, Virginia

Abstract

Open Building is an approach to the design, construction and long term management of buildings. It is grounded in principles observed in historic environments which have remained stable while adjusting to new conditions of life. Open Building distinguishes between building parts which can have a log life and those which can change more quickly, and organizes the building process accordingly. The parts of buildings representing long term community values and investments are the parts which contribute a sense of permanence, place and environmental coherence - that are, in a word, sustainable. The short term physical elements represent values of a more individual nature. These are elements which wear out and should be replaced by new and better ones, but which also reflect the autonomy, freedom and the care individuals give to their surroundings.

Open Building is also a set of principles for professionals. With more parties involved, with more sophisticated products, and with more rapid change in all respects, creating stable but changable environments respecting individual differences is increasingly difficult. A key to making sustainability real is an understanding of the life spans of physical and social orders in complex interplay. Open Building offers tools for professionals to use in meeting these challenges.

An example of Open Building is the North American office building. Aside from architectural style, such buildings distinguish between a long term investment - a base building meant to be sustained over time - and a number of shorter term investments comprising the (mostly) interior fit-out for each occupancy. Base buildings do not determine fit-out but offer capacity for variation at a lower level, over time.

However, Open Building is not only for office buildings. It is also for residential and mixed-use architecture. Many residential Open Building projects have been constructed in Europe and Japan during the past two decades, and some have recently been realized in China and the United States. In Europe, an advanced interior fit-out system is on the market for new construction and renovation projects, providing customized residential fit-out at a competitive price. In Japan, dozens of such new initiatives are currently underway. In North America, market trends point to the adoption of residential Open Building in the future, based on the work of pioneering developers in the new construction, re-use and rehabilitation markets.

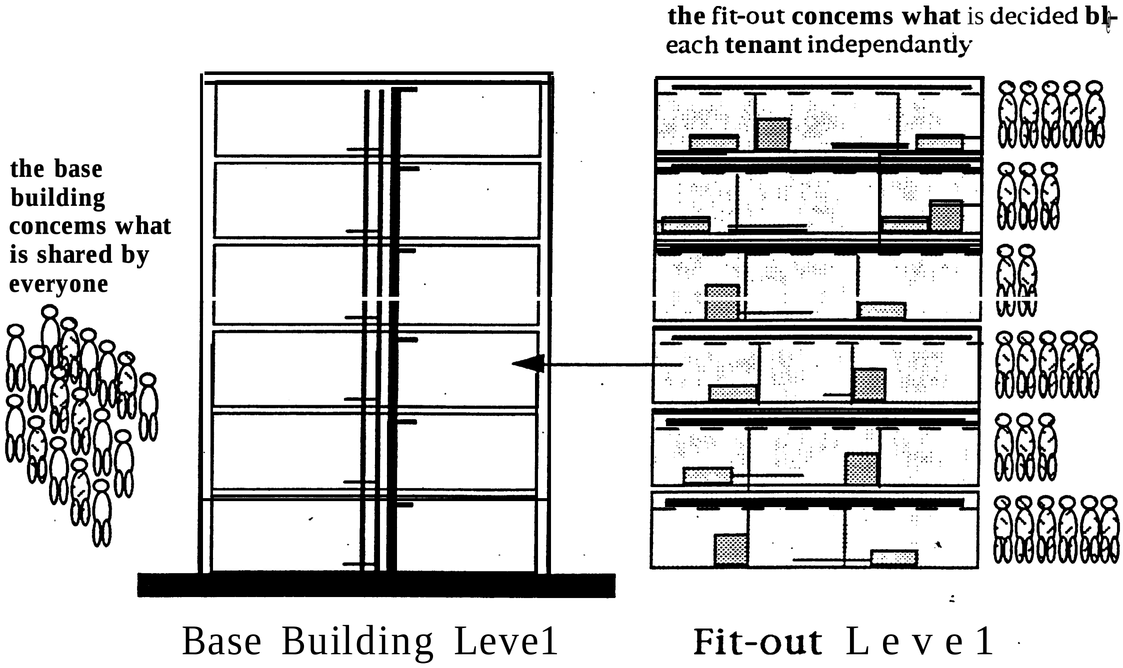
Despite the fact that Open Building is not new, it is not sufficiently discussed or studied. Many problems remain to be solved at both the base building and the fit-out levels and their interface, both technically and organizationally. The implications - and benefits - for all parties are significant. Despite the problems to be solved, this is perhaps the most fertile, wide-reaching basis for advances in sustainable architecture.
Keywords: base building, fit-out, Open Building, residential and non-residential construction, sustainable architecture.

1. Non residential Open Building

For decades, non-residential design, construction and management practice has used and improved Open Building principles. Commercial and retail base buildings in any style and construction type are routinely built without determining interior layouts, and are then fitted out to suit individual occupancies. Older buildings are "revalued" by investing inside - and refitting - existing shells. New "build-to-suit" facilities are designed for the time when the owner will vacate it, making room for other tenants with different requirements for space, equipment and systems.

Construction, manufacturing, cost accounting, building design, management and regulation have adjusted to suit this approach. For example, witness the trend toward complete slab-to-slab fit-out systems in the commercial office market; the increasing use of access floors and modular cabling for adaptable infrastructure; and the increased use of decentralized mechanical and air conditioning systems and controls. In addition, we see a shift in investment patterns in buildings and equipment, first noted in the 1980's (1). To a significant extent, investments are migrating to the fit-out, equipment and furnishings levels of work, with important ramifications for all parties involved.

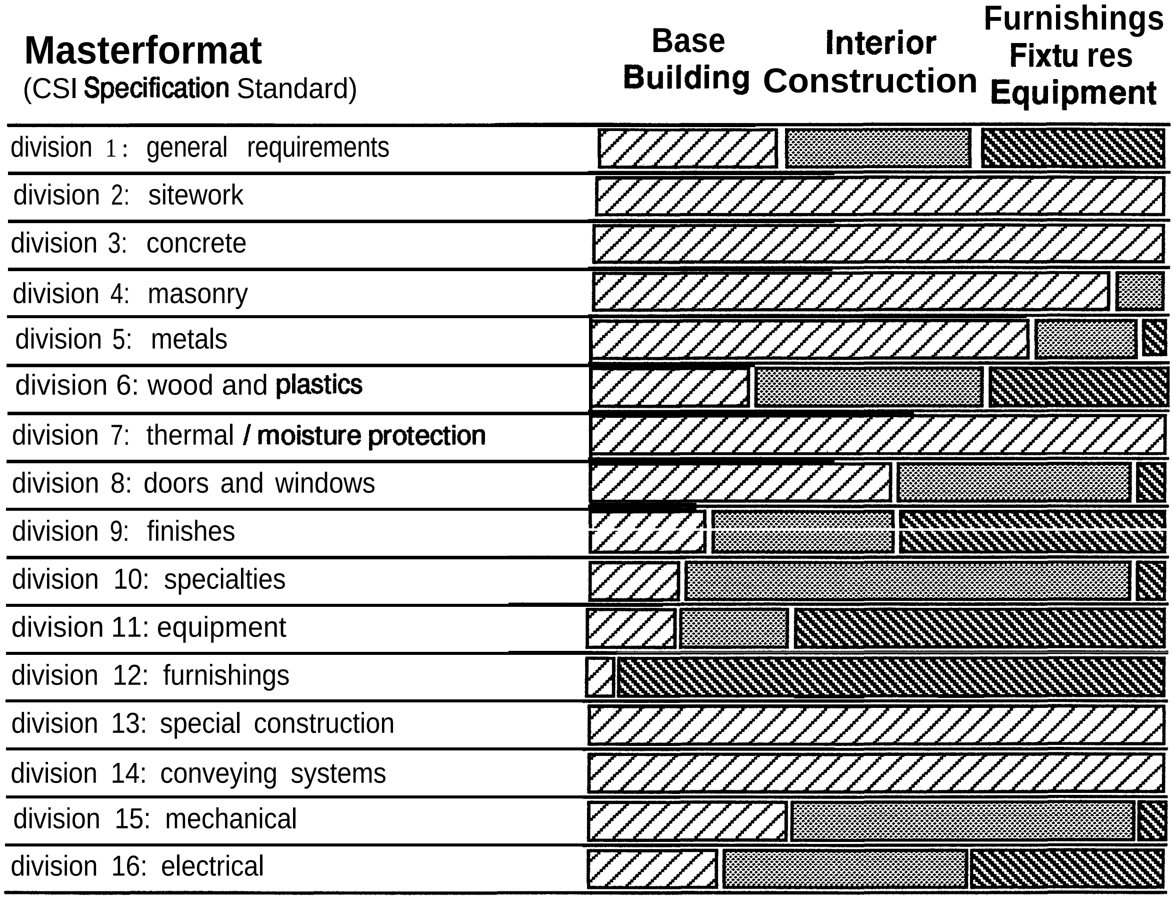
The following diagram shows the distinction between base building and fit-out, emphasizing the close interplay between physical and social realities:



This way of working is pervasive. Building procurement methods and technical terminology have changed to match the separation of levels. Best practices - in use of building systems and organizational procedures - are changing because of the separation of levels.

Another way to see the distinction between the permanent part of buildings and the more changeable is in a diagram based on the Construction Specifications Institute Information Divisions. In the following diagram, both technical subsystems and distribution of control on levels (base building, interior construction and FF&E) are shown together.

Three Tier Model of Control Distribution



In this diagram, each "tier" of control reflects actual distribution of control in most non-residential buildings. Some work is only found in the base building contract, some is principally in the fit-out and FF&E levels, while other work is distributed between all three tiers. Each project will have its own diagram.

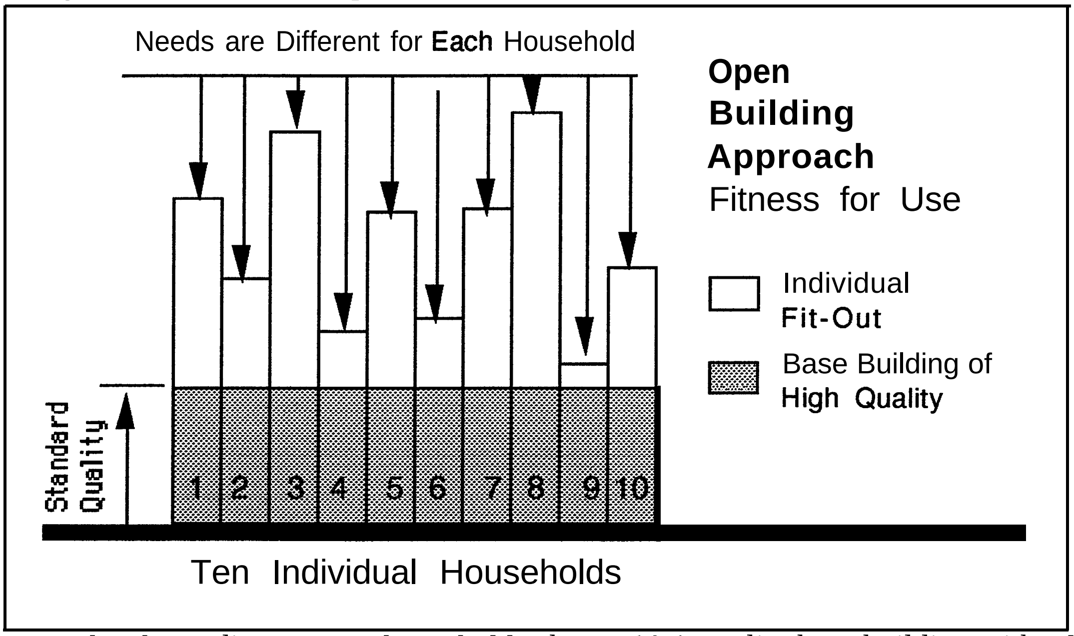
2. Residential Open Building

At the same time that office and retail Open Building has been maturing, many professionals - architects, contractors, lenders, manufacturing companies, government agencies - have been pioneering developments toward residential Open Building, an idea first set out in the early 1960's. (2). In the Netherlands and Japan, for example, the idea of constructing residential "supports" (base buildings) without determining ahead of time the individual layout of dwellings has become increasingly practical(3). Studies (4) and completed projects show that base buildings (supports) can cost less. (5)

For decades, residential Open Building projects remained experimental, hampered by existing development practices and the lack of economically viable "fit-out" or infill systems. Recently, however, development organizations, pension funds and others in the Netherlands who manage large numbers of housing units have begun to discover the advantages of making a sharp distinction between the individual dwelling and the building they occupy(6). With changes in the market in the United Kingdom (7) and the United States (8), a market may be emerging for advanced fit-out systems which enable affordable, customized dwellings in multifamily base buildings - in new construction and in the renovation of older structures.

In part, these developments in the market are founded on the recognition that natural diversity - in income and make-up - so familiar in many urban neighborhoods which have matured over decades - is an important goal both in social policy and private investment. Open Building is a way to accomplish this goal: variety is more costly - and is more equitable and socially desirable - than uniformny, a reversal of long held assumptions.

The following diagram (9) indicates this principle: Open Building offers a solution by distinguishing the more enduring, common part of a building from the more changeable, individualized part:



In the above diagram, ten households share a high quality base building with a long life. Each individual can have a fit-out suited to its budget and preferences. The base building has the capacity for a sustained relevance, while the fit-out can remain in place as long as it matches the priorities and preferences of individual households. The basic unit of social life - the household - can now be matched by the way the building is organized in respect to community values. This is in contrast to normal residential architecture in which the individual unit is largely subjugated to the needs of the whole, producing a rigidity out of touch with the natural diversity of a modern society.

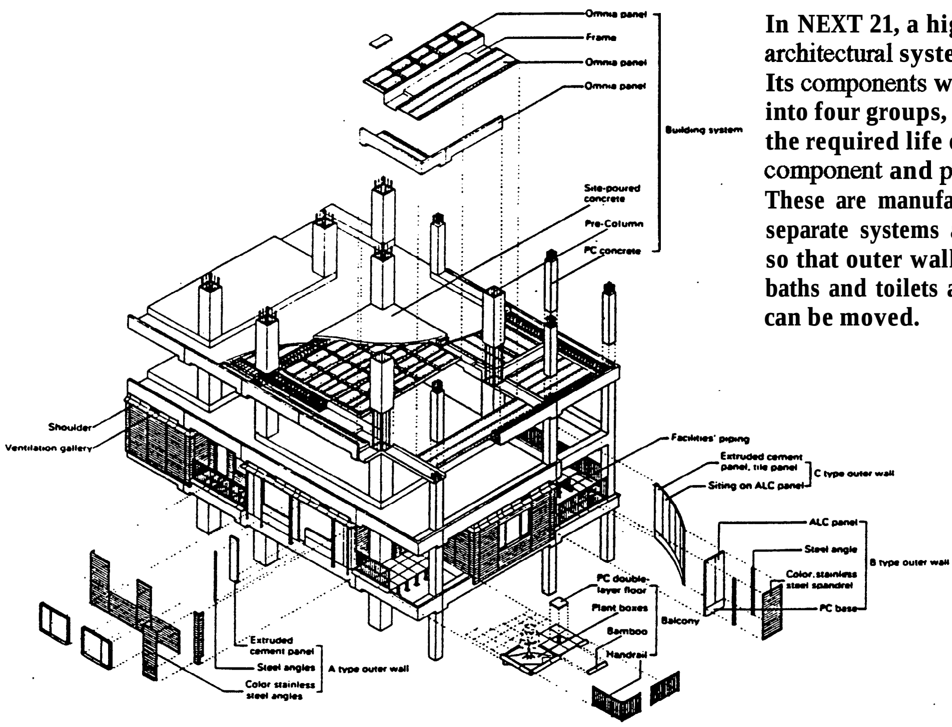
3. Examples of Open Building projects

In Japan, private corporations, the Ministry of Construction and its Building Research Institute, the national govemment's Housing and Urban Development Corporation, the Minisby of International Trade and Industry, and local Housing Authorities are setting the trend. They are investing to implement Open Building as part of a widespread effort to replace the "build, scrap and rebuild" pattem with a new approach to sustainable environments. Many dozens of projects have been built and many more are planned, each breaking new ground.

The most advanced project in recent years is the NEXT 21 project in Osaka, completed in 1994.(10) Sponsored by Osaka Gas Company, it is an experimental mixed-use project designed to come to terms with urban living in the next century. It focuses on issues conceming the right mode of housing in a changing society: where lifestyles are becoming more diverse; where the information society is becoming more advanced; where the problems of natural resources and pollution countermeasures that come with increased energy requirements become more severe; where houses are needed which can adapt to changes in society and lifestyles.

One architect designed the building's framework and infrastructure; another designed the facade system; and **13** other architects each designed an individual house, using the basic frame and infrastructure and the "kit-of-parts" facade system.

NEXT **21** is currently being modified and monitored. One unit was recently altered including its exterior facade and bathroom and kitchen location. Thus, the building acts as a living laboratory of advanced technology and energy conservation processes.



In NEXT 21, a highly flexible architectural system was used Its components were divided into four groups, according to the required life of each component and production path. These are manufactured as separate systems and modules so that outer walls, kitchens, baths and toilets and gardens can be moved.

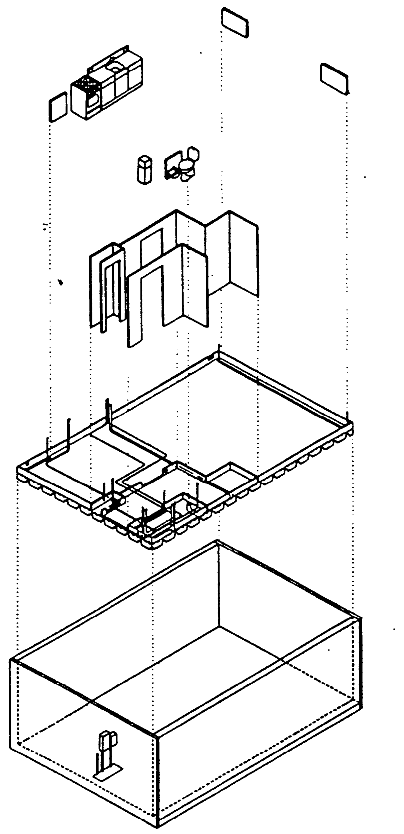
NEXT 21 Experimental Housing Project in Osaka, Japan

In Europe, a major German Company will soon begin routinely using a residential infill system developed in the Netherlands. The same product is already being used in multifamily rehabilitation and new construction projects in the Netherlands.

This infill system is a so called "open system". Given an empty shell, Matura® offers a fully prefabricated and adaptable infill system for residential construction. It includes spatial partitioning, as well as all technical subsystems, and kitchen and sanitary equipment, providing a fully equipped and habitable dwelling unit. **(11)**

It utilizes subsystems and parts that are readily available on the market like wall systems, doors and door frames, various finishes, as well as kitchen and bathroom equipment. It can accommodate new developments of such off-the-shelf products. All these subsystems are integrated into an adaptable whole my means of two newly developed elements: the "Matrix Tile" and the "Base Profile". These new elements provide flexibility in design, fast installation on site, and changeability in the future.

In a typical renovation project, removing the old apartment's elements may take two weeks, during which time the new plans are made and the technical work of preparing the infill package commences at an off-site facility. Days later, the package arrives in one or two containers, accompanied by a trained team of 3 or 4 multi-skilled people who complete the installation in another 10 - 14 days. Because the system is pre-approved, no building inspectors must be scheduled for site visits. It is, therefore, a completely new and unique and product for residential architecture.



The Matura Infill System fits in any given physical context. Installation does not pose special demands on the base building or the facade. Thanks to the free distribution of pipes, ducts, conduits and cables, the position of vertical shafts does not determine floor plans. This makes the Matura Infill System particularly attractive for renovation projects.

Schematic of the Matura Infill System

In Finland, rehabilitation of 30 year old multifamily buildings following Open Building practices is starting.(12) In the United Kingdom, a number of private companies and government ministries are actively engaged in Open Building developments, both for new construction and renovation.(13)

In China, work is moving beyond experimental projects (14) to wider applications. Open Building is becoming more popular though a variety of terms are used: "empty shell" houses; two-step houses; adaptable houses. More significant, the Open Building concept has been accepted by the authoritative bodies such as the Ministry of Construction as a major direction in the development of housing technologies.

For the time being, North American residential development does not follow Open Building principles, except for a few high end condominium projects which nevertheless do not have the benefit of a comprehensive infill system. (15) While we understand the historical reasons' for this reality, evidence from other countries and from current trends in North America suggest that we should - and ultimately will - also adopt Open Building in our residential architecture. Already, an American timber frame home builder is committed to Open Building in its operations.(16)

4. A watershed period for architecture

Such developments - in residential and non-residential work - are of major significance, even though they are not yet recognized for their merits. We are without doubt experiencing a watershed period of change. To facilitate exchange ofinformation and to support implementation, CIB (the International Council for Building Research Studies and Documentation) has formed a Task Group on Open Building. Members come from around the world from the design, construction, manufacturing, regulatory, lending, and academic research fields, and meet twice each year, in different countries to discuss their work, organize studies, and otherwise collaborate in implementing this approach to sustainable man-made environment. Its web site is www.decco.nl/obi

5. Open Building as a way toward sustainable architecture

The basic principles of Open Building are aligned exactly with the goals of sustainability in buildings and man-made environment for several reasons.

First, sustainability rejects throw-away cultures where buildings are made to last only a short time. Equally important, sustainability argues for investment incentives aimed to align long and short term values in the use of real estate assets.

In Japan, and in other countries with large central government building programs, the result of throw-away incentives was the "scrap and build" tradition in which buildings were rigidly constructed based on then current standards, quickly became obsolete, and were then found to be too entangled to bring gradually up to date. Now, this investment strategy is rejected in favor of a "stock" approach, in which emphasis is placed on maintenance programs and building for change.

Open Building offers a strategic contribution to the question of long term vs. short term. By making a clear distinction between the parts of a building that should last for 100 years and the parts that should - and realistically cannot - last so long, it is possible to accurately account for value and responsibilities, and to decide clearly about longevity of a building's subsystems. The separation between a base building - designed for capacity for change - and the fit-out - designed for individual freedom and for a shorter span of use - enables all parties to balance long and short term priorities.

Second, Open Building supports the development of "click-together" components with high re-use value. This has direct bearing on sustainability. Too much of the fit-out of office buildings, for instance, is discarded upon reconfiguration of space, in part because it is priced without accounting for embodied energy or "cradle to grave" costs. But equally important to the problem is that even the higher value-added components - too expensive to become throw-away products - are not easily reusable in new circumstances because interface standards have not yet maturred.

Open Building has a goal of "manufacture and design for assembly, disassembly, and reuse". This means that product manufacturers will make products compatible with other products having tight interfaces, but which are made by other companies. For instance, Molex's cabling and power distribution system used in Haworth office fumiture is not compatible with Steelcase's equally sophisticated wiring system used in its own office fumiture. But product compatibility in building subsystems made by different manufacturers is inevitable. Open Building provides tools to help achieve this.

A Regionally Adapted System for Assessing Building Performance

Nils K. Larsson
Natural Resources Canada, Ottawa, Canada

Abstract

The development and structure of a second-generation system for assessment of energy and environmental performance of buildings is described. The system is being developed in a process that involves 14 national teams in the adaptation of a core framework to suit regional conditions. Performance benchmarks are developed for three generic building types, schools, office buildings and multi-unit residential buildings. The system has been developed in a computerized format and the structure will be made available to interested organizations.

The system is being tested in 1998 on a minimum of two projects per country and results will be presented at an international conference in late 1998.

Keywords: environmental assessment, international, regional, energy, framework, testing

1. Introduction

The testing and labelling of buildings is in its infancy and there is no consensus yet on the range of performance characteristics that should be covered, nor how much rigour needs to be applied in the application of such a system.

However, it is clear that there is increasing interest in some sort of robust and validated system that can provide comprehensive performance assessments of buildings.. Further, there is a need for a model that can encompass the wide variety of physical conditions, building traditions and environmental priorities that occur in different countries and in regions within countries. This paper describes the features of a model that has been designed through an international collaborative process to meet these objectives.

2. The Green Building Challenge Project in Brief

Before getting into details and issues, it will be useful to have a short overview of the project, called Green Building *Challenge'98* (GBC '98). It should be noted that GBC '98 consists of two related elements: a two-year process of developing and testing a performance assessment model, called Green Building Assessment Tool (GBA Tool), and an international conference to mark the end of this process. The overall goal of GBC '98 is to test and demonstrate an improved method for measuring building performance, and then to inform the international community of scientists, designers and builders about the results. The project was initiated by Canada, but is being carried out in partnership with representatives from thirteen other countries.

Specific objectives of GBC '98 include:

- To develop a second-generation method for assessing building performance, with an emphasis on energy and environmental performance;
- To develop the method through an international and collaborative process;
- To test the system on buildings in each participating country; and
- To report on the results of the process in an international conference.

International projects are always expensive. Why, then, has this ambitious project to develop an environmental performance assessment system been launched, especially when several systems already exist?

There are several reasons, but the one most relevant to this paper is the nature and limitations of the existing first generation environmental performance assessment systems. We will provide a quick overview of only three of these in this paper.

3. Existing Performance Assessment Systems

BREEAM
The first and most widely known is the Building Research Establishment Environmental Assessment System (BREEAM) [1], which is jointly operated by the Building Research Establishment (BRE) and a private firm, ECD Ltd. The BREEAM system has now been adopted in a number of countries and is reportedly used to assess some 15% to 20% of new office buildings in England.

BEPAC
Another first-generation system is the Building Environmental Performance Assessment Criteria (BEPAC) system [2], developed at the School of Architecture, University of British Columbia. The developers had the advantage of having BREEAM as a prior model, and the result is that BEPAC is more detailed and comprehensive than the first BREEAM variants, although BEPAC is limited to office buildings.

LEED
The U.S. Green Building Council (USGBC) funded by NIST, has launched a system designed specifically for use as a green labelling system for rating the performance of commercial office buildings. The system [3], known as Leadership in Energy and Environmental Design (LEED), is very simple in its structure in that all criteria are placed at the same level of importance. However, the criteria in the system are linked to a series of existing performance standards established by other credible bodies, which is an asset. Also, an elaborate management system has been established to implement it and several major industrial suppliers are strong backers, which give the system a significant chance for widespread adoption in the U.S.A.

Design limitations of existing systems
Although the BREEAM, BEPAC and LEED systems are all ground-breaking initiatives, there are some factors which are likely to limit their widespread application, including their difficulty in handling different levels of detail in assessments, and the difficulties resulting from attempts to use them as design guideline instruments. For the purpose of this paper, however, the most relevant problem is the

difficulty encountered in adapting these systems for use in different regions and countries.

For example, although we can compensate for climatic differences in analyzing the energy performance of office building in Zurich with one in Toronto, it would be misleading to directly compare the normalized results, since large differences in energy costs underlie a large number of decisions made by the owners and designers with respect to systems used and levels of performance sought.

Regional differences are not confined to energy costs and climate. The European building tradition places greater emphasis on daylighting and access to operable windows, which make the deep floor plates typical of North American practice unacceptable there. Can we therefore meaningfully compare the inherently more energy-efficient shapes of North American office buildings with their European counterparts?

Even cultural differences come into play. Office workers in Japan and Europe are more willing to accept short-term deviations from a thermal comfort envelope than are their North American counterparts, and this can have major implications for the designed capacity of heating or cooling systems.

In summary, our view is that regional differences are of such significance that meaningful performance assessments must take them into account from the outset. This results in the use of locally-valid benchmarks of performance, so that an assessment is more a reflection of improvement within the region rather than the production of a set of results that can be compared across countries or continents. The trade-off is that some information relevant to international performance benchmarks may be lost, but at least one can be sure of the validity of the regionally-based results.

In the GBC '98 assessment framework, an attempt is being made to develop a system that addresses these requirements.

4. The GBC '98 Development Process and Framework Structure

The process being followed in the development of GBC '98 can best be described as an international partnership. Canada took the lead, but the other thirteen participating countries are making substantial staff and financial contributions, and have a decisive influence on the development of the system through their participation in the International Framework Committee (IFC), the committee that contains representation from all participating National teams.

The design of the framework began in the summer of 1996 and underwent several iterations in its design, based on extensive feedback from the IFC. At the time of writing (December 1997) the framework and software, called GBA Tool, has been completed and national teams are about to start testing the system in their own countries.

The GBA Tool is designed to be modifiable by national teams, based on their interpretation of applicability to local conditions. It includes the following elements:

- Parameters descend in generality from Performance Categories to Criteria and, at the most detailed level, Sub-Criteria;
- a scoring system has been established that ranges from -2 to +5, with the 0 (zero) level being the reference level;
- the performance level required to achieve a certain score is based on the 0 (zero) level being the locally relevant reference or industry norm level; a -2 is significantly inferior and a +5 is set so that is extremely difficult to reach;
- each parameter contains written statements related to each relevant score so that assessors can relate the actual performance to the nearest relevant statement, and National Teams can modify these statements within limits;
- weighting is possible at both the sub-criterion and criterion level, again modifiable by National Teams;
- criteria and sub-criteria can be declared critical at the option of National Teams, and failure to meet a critical level can disqualify the subject building;
- versions of the system are being prepared for each of three major building categories, including office buildings, multi-unit residential buildings and schools. These were selected by the IFC as representing some of the most generic building types extant, thereby maximizing the value of international comparisons; and
- the GBA Tool system is being implemented in the form of two distinct software modules; a Green Building Input (GBI) module, and a Green Building Assessment (GBA) module. These modules are being developed within a user-friendly database program. Conceptually, the system is relatively simple, although both modules include some calculation fields. The software system is also intended to facilitate the work of National Teams in specifying the characteristics of hypothetical reference buildings to serve as benchmarks, and in modifying scoring statements and weighting values.

The completed framework covers issues that are given in-depth assessments down to the level of sub-criteria. These include four *Resource Consumption* categories, four *Environmental Loadings* categories and five categories relating to *Quality of the Indoor Environment..* Other sections deal with *Longevity,* Process and *Contextual Factors,* which are assessed only at an upper (Criterion) level. The current organization reflects the view of the IFC that in a process with limited time and resources, there is a need to focus the detailed assessments on factors that are most germane to the goals of the process, e.g. resource consumption, environmental loadings and health/comfort issues.

5. Future Applications

The presentation of the results of this ambitious process at the GBC '98 conference in October 1998, should be not be viewed as an end-point. We may be closer to achieving consensus on what factors collectively constitute excellence in environmental performance, but it is likely that much further work will be necessary to position the system as an implementable system in the industry. Givkn this, it is likely that the process will continue and that a GBC 2000 conference will take place in another country.

In addition, work will begin this fall to extend the system so that it can serve as a related guideline system for building designers and developers. The GBA Tool could be pressed into service for this purpose, but to make it a fully effective guideline system many specific recommendations will have to be prepared that relate to each assessment parameter.

Given that there is need and potential demand for an assessment system, how could such a system be launched? Existing systems such as BREEAM, BEPAC and LEED were developed to serve the specific requirements of the context in which are used and have invariably been tempered by the necessity to meet the compromise of stake-holders and the practicalities of implementation. Each of these methods will continue to evolve and mature. The GBC '98 assessment framework will offer new assessment methodologies for them to consider and, if they so desire, to use.

However, if a consensus emerges that the system provides a substantial improvement over current systems, there may be a desire to implement GBC '98 or GBC 2000 as a complete stand-alone system for commercial building performance assessment. If this occurs, there are a number of desirable organizational features that should be considered:

- the body that develops and continues to improve the system should establish links with one or more recognized standards bodies;

- agencies that implement the system should be quite separate from the development agency;
- the development agency should be in a position to certify that implementing agencies are "100% pure GBA Tool" in terms of their system structure, procedures and staff training requirements; and
- the high cost of developing hypothetical reference buildings to serve as benchmarks will have to be reduced; possibly by developing a library of off-the-shelf stock reference buildings or benchmarks based on archetypes of common building types and forms.

6. Conclusions

The development of the core GBA Tool is now complete, but it will only be possible to evaluate success or failure after national teams have gone through the process of adapting it to their own conditions and have tested it on several projects each. Considering the effort, resources and collective expertise of the sponsoring countries that is going into its development, however, it is likely to at least make a substantial contribution to the state-of-the-art.

7. Acknowledgments:

The principal technical consultant for GBC '98 is Dr. Raymond Cole of the School of Architecture, University of British Columbia, and the software has been developed primarily by Woytek Kujawski of Inpol Consulting Ltd. The following individuals lead their respective national teams and have also greatly contributed to the development of the GBC '98 framework:

Ilari Aho, Finland
Roger Baldwin, UK
Chiel Boonstra, Netherlands
Drury Crawley, USA
Steve Curwell, UK
Jorn Dinesen, Denmark

9. Appendix Sample of Scoring Statements from GBA Tool - for Operating Energy Consumption

Score	Default Performance
-2	The annual operating energy per m^2 of net usable floor area of the case-study building is 45% GREATER than that of the Reference Building.
-1	The annual operating energy per m^2 of net usable floor area of the case-study building is 20% GREATER than that of the Reference Building.
0	The annual operating energy per m^2 of net usable floor area of the case-study building is EQUIVALENT to the Reference Building.
1	The annual operating energy per m^2 of net usable floor area of the case-study building is 25% LESS than that of the Reference Building.
2	The annual operating energy per m^2 of net usable floor area of the case-study building is 40% LESS than that of the Reference Building.
3	The annual operating energy per m^2 of net usable floor area of the case-study building is 55% LESS than that of the Reference Building.
4	The annual operating energy per m^2 of net usable floor area of the case-study building is 65% LESS than that of the Reference Building.
5	The annual operating energy per m^2 of net usable floor area of the case-study building is 70% LESS than that of the Reference Building.

Modelling cash flow in construction projects in countries in transition

Mladen Raduj kovic
Faculty of Civil Engineering, University of Zagreb, Zagreb, Croatia

Summary
The paper describes the modelling of cash flow in construction projects in countries in transition. Data of construction contribution in investment is shown, as well as GDP and total employed personnel in Croatian construction industry. Analysed are the most important changes which affect construction in a country in transition as well as those changes which affect the modelling of cash flow.

In the central part of the paper, the effect of risk and time slacks on the ability to form theoretical curves of cost flows is analysed. Results of research related to the effect of risk on time and cost, performed on 100 randomly chosen construction projects, are presented. The main sources of risk are described. The analysis of the effect of risk is performed with the aid of interpolation of various curves for costs between planned and actually recorded cost curves on the observed projects. Testing for each individually obtained curve for costs is performed through the bestfit approach with 18 theoretical functions. Ranking is performed according to the Chi-square and Kolmogorov-Smirnov tests. The analysis shows that the effect of risk increases the interval of possible shapes of the cost curves and the various possible forms of best approximation. The testing of the effects of reserves for completion also indicates various possible deviations from "a single curve". From that then, this paper proposes the creation of a value interval instead of a single theoretical curve. In order to ensure a practical value of results, proposed are criteria by which projects can be grouped.

The concluding part of the paper discusses possible application of modelling of cash flow in connection with possible directions of development in a particular country in transition. For example in Croatia the emphasis is oriented on tourism, which like most human activities affects the natural resources which acted like a base for its development. From this then, the paper discusses the need for the development of a model of sustainable development, which includes a balance between commercial success of a project and environmental protection. In the calculation of cash flow it is necessary to include costs of protection of natural resources, but according to a model which protects and unites the interests of investors, government and institutions of environmental protection.
Key **words:** cash flow, country in transition, construction projects, risk, development

1. Cash Flow

Data related to monetary transactions is not complete if it does not indicate time duration along with cash amounts. Planned cash flow is, therefore, equally important for all partners in construction projects. From the early phases of projects up to the time of contract signing, no partner has the necessary information for the creation of a precise plan for billing or payouts of money. The flow of cash is exceptionally difficult to determine ahead of time due to the influence of a large number of variables which give an unlimited interval of possible profiles. With an insufficient amount of exact information, every partner relies on estimates based on personal experience attained on previous similar structures. Complete repetition of previous steps is acceptable if measures and factors are the same on both projects. In this case it happens seldom, so precision in planning calculations is not guaranteed.

During recent years, certain methods of prediction and modelling of cash flow profiles in projects have been developed. All approaches are generally based on the use of certain mathematical formulas and computers. The product is usually a profile with the shape of an S-curve which shows the cumulative value with weaker beginning and ending growth rates in phases of work start-up and finishing. Developed models follow the same concept of cash flow development. That is, the difference of cash in and cash out originated through the conversion of cumulative value curves and cumulative cost commitment curves, using time delays and retention [1] . The primary emphasis of the research is placed on the creation of ideal curves for the various types of projects - Bromilow & Henderson 1977 [2], Hudson 1978 [3], Singh & Won 1984 [4], Tucker 1988 [5], Skitmore 1992 [6], Kaka 1996 [1]. The importance of past researches have been pointed out by various authors [8, 9], but there still remain various opinions about the level of precision of the proposed methods.

2. Construction in economies in transition

Development and construction activity in previously socialist countries was significantly determined by political ideals. In the former Yugoslavia, politics favoured large industrial projects and massive residential building. This was primarily due to the political idea that every worker must have a permanent job and a flat in which to live for a minimal cost. Together with permanent investment in infrastructure, that insured the construction industry in Croatia a portion of about 50% in investments and about 10% in GDP, and 8-10% of all employed people worked in the construction industry [IO] . Like the other industrial branches, construction had insured employment and market through required government support in cases of poor functioning of some company. So, for the evaluation of the success of a construction project, emphasis was placed on the technical correctness and functionality of a structure, while cost and time were not primary criteria for the evaluation of success. Methods of evaluating and keeping record of cash flows in construction projects were only partially used.

There are few examples in modern history where such a large amount of significant changes occurred in a short period simultaneously like in Croatia: war, creation of state, change in social organisation, change in the economic system and a shift to a market economy, privatisation,. . . For the construction industry, the following changes are especially significant:

1. Reduction of investments and employment in construction.
2. Insufficient capital in companies.
3. Absence of government support in cases of poor performance.
4. Opening of the market for foreign competition.
5. Significant reduction of the number of employees in large companies, with simultaneous changes in the structure of employed personnel in favour of production workers and the opening of a large number of smaller companies.
6. Change in the ownership structure of the company in which significant shares are taken over by groups of individuals, therefore, a change in the manner of managing and decision making.
7. Removal of non-construction and secondary activities in the structure of the company.
8. Time and money spent on construction and later on maintenance of the structure become important criteria for evaluating success.

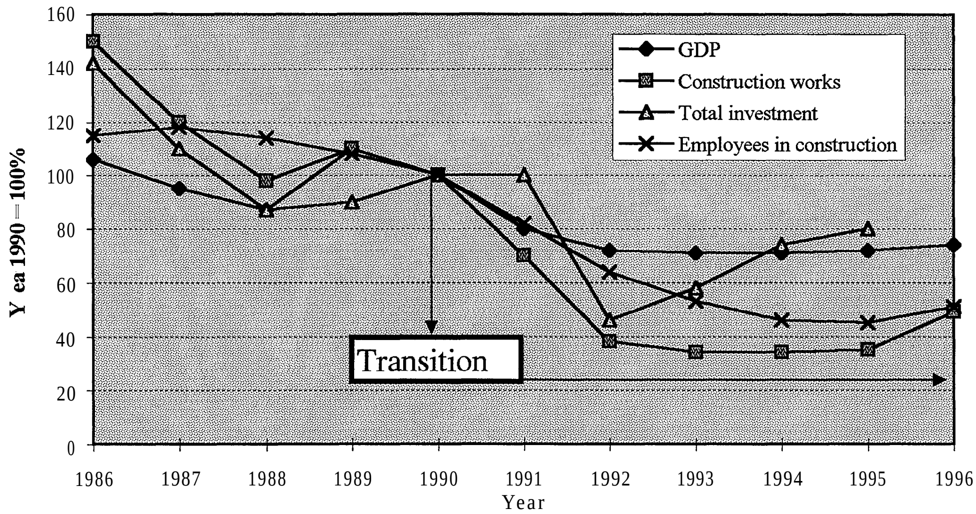

Fig. 1: GDP, investment, construction works and employment (1990. y. =100%) [10]

In each of the mentioned changes the significance of money, which is much in demand on the market, was emphasised. The way money is managed becomes a key factor for success for individuals and companies, and, therefore, for the general economy in transition. Planning and control of cash flow in construction projects becomes exceptionally significant for every contractor and investor.

3. Influence of risk on cash flow

The formula which was most commonly used for predicting cash flow in construction projects was the one published by the Department of Health and Social Security in Great Britain [3]. That is one formula with which it is necessary to use a series of pairs of parameter values for the creation of the correct curve for a project of a particular size. The DHSS formula was tested by numerous researchers with the goal of improving and simplifying it. Skitmore 1992. [6] analysed the DHSS formula on 27 completed construction projects grouped into four basic types. Research into various models for predicting best values for parameters shows that they are all equally productive, and that well grouped structures significantly improves the quality of forecasting. Tucker 1988 [5]. proposed an alternative form and use the Weibull function with seven parameters. Kaka and Price 1993. [8] performed research on about 150 completed construction projects, who's individual and group analyses determined that cost commitment models are more accurate and reliable than value models. Kaka 1996 [1] proposed a model with a large number of variables and stochastic simulation which includes analysis of the effects of risk. Taking into consideration results of previous research which indicated that the shape of a curve depends on the sum of costs [5], type and size of project, and type of contract [6, 8], we have attempted to look into additional effects - especially risk and activity time slacks.

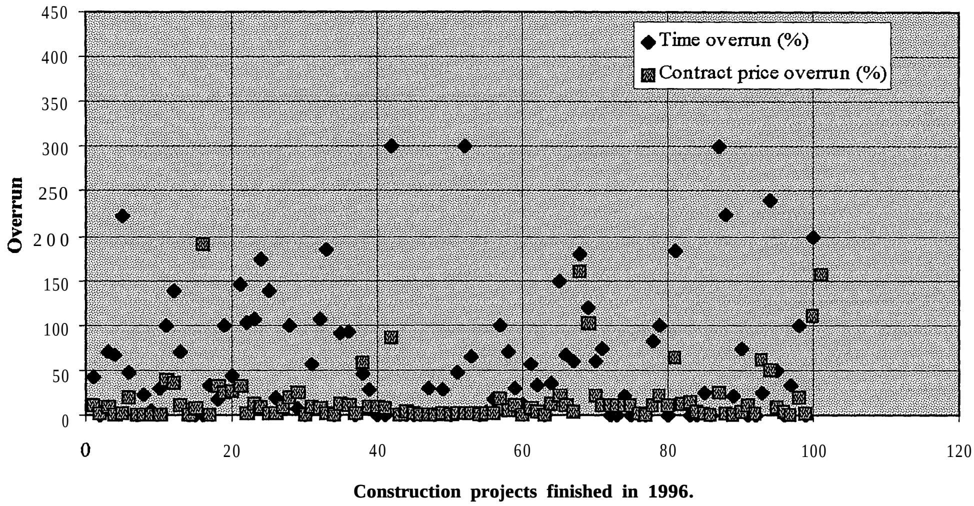

Fig. 2: Occurrence of overruns of planned times and planned money in samples of construction projects in the year of 1996.

Our beginning research [11, 12] consisted of creating project plans for a large number of construction projects. Curves of planned costs were then constructed from these project plans. At various points of completion, status control was exercised and data was collected. With the data it was possible to:

1. Construct an actual cost curve.
2. Perform further forecasting for a planned curve at individual points of completion.
3. Analyse the causes of deviation between planned and actual cost curves.

For modelling cash flow especially significant are results related to deviations between planned and actual cost curves. Research into 100 randomly chosen construction projects showed an average of 66% overruns in planned times and an average of 1'7% overruns in planned costs [13], with about 18% of extreme cases with a time overrun of over 100%. Added research in the year of 1997, with data from 1996/97, shows that overruns of planned times occurred in 74% of projects, and overruns of planned costs in 69% of projects. Research shows that in about 2/3 of construction projects there exists a general trend of problems with overruns of planned times and costs. The analysis of risk indicates that a dominant portion, 58%, of risk is from internal sources which have causes rooted in the project. That shows that although there exists a problem of large changes in the transition market, individuals and companies that adapt too slowly to the changing global market are largely responsible for project shortcomings. Five dominant sources of risk according to occurring frequency are climate, local permits, poor project preparation and participant optimism, unsolved financing of the project and incomplete technical documentation. The analysis of sources of risk in a transitional market like in, Croatia, indicates that according to occurring frequency criteria and degree of negative influence on planned time and cost goals in construction projects, the dominant problems are unrealistic and overoptimistic planned goals and unsolved financing along with various forms of limitations.

The effects of risk are a significant factor which creates differences in cash flow in construction projects. Risks cause differences even between completely similar projects, so it is therefore difficult to group projects by particular criteria and automatically have similarities in cash flows. For the analysis of effects of risk we have performed an interpolation of various cost curves between planned and actually recorded cost curves on observed projects. We took into account that initial plans were overoptimistic and varied the effect of risk. Testing of individual obtained cost curves was performed through the bestfit approach with 18 theoretical functions [14]. Ranking was done according to the Chi square and Kolmogorov-Smirnov tests. Analysis shows that with increased elimination of effects of risk normal distribution becomes dominant, however, if risk is included in projects then variations in results are increased.

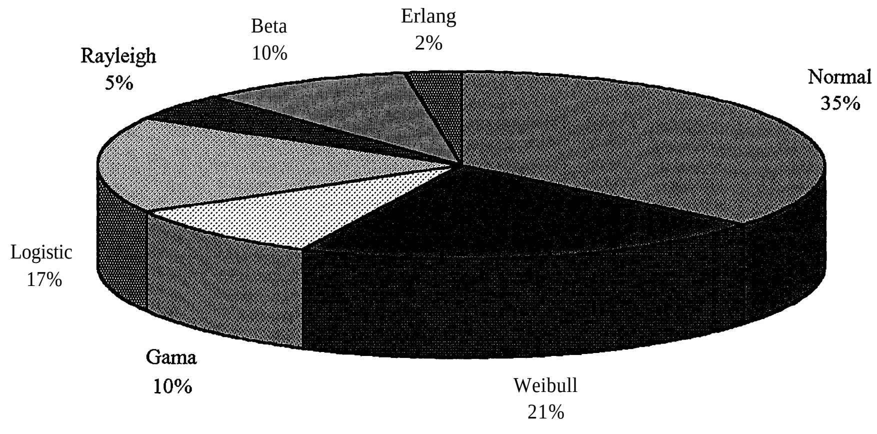

Fig. 3: Results of bestfit approach - rank according to Chi square test - minimal risk effects included

Performed research indicates that:

1. Effects of risk significantly influence the possible shape of cash flow curves.
2. Considering the impossibility of eliminating all risks in a project, or the ability to exactly forecast all risks in early phases of projects, research shows that the precision of individual theoretically obtained curves is questionable. It is, therefore, better to determine an interval of possible values instead of attempting to predict exact individual values.

4. Influence of time slacks on cash flow

The other significant factor affecting the shape of cost flow curves is the allowance to complete certain activities at various times. The use of network planning techniques enables the identification of noncritical activities who's planned completion is always within the area of "Early Start" (ES) - "Late Start" (LS). In practice, this means that instead of one specific cost flow curve it is possible to construct an area of cost flow with boundaries ES and LS curves. All values within the boundary area are possible and represent completion according to plan. Reserves in completion an activity time are positive in every case of management, and contractors closely study them during preparation. From this point of view as well, then, it is also difficult to determine one particular curve which will absolutely represent cash flow in a construction project.

On Fig. 4., shown is the area of LS cost flow curve for a group of projects concerning small tourist structures with 4 floors and an average completion time of one construction season and an average price of construction works of 1.5 mil. DEM (without furnishings). In comparison shown is cost curve obtained through the application of theoretical formulas from literature [5], for which it can be said that it probably represents an interpolation within ES and LS areas.

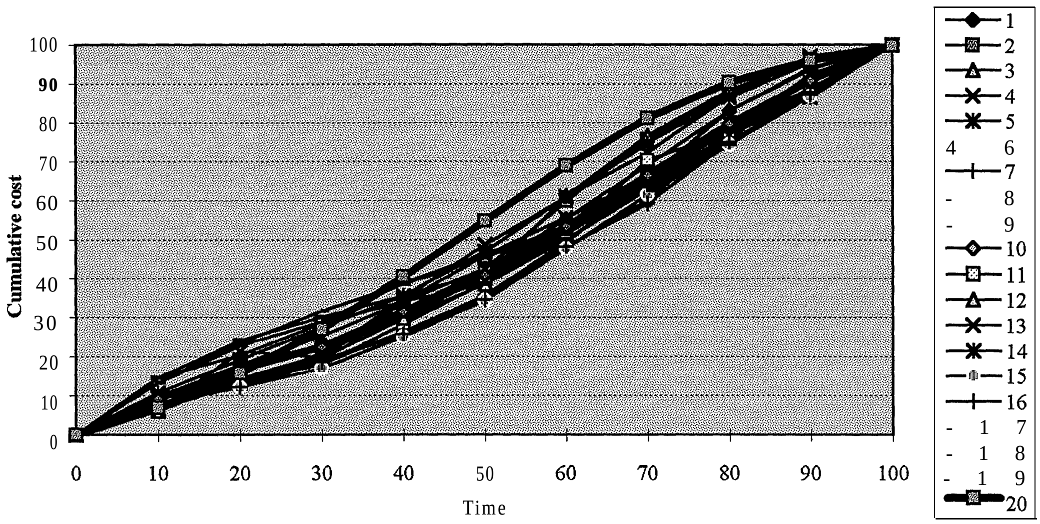

Fig. 4: Examples of cost curve areas for late start and minimal effects of risk (19 = average sample for late start Weibull(l.92 ; 0,60); (20 = theoretical Weibull curve (1,98;0,53) [5] ;)

The area between curves 19 and 20 might represent an interval of probably values for cost curve in this case, with included minimal effects of risk and no final time and cost overruns . Using results of our work and work done by other researchers, for a practical application we have adopted an approach which dictates that for determining cost flow curves, boundaries of curve group intervals should be set. In order for results to have practical values the interval has to be sufficiently narrow. This is achieved by grouping projects by numerous similarity variables:

1. Similar technical characteristics of structures.
2. For costs in intervals up to 1; 1-2; 2-4; . ..(mil. DEM).
3. For project duration in intervals up to 0,5; 0,5-1; l-2; 2-3, more than 3 (years).
4. In conditions of control or effect of similar primary sources of risk.
5. Same type of contract.
6. Same size of contractor.

5. Sustainable development and cash flow planning in economies in transition

The motive for a new project in every economy is the desire for development and profit. In an economy in transition these wishes are even more evident but at the same time are limited by a shortage of cash for investment into development. During the socialist era, development was carried out in the name of development through which the success of political ideals was proved. Through political and economic changes, countries in transition are trying to follow economic laws of market economies in order to achieve a standard and level equal to that in developed countries. In this approach, complete copying of development paths and development of the same areas could be contraproductive. Economies in transition have to follow their own development path in which the speed and quality of development will be harmonious. It is precisely the quality of development which points toward a need for orientation in the direction of traditional resources and wealth of a country in transition. An alternative to secondary or unclear production which is simply transferred from developed countries can be found in modelling of sustainable development. For example in, Croatia, this could be an emphasised orientation on services in which tourism development dominates. Tourism is a significant factor in development plans in many countries in transition. Culture, history, and natural beauty can serve as an excellent base for the development of tourism if the safety of tourists and acceptable prices and quality of service can be guaranteed. However, like most human activities tourism has consequences that affect the base which determines its initial development. This implies a spiralling reduction in natural resources: scenery, water,. . . A high level of information, a conscientious plan of environmental protection and the monitoring of laws and bylaws in developed countries enables countries in transition to make good decisions on time. In the case of tourism this is controlled sustainable development, in which at the project planning phase it is necessary to include plans for protection of natural resources.

In, Croatia, research looking into air and water pollution control, and solid waste disposal is being developed. Some results for example indicate that it is possible to solve the solid waste problem of the tourist area of the southern Adriatic coast in, Croatia, with a yearly investment of about 4 mil. DEM [15]. With cash flow modelling, or economic parameters of projects, it is possible to find a model for parallel tourism development and environmental protection. Since investors are significantly burdened with expectations of maximum profit, and, hence, minimum costs, it is probable that local and government authorities will have to control the process. This could happen through permits, concessions, regulations, laws, bylaws, and a system of penalties or benefits. That is an important co-operative effort between the investor, government, and institutions which ensure environmental protection. Success primarily depends on the modelling of an acceptable cash flow solution in projects according to balanced criteria settled by all parties involved.

Open Industrialisation: State of the art and future perspectives

Asko Sarja
Technical Research Centre of Finland (VTT), Espoo, Finland

Abstract
All technological development, and building technology even more so, is bound to the general development of society. Globally, societies are at very different stages of development: early industrialised ones are rapidly moving into the post industrial information era, while developing countries still are at the very start of industrialisation. This is one reason why possibilities for industrialisation differ between countries and from one region to another.

In industrialised countries the advanced industrialisation of building technology is necessary to meet the requirements of economy through increased productivity and general life cycle sustainability, including quality for users and ecological aspects. State of the art analysis has shown that the industrialisation rate in building is highest in countries where open industrialisation is applied. This is because of increased competition between suppliers who can exploit the high increase in productivity in factories through product development. Organisationally, open industrialisation supports a horizontally integrated production and networks which are becoming increasingly international. Special technologies may even be global. However, building concept applications and individual building designs must be local thus respecting local cultural and architectural traditions. In all industrialised countries, particularly in earlier socialistic ones, a clear change from the image of mass production time is necessary. Computer assistance and computer aided communication are provide crucial support to advanced technologies.

In developing countries the significance of locality is very strong, and because of a lacking general industrial environment manual working methods are expected to dominate well into the future. Also important is the use of local materials and products.

Much research work is still needed in the development of products, management, design and manufacture, as well as assimilation of the research results into knowledge through education.
Keywords: Building, industrialisation, open, productivity, future perspectives, state of the art, research needs.

1. Background and current state

Building production world-wide is a vast business arena with great importance for the entire welfare of the people, for the economy of organisations and companies, and for general sustainable development of societies [1, 2, 3]. Building technology, even more than other technical sectors, is closely linked to the development of the society as illustrated in Figure **1.** [2, 3]. This is why the possibilities of building industrialisation differ widely from country to country. In early developed countries the prerequisites are good for industrialisation, while in developing countries several social and economical factors still prevent it.

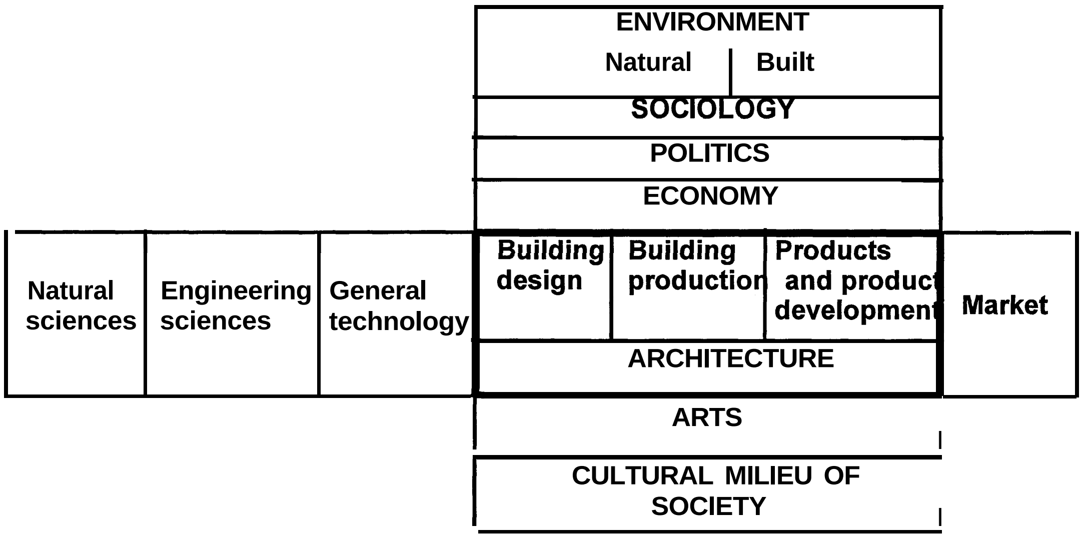

Fig. 1. The development environment of building technology /2/.

The societies in most developed countries have already passed from the industrial era into the post-industrialised information era, whereas newly industrialised (NIC) countries are at a fast developing phase of industrialisation and developing countries are at the very start of it.. However, even in early industrialised countries building production has been developing somewhat slowly towards industrialised production, lagging behind e.g. the automotive, shipbuilding and mechanical industries by as much as two generations. This is one reason why buildings for housing and for business and industry are usually expensive and production is sensitive to recession.

It is being recognised that the slow increase in productivity of the building sector has already led to increasing costs, and that therefore the building market in developed countries lies in a long term stagnation phase. An important tool in re-activating the building market is the reduction of price levels. In the NIC countries the need for building is high and the main prerequisite for effective industrialisation is an increase of production capacity.

During the mass production era of the 1960s and 1970s the production requirements dictated town planning and architecture at the expense of social and aesthetic considerations of both buildings and built up areas. The technical quality was sometimes insufficient, and especially poor in socialistic countries, which has led to generally negative attitudes towards industrialised building. Consequently many traditional prefabricated building systems still exist, which apply mostly the principles of closed or semi-closed systems (Warzawski) [S].

Advanced open system building is dominant in some countries like Finland, the Netherlands and Denmark. In several countries, such as Japan, France, Germany and the USA, closed company-wise applications dominate. In the countries where open systems are dominant, the market share of modern industrialised production is high, whereas in countries with closed systems the rate of industrialisation is considerably lower. This indicates that open systems strongly undergird industrialisation [1]. In countries with open industrialisation, today industrialised building means the exchange and application of products, services and information between the players in the building process, nationally and internationally, and between countries and regions with major differences in the structure of the building industry (Adler) [5].

2. Principles and definitions of open industrialisation

In order to meet economic requirements together with other requirements like aesthetics, functionality, ecology, durability, health and comfort of living, we have to rethink the entire content and solutions of industrialised building. Increasing international exchange of technology and building products could activate industrial development through increasing competition and evolution with the help of a continuous selection of the most competitive technologies and products. This requires international openness of building, product and information systematics, because only in this way will we activate and accelerate the internationalisation trend. Buildings play a major role in defining the local culture of our built environment. Therefore even international technologies and products must be highly adaptable to both local traditions and the natural environment. Industrialised building is not an objective in itself, but has to be understood as a tool for sustainable production of buildings for housing, working, leisure and industrial production. Openness is a road to all kinds of co-operation between the partners of building. The required openness refers to the capability to assemble products from alternative suppliers into the building and to exchange information between users, clients and partners of the building process and inside the consortia and business networks.

There are many different terms and definitions for open industrialisation [1]. Some are presented in the following.

Today the industrialisation of building means the application of modern systematised methods of design, production planning and control as well as mechanised and automated manufacturing processes /2, 3/.

Open system building is a general framework for the building industry, including modular systematics of products, organisation and information, dimensional co-ordination, tolerance system, performance based product specifications, product data models etc., so that the suppliers serve products and service modules that will fit together /2, 3/.

Openness is a concept with many aspects, like [1].

- OPEN for individual designs
- OPEN for competition between suppliers
- OPEN for alternative assemblies
- OPEN for future changes
- OPEN for information exchange
- OPEN for integration of modules and subsystems.

The central scope of open industrialisation includes the following areas /1/:

- Demand Side, dealing with user requirements and with the introduction of the requirements into designs.
- Supply Side, dealing with the production requirements and with the linking of -- demand and supply.
- Building Process, including organisation and communication in building projects.

A system is an organised whole consisting of its parts, in which the relations between the parts are defined by rules. The parts can be concrete (e.g. the components of a building system) or abstract (e.g. the components of an information system) [2, 3].

An open modular system consists of modular parts at different hierarchical levels, for which it is possible to produce different interchangeable products and designs that can be joined together according to connection rules to form a functional whole (Sarja) [2, 3].

In a dimensional coordination system, the reference system consists of planes, the intersection of the planes (lines) and the intersection of the lines (points). (de Troyer) [7].

A cis aspect which is seen (a) to limit the market for the parts to the market of the whole, and (b) to constrain the freedom of decision-making of the system participants, notably the architects (Davidson) [4].

3. Future perspectives of open industrialisation

3.1 Open industrialisation in industrialised countries

The current most advanced technology is flexible to individual architectural designs also allowing easy alterations during use, future changes, and modernisation. For this aim, systematic modular design and products are applied, including dimensional modulation, tolerance system, compatible joints and modular products disposition. As technical tools, highly mechanised and automated methods are increasingly applied to the manufacture of components in factories as well as in assembly and some phases of on-site manufacturing. Computer aid is increasingly applied throughout the building process: in analysis, design, manufacturing, production and operation. INTERNET is serving as a rapidly growing support for communication both locally and globally.

Future perspectives of open industrialisation in building are promising, because there exist several driving forces in general development of societies, which are pulling the development into the industrial way. Such kinds of driving forces are e. g. the following:

Future perspectives of open industrialisation in building are promising. Several driving forces in the general evolution of societies are pulling development in an industrial direction. These include:

1. A global need for increased productivity in the building sector, in order to cut production costs in developed countries and raise production capacity in developing and newly industrialised countries. Statistics show a drastically higher growth of productivity in factories yielding building products than at site works (Fig. 2)
2. Growing demand for guaranteed quality. This is best fulfilled in industrial and automated production both in developed and in developing countries.
3. The increasing goal towards sustainable development in building. This is best solved in industrialised countries through industrial production, which saves energy and materials, and where wastes can be recycled better than in manual production on site. However, in the least industrialised countries an alternative solution can be a very local production in manual methods using local natural materials.
4. Loss of manual skills in industrialised countries. This trend continues and threatens the building sector unless modern methods and industrial ways of production bring skilled workers into the building sector.
5. Reluctance of workers in industrialised countries to work in harsh and/or unsafe site conditions. This is already creating a shortage of workers at a time of high unemployment.

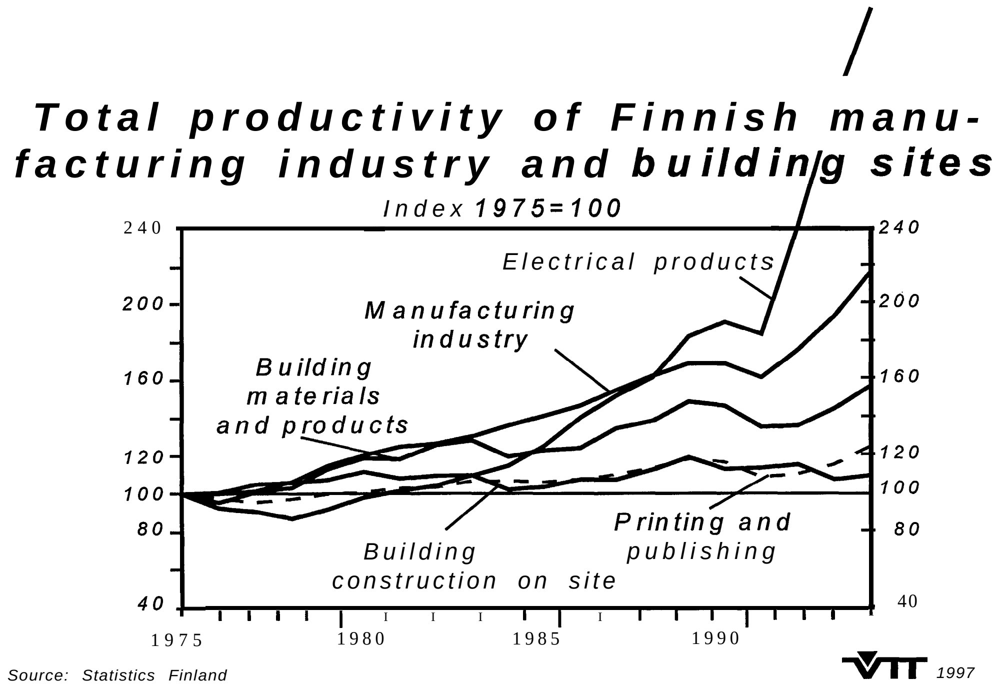

Fig. 2. Development of productivity in factories of building materials and products compared with construction sites and other branches of industry.

Industrialised building technology is developing globally and internationally, but applications into building concepts and designs must be made very locally in order to fulfil the local cultural, environmental, operational and economical requirements (Sarja [2, 3, 4], Weber [4]. . Individual buildings have to be adapted to the needs of their owners and users.

General industrial principles and methods can be applied in building [2, 3, 5]. Open industrialisation can be developed as a global technology which can then be applied regionally and locally in different ways using locally and regionally produced products and materials. The general rules and models can be concretised into building concepts for defined consortia or networks of contractors and suppliers.

In all subareas an important task is the transfer of generic principles and models from other fields of technologies into building, and participation in applied technical research in the core areas of industrial technologies. Such research areas include e.g. the STEP systematics of product modelling and several IS0 standardisation works regarding technical specification systematics. Open computer aided design systematics includes design organisation and rules enabling exchange of data in real time between partners. The openness includes the rules and systematics of general data bases, of data structures in design and of standard data interfaces between the partners (Fig. 3.).

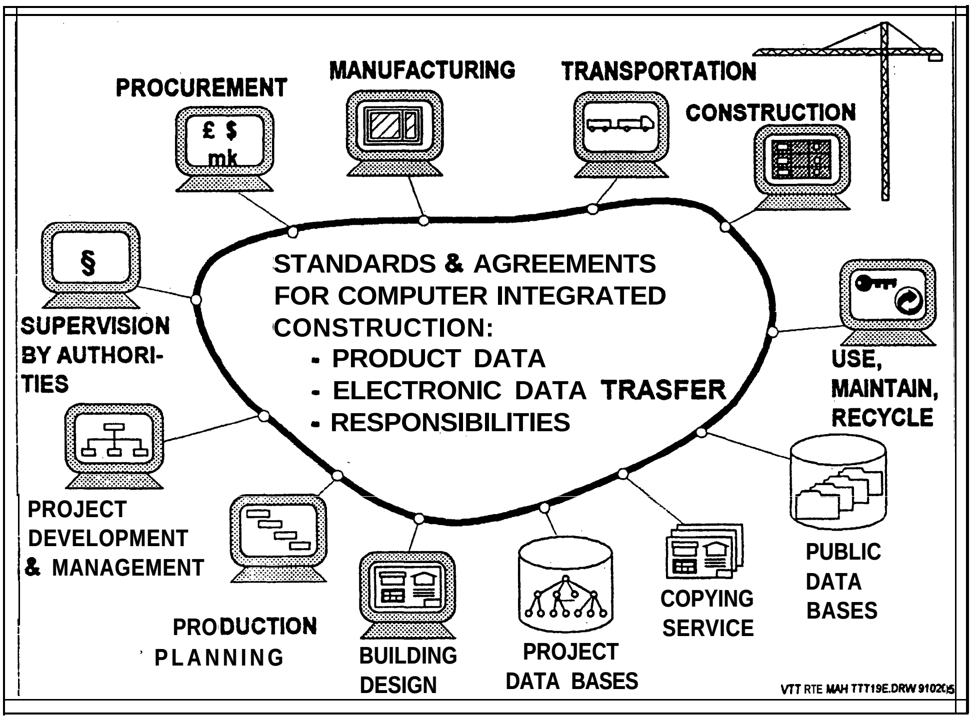

Fig. 3. A general scheme of open computer integrated construction [3].

It has been proposed that future open industrialisation in industrialised countries should be concretised through horizontally integrated production — mainly through the open building system and open design in horizontally integrated companies marketing alternative, mutually compatible deliveries (materials, components, modules, assemblies and services) for contractors or clients, thus fostering competition [3]. However, the contractors each apply the systematics to their own building concept, which means a closed business network.

The building process is moving from current sequential production toward parallel production, where several phases of manufacture are carried out parallelly and simultaneously under control of the project management (Sarja) [2, 3] (Fig. 4).

A special case among industrialised countries is the former socialistic countries, where a rapid collapse of industrialised building followed in the wake of changes in the society. Prefabrication is still regarded as a symbol of socialism; the quality is considered too low and the appearance extremely monotonous. This image is expected to prevail for a long time and to be a significant barrier to effective development of industrialised building. Another factor against industrialisation is the continued focus of building and development on renovation. Once this is satisfied through radical technical and architectural changes, the recovery of industrialisation is both possible and likely.

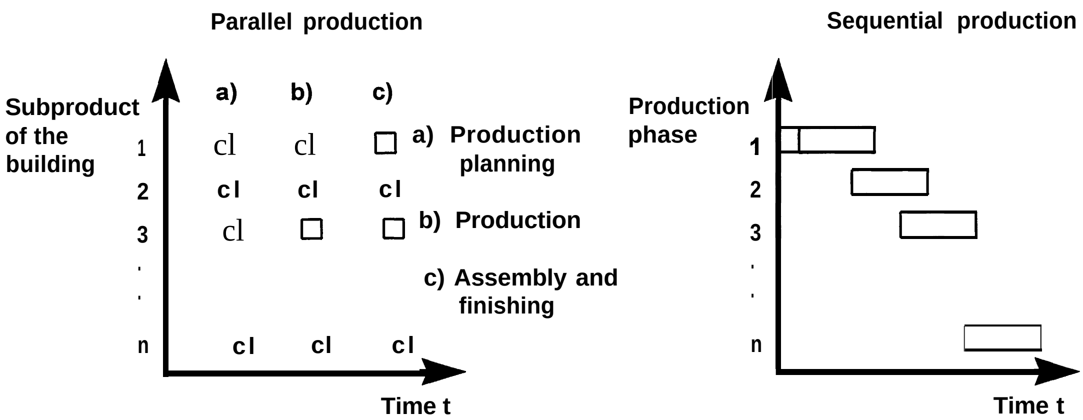

Fig. 4. Schematic presentation of parallel and sequential building production.

3.2 Newly industrialised countries

Newly industrialised countries tend pretty much to follow the development trends of the 1960s and 1970s, which were characterised by mass production. However, the technology now applied is better developed, and more open and flexible systems are used. There is now a good opportunity for newly industrialised countries to develop their production infrastructure, organisation and management, and design and product systematics with application of open industrialisation and general industrial methods. They also have the advantage of being able to learn from the mistakes of countries which developed sooner.

3.3 Developing countries

In developing countries it has been recognised that building technology and housing development must follow ways which are related to local traditions as well as social, environmental and technical possibilities. Thus the development of industrialisation, although certainly expected to continue, will be slower and different from that in the developed countries.

4. Research and development

In order to accelerate development of international industrialised building technology, research should be directed at further systematisation of performance concepts and of modularised system rules in product systems, organisation systems and information systems. The systematics should be presented as model designs, alternative organisational models and applied product data models. It is important to identify and analyse productivity factors and use the results to develop methods for improving productivity.

For implementation of the results into practice, companies have to develop long term strategic development projects over 5 to 10 year periods. These should include overall business strategy, product and method strategy and information system strategy.

The strategies should be followed by development of business networks and consortia and definition of the building concepts for them. These building concepts can be described and tested through model designs and experimental building projects

5. Acknowledgements

I am privileged to have the possibility of working as a coordinator in CIB W 24: "Open Industrialisation in Building", which discusses state of the art future perspectives in this branch. I would like to thank those members of W 24 who contributed their expert evaluations and reports to the state of the art project, as well as the great number of authors to whom I refer in this study.

ENVIRONMENTAL CONCERNS FOR CONSTRUCTION GROWTH IN GAZA STRIP

Adnan Enshassi, Ph.D
Civil Engineering Department, Islamic University of Gaza, Palestine

Abstract :
Gaza Strip region is a fragile ecosystem suffering from increasing environmental assaults due to the escalating population growth and the very limited natural resources available to support their development demands. Currently, there are a number of large scale construction projects being implemented in the process of newly developing Palestine. Environmental impact assessment of the proposed projects should include the social and economical dimensions. The major challenge in the development context is to maintain ecological balance which is often sacrificed when rapid economical growth is pursued putting enormous pressure on the natural endowments. This implies search for innovative and new building materials and construction technology in order to minimize the pressure on environment. The aim of this paper is to study the impact of rapid construction development on the environment in Gaza Strip. It is strongly recommended that Palestine should follow a program to promote sustainable development through the building of better institutions, and providing appropriate information and investment. It is necessary to assess the impacts of the proposed projects in Gaza Strip and to take certain measures to mitigate the negative impacts. There is a need for raising environmental public awareness and training.

Keywords: Ecosystem, sustainability, construction, emergency development.

1. Introduction:

In Palestine, environmental problems are dominated by the absolute need to better manage limited natural resources to meet the needs of its population. Such a population which is not only growing at a rate of 4.2% annually but also is adopting new life styles and consumption patterns which are more environmentally demanding. The fact that the population / resource variables are set on a collision course imposes the urgent environmental imperative of containing excessive population growth, and dictates a development strategy based on a more efficient use of limited physical resources (1).

Engineering team and construction contractors are responsible for the resource demands of the environment they create, on the other hand owners and occupants are accountable for the waste products they produce. Buildings have to be designed to take into account ecological principles, such as the reduction of pollution, sustainable growth, recycling of waste and energy, energy effectiveness and conservation of resources (2). The design of infrastructure projects in Gaza Strip needs a sensitive analysis of environmental requirements, but the process of procurement, construction and operation also need careful judgment and development. Consultant engineers and manufacturers need to develop a green ethic which encourages donors and developers to plan a project in an environmentally friendly way.

Disputes still exist about environmental issues with respect to their causes, effects, acceptable levels, and the desirable measures. However, there is a basic agreement on the need to monitor the situation, seek to understand the complex processes involved and adopt suitable strategies. Most countries now follow the concept of sustainable development. They seek to ensure that economic growth is achieved without eroding the resource base, causing pollution or upsetting ecosystems (3). Analysis, synthesis and evaluation of social, economic, as well as technical issues, will be vital if a holistic approach for producing environmentally responsive buildings is to be achieved.

Building and construction in Gaza use scarce land and utilize many physical inputs. Their products are used for most productive and social activities and owing to their durability, continuously interact with the physical environment. Construction can be a vehicle for effecting schemes for protecting the environment. Environmental issues are seldom considered on construction projects in Palestine because of the emergency nature of the projects. However, most donors like the World Bank and EC require environmental impact assessment study during the planning stage for most projects in order to be considered.

The purpose of this study is to consider the implications of the increasing concern with the environment for construction industry in Gaza Strip.

2. Geographical Background:

Palestine, as it stands now, is divided into two distinct regions covering a total area of approximately 6,183 square kilometers (6 million dunums). These regions comprising the inland region known as the " West Bank ", The coastal region known as the " Gaza Strip " and the proposed " corridor " connecting the inland and coastal regions.

The inland region has a maximum length of 137 kilometers a long the longitudinal axis between Zububa in the north and the southern most boundary line south of Al Samu. Its width varies from 31 kilometers along the latitude connecting Jerusalem with the northern tip of the Dead sea, to 58 kilometers along the latitude starting from Qalqilia along the western boundary and intersecting the Jordan Rever north - east of Zubeidat. The total population in the West Bank is estimated at approximately 1.6 million.

The coastal region, Gaza Strip, is a semi - arid coastal land of roughly 240 kilometers of arable land along the eastern Mediterranean Sea, the total area is about 365 square kilometers. It has an average maximum length of 45 kilometers between the boundary near Beit Hanoun in the north, and Rafah on the Palestinian - Egyptian border in the south. Its width varies from 6 kilometers along the line transferring through Deir El - Balh in the center, to 13 kilometers along the Palestinian - Egyptian boundary in the south. In this narrow strip, almost 1 million of the Palestinian people live and work. There are 575.000 refugees in the Gaza Strip, of which about 32.000 live in eight refugee camps. The population density in the camps is one of the highest in the world and varies from 30.000 to 100.000 persons per square kilometer.

The proposed connecting " corridor ", which is essential to ensure territorial integrity and viable socio - economic integration, has an area of around 136 square kilometers and extends from Idna in the south - west of the inland region to Beit Hanoun in the north - east of the coastal region. It has a total length of about 35 kilometers and an average width of 4 kilometers.

3. Environmental Situation:

Environmental conditions in Gaza appear to be among the worst in the Middle East. Serious environmental problems exist in several sectors, e.g. water, wastewater, and solid waste. Successful economic recovery will require effective integration of environmental, cultural and tourism resources into the development process. In Gaza Strip there are more than 500 industrial units which dispose their waste (solid and liquid) either into improper sewage systems or on the ground, causing pollution of the soil with organic and inorganic chemicals and other pollutants (4).

The major source of air pollution is the exhaust of about 30.000 to 35.000 motor vehicles, most of which are more than 15 years old outdated. The exhaust contains large quantities of carbon monoxide, carbon dioxide, nitrogen oxides, hydrocarbons and lead that are detrimental to the respiratory and nervous systems (5). Domestic and agricultural solid wastes are dumped freely, with the resulting leachate adding to the ground water pollution. Some of the wastes are burned, causing air pollution.

Fresh water is a scarce resource in Gaza. The main water resources are the coastal plain aquifer and the water transmitted from other locations. The quality of the ground watering the Gaza Strip is poor. Water quality is deteriorated due to infiltration of sewage, solid waste leaches and agricultural chemicals. Water quality in Gaza fails to meet international guidelines (chloride content 200 - 1000 mg/1, 77% of wells with nitrate concentrations greater than 50 mg/1 and 44% greater than 100 mg/1) while although water quality in the West Bank is generally satisfactory at present, sewage infiltration creates local problems (6).

Sewage ponds, and the Mediterranean Sea are used for the disposal of domestic, agricultural and industrial waste water. More than 50% of the raw sewage is discharged untreated into the sea, causing sever water pollution. Most areas in Gaza Strip still have unsatisfactory waste water collection and treatment system, there is great reliance on septic tanks, cesspits and percolation pits that are usually designed to serve a single home or a small group of homes. These alternatives require frequent discharge by vacuum tankers, and also pose a great threat to ground water (7).

In Gaza City the sewerage network only covers 65% of the residents. While the villages of Jabalia, Beit Lahia, Beit Hanoun, and Nazla are currently being connected to sewerage systems, only waste water collected from Jabalia and Nazla is transferred to Jabalia treatment plant. Some residents in Rafah are connected to a sewerage system which pumps the collected waste water from the Tel El - Sultan pump station to a lagoon in the area.

Per capita water consumption in the Gaza strip is expected to increase due to the housing and building projects which aim at extending the water supply network and providing a rather continuos supply to the customers. Many locations in the Gaza Strip suffer from broken water supply where they receive water for a few hours per week. the projects which purpose to provide a sewage collection network will also cause an increase in the domestic water consumption. The reason is that many houses face a problem in disposing off their wastewater due to the use of unsealed vaults of a limited capacity (8).

The rapid growth of population and development in the Gaza Strip have contributed to the magnification of solid waste problems. Estimates of the quantities, composition and density of solid waste produced by Palestinians is still very limited, with estimates ranging between 1.4 and 1.7 liters per capital daily. It is further estimated that up to 60% of this waste is organic (9). Table 1 shows the composition of solid wastes in Gaza Strip. Currently, solid waste management is the responsibility of the Palestinian municipalities and village councils, The United Nations Relief and Works Agency (UNRWA) has been responsible for services necessary for the refugee camps (10).

Table 1: Composition of solid wastes in Gaza Strip

Composition	by wet weight %
Organic Materials	67%
Paper	1.5%
Metal	1.5%
Glass	1.5%
Cloth	1.5%
Plastic	2%
Sand	23%
Other	2%

(source : UNRWA, 1993)

In many areas, solid waste is left in near by fields, abandoned plots and streets creation dangerous odors and providing breeding grounds for pests in the summer time, especially mosquitoes and rats. No system exists for collecting and disposing of waste from construction sites. Stones debris and powder resulting from stone processing are scattered throughout the countryside. The impact of poor solid waste management systems on human health and environment could be considerable in Gaza Strip.

4. Environmental and Social Concerns:

Environmental regulation and promotion of the efficient use of infrastructure projects help reduce adverse consequences from existing infrastructure. More options are available with new projects, although investment decisions can be consistent with environmental objectives only if environmental impacts are identified and assessed. Experience with environmental assessments in Gaza Strip demonstrates that construction projects are least likely to impose stress on the environment if such assessments occur early and influence the design of individual projects.

As the scale of construction projects grows, environmental consequences became increasingly significant. Environmental assessments should take a broad perspective capable of recognizing regional effects and induced economic impacts, as well as the potential consequences of broad economic conditions for the project. Moreover, even though large investment programs may be broken down into sub-components and implemented in sequence, it is usually necessary to conduct the environmental assessment on the basis of the overall program (11).

Environment friendly building and construction are essential for improving living standards and offering public health protection. With sufficient care, providing the infrastructure in Gaza necessary for growth and poverty reduction can be consistent with concern for natural resources and the global environment. Well - designed and - managed infrastructure can promote the environmental sustainability of human settlements. The relationship between infrastructure sectors (water, power, transport, sanitation) and the environment is complex. The most positive impacts of infrastructure on the environment concern the removal and disposal of liquid and solid wastes. But much depends on how disposal facilities are planned and executed (12).

The fact that environmental damage hurts people, both today and in the future, provides additional grounds for rethinking our measurement of progress. Indeed it raises special concerns, for unlike education, health, nutrition, and life expectancy, which tend to be improved by economic growth, the environment is sometimes damaged by that growth. Furthermore, the people suffering from the damage may be different from those enjoying the benefits of growth. They may be today's poor, or they may be future generations who inherit a degraded environment. For these reasons it is essential to assess the costs to human welfare of environmental damage and to take account of the distributional impacts of policies (13).

Sustainable development is development that lasts. It has been argued that the adverse impact of economic growth on environmental degradation can be greatly reduced. Poor management of natural resources is already constraining development in the Gaza Strip, and the growing scale of economic activities will pose serious challenges for environmental management. But rising incomes combined with sound environmental policies and institutions can form the basis for tackling both environmental and development problems. The key to growing sustainability is not to produce less but to produce differently. Uncertainty is an inherent part of environmental problems. To reduce it, decision makers need better information about environmental processes and social preferences (14).

5. The Impact of Construction on the Environment:

Construction operations and products have an impact on the environment in - several directions, these are:

- Resource deterioration, e.g. dereliction of land from quarrying and extraction of sand, clay and limestone, use of energy in the production of materials.
- Physical disruption, e.g. soil erosion, silting of reservoirs, disruption of ecosystems, climatic changes, noise pollution.
- Chemical pollution, e.g. particles released in the production and transportation of materials, pollutants produced in manufacture of some building materials.
- Social disruption, e.g. dislocation of inhabitants of the sites of roads.
- Undesirable residual impact on the environment from temporary structures, uncompleted buildings and untidy sites.

Some materials, such as asbestos, could be harmful to the labors handling them, and occupants of buildings. Of the constituents of paints, first lead, and more recently, benzene and formaldehyde, have turned out to be hazard (15). Moreover, building services and insulation materials account for about 50% of all global chlorofluorocarbon consumption (16). Great amounts of energy are also used in the production of materials such as bricks, plastics and paints. The single largest and product of the construction industry, buildings, greatly affect the environment since they use around two - thirds of all energy used. In addition, the construction of new buildings accounts for around 5% of total energy consumption during their production processes. Buildings in use and the construction of buildings consume vast quantities of natural resources and are responsible most significantly for many undesirable environmental effects.

An unfortunate consequence of construction industry is the prevalence of developers who favor the use of new green field sites in the Gaza Strip. Whilst this is understandable in the context of ease of development and cost effectiveness, the effect upon the environment is simply one of leaving existing buildings, structures and sites in derelict and ruinous condition. Land use has also a great environmental effect on construction industry. There is no doubt that habitat destruction lies at the root of much vehement public condemnation of construction.

Environmental effects from construction industry can result from inappropriate construction site practices that discharge pollutants, e.g. oil waste into water courses or through contaminants that go into land which feed into natural water resources. Waste emanating from construction industry is a major problem leading to detrimental environmental effects. Around 11% of all waste in the Gaza Strip results from construction demolition which is deposited in land - fill dumps or just dumped on the streets.

Environmental effects of construction result in a number of comfort disturbances to individuals living and working the environs surrounding any construction project. These are included: noise of construction equipment, dust from operations and traffic, nuisance from temporary dwelling and construction traffic, and hazardous contamination from toxic wastes.

The end products of buildings do give rise to environmental effects through the need for water and sewage treatment plants, water supply and storage facilities and the environmental effects associated with supplying and maintaining water resources to new and developing infrastructures. These lead to the knock - on effects of development.

6. Looking Ahead:

Gaza Strip is one of the areas of the region which is expected to undergo considerable economic development in the coming years. In planning a strategy towards the protection of environment and sustainable development, Palestinian are faced with many of the same issues confronting other developing nations. Foremost among these are population growth and adequate water supply and sanitation, both of which are quite critical. In Gaza Strip, as in other developing countries, there is a considerable lack of environmental public awareness about the interrelated nature of all human activities and their effects on the environment. This is due to lack of education, inaccurate or insufficient information and in some cases disinterest because of severe poverty and inhuman living conditions.

The environmental effects from construction industry have to be tackled on different levels: political, economic and educational. These three variables are independent. Without theoretical and practical knowledge, people will never achieve environmental and ethical awareness, values and attitudes. Skills and behavior should be consistent with sustainable development and necessary for effective public participation in decision making.

While basic education provides the underpinning for any environmental and developmental education, public awareness raising and training should be incorporated as an essential part of learning. It should have a job - specific focus, aimed at filling gaps in knowledge and skills that will help individuals to find employment. At the same time, training programs should promote a greater awareness of environment and development as a two - way learning process. The need for raising public awareness and for training is also strongly emphasized in Agenda 21, UNCED and the Declaration and Recommendation of Tbilisi Intergovernmental Conference on Environmental Education (UNESCO and UNEP 1977).

Palestine should follow a program to promote sustainable development through the building of better institutions, and providing appropriate information, investment, and incentives. The current and proposed projects have both positive and negative environmental impacts. It necessary, therefore, to assess the impacts of the projects and to take certain measures to mitigate the negative impacts. An action plan for the future should establish program priorities and goals over the long - term, and delineate a framework for policy, planning and research based on collaborative efforts of international and local agencies as well as universities.

As Gaza Strip has scant economic resources, it is recommended to examine the potential for the reuse or recycling of construction materials. The Production of construction derbies should be minimized so that only waste of the best quality possible, which has good recycle or erase possibilities may remain. Environmental impact assessment should be taken into consideration on every construction project. Further studies to analyze the impact of construction materials and construction derbies on the environment are required.

Managing construction projects within emerging information driven business environments

A. Thorpe, and F. T. Edum-Fotwe
Department of Civil and Building Engineering, Loughborough University, UK
S. P. Mead
Department of Construction Management, East Carolina University, Greenville, USA

Abstract
In a growing globalised economy characterised by volatility and intense competition, organisations that continue to be successful are the ones that learn to adapt their systems of working to dynamic change. This requires speed as well as quality, and can be addressed through greater organisation flexibility and responsiveness. Collaborative approaches to business provide one way of attaining such flexibility by construction companies. This is significantly influenced by how companies acquire, use, store, re-use and integrate relevant information into their operating systems. The impact of information and its associated technologies on communications within construction has been considerable, albeit at a slow rate of growth. Traditionally, the construction process has been dominated at all the various key stages by the communication of information between individuals or organisations in graphic, textual, and/or verbal formats. There is substantial potential for integrated IT options to positively influence the efficiency of these information flows. As construction organisations explore more collaborative approaches to business, it will become essential to address the way information is utilised by industry for its future markets. This paper presents recent developments in communications and information technology that will have significant impact on the management of the production processes in construction. It discusses the implications of these evolving technologies and highlights the likely changes to both construction organisations and construction processes over the next decade.
Keywords: Information, Construction, Processes, Organisation

1 Introduction

The global market for construction is characterised by change: changes in technology; changes in procurement routes; and changes in finance, are all influencing the industry, its constituent organisations and project operation. Coupled to this, the increasing demands by clients for greater cost-efficiency, assured quality, and shorter time scales have led construction organisations to seek new management approaches to remain competitive. The increased use of Information and Communication Technologies (ICT) is central to most if not all these approaches. This paper examines some of the underlying factors that have contributed to the current evolving developments in the use of information and its technologies in construction. It also presents some of the recent developments in communications and information technology that will have significant impact on the management of the production processes in construction. It discusses the implications of these evolving technologies and highlights the likely changes to both construction organisations and construction processes over the next decade.

2 Construction and IT

The effective management of information resources within construction impacts both the success of projects and overall performance of individual construction companies. The introduction of IT and communications technology within construction to improve the management of such information resources has progressed through three phases. The first phase lasted up to the late 1970s. This entailed use of IT to achieve efficiency and cost savings in the processing of information. Improvements in this phase did not alter the way in which the information was organised but rather attempted a speed up of the manual processes. Many systems developed were directed at the operational level and found use in secondary activities, such as word processing and bookkeeping, to support the management of construction companies and projects. The second generation of IT developed for the construction industry evolved during the late 1970s and continued through the late 1980s. The primary aim for most of the developments in this era was to have the IT function aligned with, or supporting the functions of a construction company. The development of various application systems to tackle time-consuming or iterative operations took place within this period. The main achievement of this phase was isolated automation of tasks in the design and construction process (Anumba et al., 1997). These included stand-alone systems for project planning, estimating, and accounting and financial reporting. According to Emery (1990), many of the strategic benefits from IT systems in this period proved to be less sustainable than originally predicted. Many construction organisations emerged from this era with large IT cost structures and also doubtful opinions of IT by senior management (Cross et al., 1997; Violino, 1997). The third generation of IT dates from early 1990s, and is still evolving. This is addressing the integration of the stand-alone systems developed in the second phase, in order to maximise the use of IT as a strategic resource for construction. It also focuses on the use of IT as a communication medium capable of establishing and maintaining favourable supply chain relationships. The developments for construction have almost exclusively taken advantage of innovations achieved in other domains, and as such have moved at a pace behind IT leaders.

3 The driving factors

Several factors have contributed to the emerging development in the use of IT. within construction. Not too long ago, the term IT meant putting a computer on every worker's desk -i.e. computerisation (Wong, 1996). There is evidence that the emphasis is switching from computerisation to business enhancement. Thus there is greater concentration on automating the processes of the project and the construction organisation. The project management function is based on the timely delivery and documentation of construction information. The delivery of construction information has traditionally been dominated by paper documents like blueprints and specifications (Laflin, 1997). These take the form of graphic, textual, or verbal information formats exchanged between project team-members. Typical information components include drawings, specifications, change directives, estimates, management logs, and field reports (Tenah, 1986). Because all members of a project team share these information components, the exchange of construction information is seen as one of the critical tasks in the construction management process (Miah et al., 1998). In today's highly competitive world, meeting the need to compress project lead times and to achieve cost optimisation is vital. At the same time, the growing involvement of construction organisations in multi-partner projects is increasing the complexity of managing projects. For any construction enterprise involved in the running of such large and complex projects, being able to handle the volume of documentation more efficiently can have a major impact on reducing project time scales and costs. The potential for such cost and time savings exist in the form of integrated information technologies (Cross et al., 1997).

3.1 IT factors

The main benefits of the change brought about by IT are speed and *virtual proximity* two critical elements essential for achieving success in managing construction projects. Large volumes of data can be processed faster, and distributed to disperse geographical locations much quicker (Miah et al., 1998). This creates a virtual proximity for distant geographical locations. These benefits have been widely shared by both industry and the general society because of the falling cost for computers, an explosion in software development, and cheaper telecommunication costs.

3.1.1 Hardware and software revolution

While construction computing was once the domain of large, well-capitalised construction firms, the diminishing cost of personal computers has put computing power within the reach of even the smallest contractors. At the same time, rapidly developing hardware performance, coupled with the development of ROM storage drives, modems, scanners, and back up devices have added much needed functionality to personal computing. The evolution of connectivity hardware such as servers, network cards, modems and routers have linked computers together providing a forum for community collaboration. Construction software industry has matured as well. The rapid development of the Internet has also levelled the software playing field through the use of simple "open architectures" like TCP/ IP and HTML (Hypertext mark-up language). For example, the newest versions of the CAD programs Autocad, and Micro-station include features that allow multiple users to post, view, redline and collaborate through the use of an internet based web browser.

3.1.2 Lower cost of communication
High telecommunication tariffs have long been a major stumbling block for exploiting technologies that rely on electronic communication (ESPRIT, 1997). However, the implementation of the package of telecommunication liberalisation measures is already leading to lower prices and to more flexible pricing schemes. The WTO Agreement on Basic Telecommunication will contribute directly to the emergence of a global marketplace in electronic commerce. Similarly, recent international agreements to eliminate tariff (ITA) and non tariff barriers should rapidly bring down the cost of key Information Technology products, encourage the take up of electronic commerce and reinforce competitiveness.

3.2 The economic imperative

3.2.1 Hyper competition
For the construction industry, these business changes are reflected in diminished project schedules, increased global competition, and limited profit margins. The increasing cost of capital and shortened life cycle of business products has put added pressure on construction firms to reduce project schedules, increase quality, and reduce cost (Kubal, 1995). At the same time, the recent consolidation of several large construction firms shows that there is increasing global competition for construction services. Today, these changes are forcing many construction firms to analyse their business processes in an effort to do things faster, better, and cheaper.

3.2.2 Changing financing arrangement
Given the dynamic conditions of the global marketplace, owners are now demanding reduced schedules, and increased flexibility between members of the design and construction team. Increasingly contractors are moving to flexible design-build contracts and project partnering agreements in an effort to meet the demands of the rapidly changing marketplace. In the US clients are now expecting contractors to provide turnkey projects, which include services that range from financing to facility management. While developments have not progressed at the same pace in Europe, the on-going harmonisation of the single market is likely to impact heavily on financing mechanisms for construction projects.

3.2.3 Globalisation
Globalisation is the consequence of political and economic developments in the latter part of the twentieth century, whereby worldwide resources are employed to increase the gap between costs and turnover. This has in recent times been facilitated by the availability of technology and regulatory frameworks put in place by the WTO. The effect of globalisation is increased competition, as markets open up to worldwide competition.

4 Emerging trends

Current developments in IT for construction have progressed along four main line, standardisation (examples include the use of ED1 and bar coding), visualisation (comprising CAD, VR, and Augmented Reality), communication (including video/data conferencing, Intranets), and integration (employing infobases and project specific databases). The impact of these developments is leading to a new agenda for the construction industry.

4.1 New links for business

In recent years, both academia and industry practitioners have suggested that the way companies organise themselves, do business, and undertake projects is inherently flawed (Cross et al., 1997). As a result, traditional models of hierarchy, standardised procedures, functions, responsibility centres and performance measures for both the construction companies and projects have all come under scrutiny. So nothing short of organisational transformation has been advocated. Contemporary corporate activity such as downsizing, out-sourcing, de-layering, and re-engineering have found frequent use in the management of both the company and projects within construction. The resulting lean organisations have to rely on greater collaboration to achieve project and corporate goals, and have given rise to a growing trend in partnering. This affects the length of the communication chain for both project and company, as several parties become privy to decision-making, which hitherto had been the sole responsibility of one organisation.

4.2 Internets and Intranets

The Internet has a huge potential as it relates to construction. This is an industry that continually moves information back and forth between offices and remote job sites. Given the simplicity of web browsers, and a new generation of Internet ready software, many corporations are now using the Internet to publish and transfer information within a company or to members of a project team. This includes access to a wide range of construction documents, including drawings, specifications, requests for information, budgets and meeting minutes (Vanier et al., 1995). Currently, several construction and design firms are using Intranets to form project specific web sites (ENR, 1996). These new information technologies may help construction and design firms re-engineer the way they communicate on increasingly complex projects. The use of project specific web sites can be employed to save time and shipping costs as well as improving communication between isolated members of the project team (Novitiski, 1997). Authoring tools like Java or Active X provide potential for creating custom web centred applications that are geared specifically towards the clients' needs (Thompson, 1997).

4.3 Electronic commerce and virtual business

Electronic commerce is about doing business electronically. It is based on the electronic processing and transmission of data, including text, sound and video. It encompasses many diverse activities including electronic trading of goods and services, on-line delivery of digital content, electronic fund transfers, electronic share trading, collaborative design and engineering, on-line sourcing, public procurement, direct consumer marketing and after-sales service. It involves both products (e.g., technical goods such as material components in construction) and services (e.g. information services, financial and legal services); traditional activities (e.g. healthcare, education) and new activities (e.g. virtual malls). It is estimated that electronic commerce revenues on the Internet may increase to ECU200 billion world-wide by the year 2000 (Council for Economic Co-operation, 1997). This revolutionary growth will lead to profound structural changes in construction. Electronic commerce is not a new phenomenon. But there is now accelerated expansion and radical changes, driven by the exponential growth of the Internet (Faucheux, 1997). This involves transactions on a global scale between an ever-increasing number of participants, corporate and individual, known and unknown, on global open networks such as Internet (Hardwick and Bolton, 1997). Electronic commerce, of course, is not limited to the Internet. It includes a wide number of applications in the narrow-band (videotex), broadcast (tele shopping), and off-line environment (catalogue sales on CD-ROM), as well as proprietary corporate networks (banking). Also, the Internet is generating many innovative hybrid forms of electronic commerce - combining, for example, digital television infomercials with Internet response mechanisms (for immediate ordering), CD-ROM catalogues with Internet connections (for content or price updates), and commercial Web sites with local CD-ROM extensions (for memory-intensive multimedia demonstrations).

4.4 Digitisation of Construction Data

According to Negroponte, we are rapidly moving from a world dominated by atoms to one dominated by bytes (Negroponte, 1995). In the past design and construction relied on paper based documents to exchange information. Developments in information technology are changing the way that construction teams generate, store, transmit, and co-ordinate information (Basu, 1996). Over the past decade, many design firms have moved toward digital production of construction documents (bytes). Today, most design and engineering work is completed using computer aided design (CAD) software, and this is slowly replacing traditional paper based construction drawings. Traditional text based documents are taking on a digital form as well. Specifications, transmittal letters, memorandums, and other text based construction documents are increasingly produced using word processing software or spreadsheet programs.

4.4.1 Video conferencing

Rapidly developing video conferencing tools are also changing the way the construction projects are run. Virtual conferencing tools like CU-SeeMe, Microsoft’s Net Meeting and Netscape’s Collabra are now being bundled with standard computer software packages, and these tools will enable project teams to collaborate, redline drawings and solve problems without having to travel to the job site. These advancements will help reduce travel costs and improve project communications.

4.4.2 Infobases

Increasingly, construction manufacturers are using the Internet to publish information regarding their product lines. Traditional paper based brochures, catalogues, and specifications were cumbersome to use, take up room, and information goes out of date quickly. Digital catalogues are now being posted to a manufacturers web site where specifications and pricing can be updated regularly. Currently, several web sites provide access to manufacturers data including, FM Link, Construction Net, Canadian Engineering Network, Building On Line and others. There are other projects under development to ensure effective exploitation of these technologies for the engineering sector. For example, the GENIAL project under the Global Engineering Network Initiative is an ESPRIT. programme aimed at developing Intelligent Access Libraries to meet the particular needs of the engineering sector within the EU (Radeke, 1997).

5 Scenarios of the future

Soderberg (1996) in a view of the future construction process presented three scenarios of working within the industry from the design, production, and the property management stages. While these scenarios incorporate various applications of IT and communications technology, they still present the industry from a functional perspective. According to Mowshowwitz (1997) and Xian-Zhong and Kaye (1997), there is ample evidence that the future of industry will not be driven by this functional approach.

5.1 Business of construction

Electronic commerce is an emerging market. In this fast moving and highly fluid environment, we are seeing the development of a wide array of innovative virtual businesses, markets and trading communities. Companies are now routinely outsourcing over the Internet functions such as order fulfilment to specialist firms. Materials suppliers and distributors are "going virtual", outsourcing the physical warehousing and movement of goods to logistics specialists. Buyers, sellers and intermediaries are forming industry-specific Internet markets in such diverse fields as real estate and construction equipment. Similarly, global construction and engineering industries, such as automobile, computers and aerospace, are actively integrating their supply chains through the Internet. New functions are now being created. Innovative virtual middlemen are providing value-added services- such as brokering, search and referral- to businesses and consumers.

5.2 Winners and losers

These emerging trends will result in an industry with organisations with little direct semblance to the present state of construction. The industry will witness some *winners* and losers as it goes through this structural change. Traditional professional disciplines that give rise to the industry's functional oriented structure will be replaced by more flexible systems, in which knowledge and capability will be widely available through global infobases. This will give rise to the loss of some job functions, and naturally result in the creation of new ones. Although the traditional functions will still be relevant, individuals will have to combine capabilities beyond the boundaries of existing professions and become what the British Computer Society has termed *hybrid managers.* Many lower-level management and clerical positions will be displaced, as work designs, work flow, reporting systems, accounting and control mechanisms are automated through the availability of IT Equally, many construction organisations will have to do business in different ways from today. New forms of *individual to individual* commerce are appearing.

6 Potential impact on construction

6.1 Organisation

The availability of current technology will enable both individuals and construction companies to form *virtual organisations.* This will help to overcome the problems of physical interaction between the various parties of the construction project, and facilitate the requirements of speed and virtual proximity. The management of projects and organisations will experience more electronic and less paper-based information particularly in the areas of specifications and regulatory instruments. There will be a move towards smaller organisational units, virtual teamwork, and a growth in tele working. In such virtual environments, team members will seldom share a common workplace, and in some cases may rarely see each other.

6.2 Project

The prevailing market forces and recent developing trends are placing new demands on the management of projects within construction. The effect is a growing awareness regarding quality, productivity, which are pushing for fundamental changes in the way projects are managed. These demands are reflected in developments such as partnering, concurrent construction (Anumba et al., 1997), total construction (ECI, 1994) and electronic management of project documentation (Polaine, 1997). The main issue that will be addressed at this level is greater integration of the construction process. Such integration will address various issues including the electronic distribution of all project documentation to allow instant access to information, and the networking of project teams.

6.3 On-site operations

Future developments in areas such as speech recognition and wearable computers may also help streamline the usability issue. Faster processors in low-cost computers and advances in programming techniques have made *automatic speech recognition* (ASR) a major focus of software developers. Currently, products like Dragon Systems allow users to dictate correspondence to their computers, and in the near future construction users may become less dependent on the keyboard as an input device. Similarly, low cost user-friendly wearable computers are now becoming available. The co-ordination of projects from remote offices will incorporate more real-time visual links. Also, electronic archiving for progress reporting at the site will find increasing application within construction. Preliminary developments in this direction have been achieved by Gaugh et al. (1997), with the development of the Vision Digital Library. The use of global-nets such as GENIAL for access to material specifications and construction detailing both at the design and construction phase will significantly impact the process and culture of construction.

7 Issues requiring attention

While these advances are changing the way that construction companies work, there are still some concerns regarding the wide scale implementation of information technologies. Some prominent issues include usability, legal issues, and training requirements.

Part of the appeal of the World Wide Web has been the user friendliness of the web browser. Because these browsers use a simple point-and-click interface, users can be trained in their use in a matter of minutes. Similarly, e-mail systems, the modern equivalent of the telegram, also provide users with a simple method of exchanging information and electronic files. In essence, the best IT tools are like FAX machines: products that are simple to use, require little training, and can be put to work immediately.

Generally the contract process dictates that information will be processed in linear fashion between legally responsible parties. As such, a typical document might flow from vendor to subcontractor, from subcontractor to general contractor, from general contractor to architect, from architect to engineer and back again. Evolving IT applications like the project specific web site, streamline information transfer by placing information at a central hub where all parties can access it. Unfortunately, this transfer circumvents the traditional chain of command, and many contractors have concerns regarding contractual liability and professional property issues.

A final concern is training the work force to stay abreast of the rapid evolution of the electronic age. While other industries have embraced the use of information technologies with dramatic production improvements, the construction industry has been slow to exploit the new developments in information technology. With an under-educated work force and low operating margins, construction firms have been reluctant to make major investments in IT. At the same time, the tidal wave of electronic change has created a paralysing situation where construction users are waiting to get a clearer understanding of the paybacks associated with their information technology investments. Recent research shows that training accounts for 55% of the total ownership investment in a business desktop computer (Park, 1997). Given the trend toward faster project schedules, global collaboration, many sophisticated contractors are now implementing some of the technologies discussed herein. Increasingly, architects, engineers, and contractors will have to make a substantial investment in employee training to realise the productivity improvements that are inherent in IT.

8 Conclusion

Developments such as market shifts and globalisations is driving construction in new directions. The increased competition resulting from such open markets is being accentuated by client demands for more effective use of their limited resources. Technology can hold the key to achieving the level of efficiency required in such evolving construction business environments. The impact of technology is bringing about a new shape to the way construction utilises and manages the information resources that are employed in its processes. The nature of the industry's processes both at the project and corporate level will be driven by these emerging information and communications technologies. This will influence not only technology aspects of construction, but also alter the present functional structures within which the industry operates. In particular, the evolution of the Internet will facilitate the establishment of electronic commerce in the construction industry. Electronic commerce offers enormous opportunities for the construction industry. It will have considerable impact on the structure and operations of the labour market Construction will need to adapt to exploit these opportunities, expand existing businesses and launch new ones. Further analysis is needed to fully assess these changes but it is likely that new employment potential will principally be in information-based, high-value services. Training and education for these new skills will be needed. The organisations that can adopt and capitalise on these changes will emerge as leaders in the global market for construction.

Sustainable design construction and the performance concept

George K.I. Ang, Coordinator CIB/W60
"The Performance Concept in Building "
Deputy Director Government Building Agency
The Netherlands

Abstract:
"Interest, interactions and implementation of sustainable development in The Netherlands "

Sustainable development is a major politic issue in The Netherlands. The growing attention for sustainable design and construction is mirrored in governmental policy of public facilities as to create interest, promote interactions and make implementations happen towards a different, sustainable attitude in the entire building branch. The developments are to be reported in the biannual reports on a so-called "Sustainable Building Action Plan".
This presentation illustrates the process of gaining mutual interest in the demand and supply of real estate by implementing a policy of exemplary effects in the procurement of public facilities. Within this context the commitment of (public) principals is an important success factor.
Referring to CIB W60 the results of the application of the performance concept in this procurement program will be emphasized, as the method facilitates a comprehensive approach from project-initiation to delivery.
The impact of new instruments and communication tools in order to facilitate effective interaction between partners in the process of project-initiation and procurement will be highlighted as well as the lessons from project-monitoring in a DFL 1.8 billion (USD 1. Billion) design-build procurement program for public buildings, during 1992 -1997.
In connection to this a decision-support system of expressing environmental matters in financial terms will be presented by, Marcel Dewever, the Dutch Chief Inspector for Environmental Affairs and a calculation model for assessment will be presented by Dr. Michael Haas from the Dutch Institute for Building Biology and Ecology, (NIBE).

Keywords: sustainability, fitness for use, design-build, comprehensive approach, assessment models, performance concept, intellectual challenge, total quality management.

1. **Introduction**

Sustainable design and construction can not be pursued as an autonomous task. It is part of the more comprehensive context of sustainable development.

This brings the issue into national and international policies and as a consequence it touches with the tension between environment and economy. Economic growth and a reduction of the pressure on the environment is a dilemma at first sight but it can definitely be successfully combined through changes in production, prices, taxation and government policy.

The aim should be to generate economic growth combined with a reduction in the environmental pressure. It affects key aspects such as:

- Environmentally-friendly goods and services which meet the ever varied needs of consumers
- Sustainable commercial practice in all sectors
- Environmentally-efficient technology in products and production, in processes, in vehicle use, in using knowledge as a production factor
- Efficient use of space, spatial quality and investments in the infrastructure
- Sustainable pricing and taxation on labor.

On the move toward a sustainable economy the Dutch government recently issued a policy documentation on Environment and Economy. The document's key areas of focus are: industry and services, agriculture and rural areas, traffic, transport and infrastructure.

The Dutch policy document covers 3 packages of activities:

- Generic government policy
- Combined actions by industry and government designed to accelerate the projected process of changes
- Other actions to be implemented in various sectors

This policy document is subject to monitoring and annual evaluation as to ensure the desired effects on society and daily life. Within this context the issue of sustainable design and construction has become a major concern of the Government Building Agency GBA.

With regard to the implementation the Government Buildings Agency GBA (in Dutch the Rijksgebouwendienst) does act as a pioneer in the quest for sustainable buildings. As one of the largest principals for the design and construction of non-residential buildings the GBA uses it's roll as a market player by aiming its public procurement policy at sustainable design and construction.

2. Sustainable construction in The Netherlands

The Dutch government has set itself the goal of achieving significant advances in sustainable design and construction in The Netherlands. The “Plan of Action for Sustainable Building”, issued by the Minister and State Secretary of the Dutch Ministry of Housing, Spatial Planning and the Environment in Sept. 1995, contains incentives for hitting that target.
A four-track policy will be implemented in consultation with our partners in the design- and construction industry. One of the tracks provides for the promotion and creation of sustainable government buildings. Another track provides for stimulation of quality management and better cooperation/interactions by demanding for integral quality guarantees.

The Netherlands is a small and densely populated country with a population of 15 million inhabitants, which is the highest average population density in Europe (407 inhabitants per square kilometer) It’s economy depends on industry - particularly chemicals and metal processing - , intensive agriculture and horticulture and on the country’s geographical position at the heart of Europe’s transportation network. These factors have led to major pressures on the environment.
The Government Building Agency GBA is the housing agency for State Civil Services in The Netherlands. It takes care of a real estate portfolio of approximately 6.5 million square meters gross floor area, corresponding with a US $ 8.7 billion present value in terms of property-management.

3. Sustainable construction and the performance concept

During the nineties a US $ 1. billion design-build program is executed in behalf of the construction of new courthouses and tax-offices all over the country in The Netherlands. The characteristic of these design-build contracts is to offer the project owner a turnkey project wholly designed and executed for a budget, for a period of time and for performances determined at an early design phase. (Since public contracts are concerned, this was done by competitive tendering). This procedure relieves the client of the management of numerous contracts and interfaces which are often blurred and potential bones of contention. Meeting the expectations of public project owners it offers them control over the building components by allowing this client/ owner to concentrate on sustainability and fitness for (sustainable) use. The coordination right at the start of the design and execution provides conditions for an integrated approach and effective interaction and as such it ensures the optimization of different aspects. Taking advantage of his role as a public procurement market player the Dutch Government Building Agency GBA introduced the application of the Performance Concept in numerous design-build

contracts in order to enhance better cooperation and interaction between parties as to facilitate the integrated approach in the building market.
The major advantages expected by applying the Performance Concept were:

Focus on output instead of input.
The main issue is to deliver the desired performance rather than to prescribe how to achieve this. As a matter of fact the skills and know-how of the design-build process belong to the supply-side rather than to the client-side. Therefore it should be proper for both sides when the client focuses on output-performances rather than on input prescriptions.

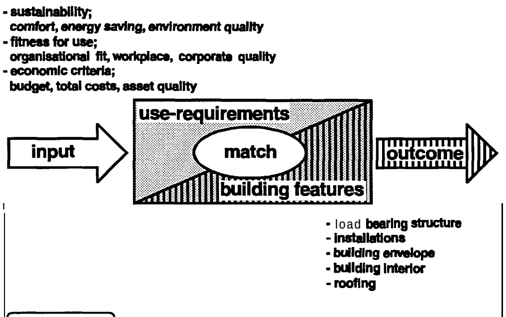
Focus on fitness for use instead of technical descriptions
For the client the building is a business asset, next to other business assets such as capital, staff, technology and information. The building is there to house the client's primary (business) process properly. Therefore the client should define his requirements in fitness for use criteria rather than in technical descriptions.

Stimulate the parties to invest knowledge and research as early as possible in the design process.
The design-build process always starts with a design-phase. The preliminary design phase is crucial, because this is where the comprehensive conditions for success in sustainability and fitness for use are determined. In the early preliminary stages of the design phase the potential on process-control is still large but the information level needed for process-control is poor. The design-build process carries on and more information will be provided but the potential on process control decreases. In order to provide the best conditions to achieve fitness-for-use performances within a reasonable budget frame more knowledge and research should be focused on upgrading the information quality in these preliminary design stages. (scheme 3).
Depending on the type of project the research can be focused on a data-bank of references (general projects) or research can be carried out on typology studies (unique projects).

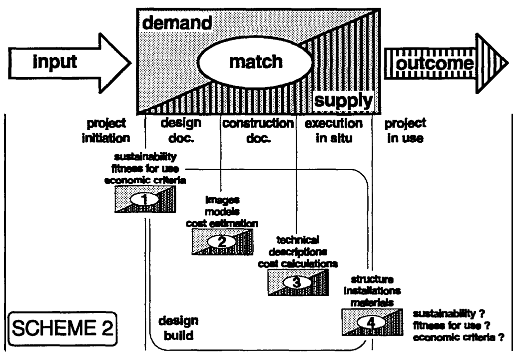
Take advantage of the private sector's efforts and creativity by allowing them to initiate an integrated design-build approach as early as possible in the design phase. The important success factor in achieving both sustainability and fitness for use is the integrated design-build approach from the very first design steps i.e. as early as possible in the design phase. Sustainability and fitness for use are both comprehensible issues that can not be treated successfully by the architect or whatever expert as a single professional. These issues need an integral approach that allows effective intellectual interaction within the fields of architectural design, building physics, construction and specific consultancies, providing environmental calculation methods, assessment-models and decision support systems. Such an approach facilitates the client in taking advantage of the supplier's efforts and creativity by allowing and stimulating them to initiate such an integrated design-build approach.

4. The problems of matching demand and supply

The design-build process can roughly be simplified by a black-box matching mechanism between the client's demand in use-requirements (fitness for use) and the tenderizer's supply in building features (scheme 1).This is not simple and there is a large risk for a mismatch at the moment of delivery.
Moreover this black-box process does in fact consist of partial demand/supply matching processes (phases), each characterized by their own "quality-language" So the mechanism of matching demand and supply in a performance based design-build contract is in the continuous process by transforming and interpreting quality criteria differently during the phases of the design-build process: (scheme 2).



SCHEME 1



SCHEME 2

- The initial phase provides the brief in terms of fitness-for-use performances and a budget-frame.
- The design-phase provides images, sketches and drawings, models, costs estimations, that should match the brief (match 1)
- The construction documents provide technical descriptions, drawings, cost-calculations, that should match the design (match 2)
- The execution phase provides materials, load bearing structures etc., that should match the construction documents (match 3).
- The phase of use provides the actual fitness for use of the building features, the infrastructure, the building envelope, i.e. the building as a whole, that should match the brief and should fit into the budget-frame (match 4)

Each phase introduces it’s own “quality-language” and it’s own risk for mismatches and at he moment of delivery it will therefore be difficult to match the integral outcome with the initial demand performance. In a design-build contract these black-box matching processes actually are of no interest to the user/client, who is mainly interested in the sustainability and fitness for use as an outcome. The tenderer is committed to deliver this outcome in a fit for use building within a fixed budget. But as a matter of fact the critical success factor to client satisfaction is in the continuous process of matching demand and supply over the phase, i.e. on allowing the client to “take a look into the black-box”.

This is where legal aspects show up as the agreement includes a fixed budget and a total quality output that the tenderer is committed to deliver. Any mutation caused by communication between client and tenderer during this process can alter the commitments and liabilities.

So the problem of matching demand and supply in a performance based design-build contract is in the continuous process of transforming and interpreting quality criteria differently during the phases over time. On the one hand the client should not be bothered by the complexity of these matching processes and in fact he is hardly interested in these. On the other hand the critical success factor of client satisfaction is determined by involving the client in these matching processes without mixing up liabilities.

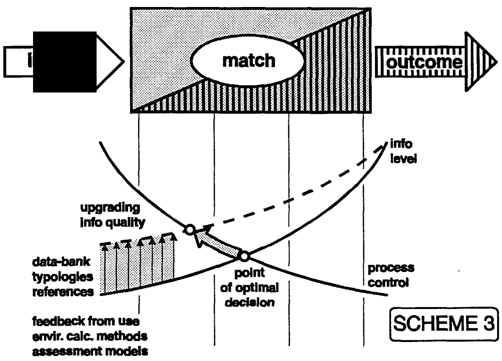
5. Monitoring the process

The matching of demand an supply appears to be a matter of keeping the initial performances on track while transforming and interpreting quality differently during the phases of the design-build process.

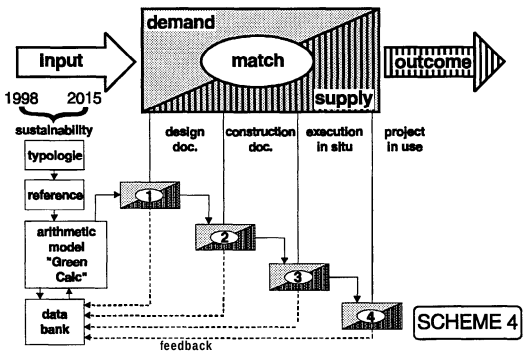
A proper way to complete this mission is by monitoring the entire process from project-initiation to delivery and by organizing communication with the client accordingly.

Referring to chapter 4 there are at least 4 moments of partial matching mechanisms involved in the design-build process.(scheme 4)

Process-control should focus on these moments as they introduce specific risks for an eventual mismatch between demand and supply.



SCHEME 3



SCHEME 4

The first moment of risk is when the performance-based brief is transformed into the conceptual design sketch. This is the first effort in creating a model of the entire integral building quality; it provides the result of an inevitable implicit interpretation of the total-performance desired by the client.
This is where the method of monitoring should be highly effective because it is yet an early stage of the process while investments are still low-profile, whereas the concepts potential for the desired total-performance is of strategic value in terms of output-control
The match is between:

- The demand in terms of sustainability, fitness for use, economic and organizational criteria, corporate identity, budget frame and:
- the supply in terms of the architectural design, potential for sustainable construction, spatial and functional performances and estimation of building costs.

In order to facilitate a proper way of matching knowledge, skills and tools are needed in behalf of decision support systems in this early phase of conceptual design.
Therefore research should be carried out on the basis of:

- a data bank providing information and references of previous projects based upon feedback from use, including maintenance and design-build experiences/skills
- typology studies providing knowledge and tools how to relate between sustainability, use-patterns and the potential design-concepts as to create best conditions for a successful match.
- environmental calculation methods in design and construction as performance concept.
- assessment models for monitoring fitness for use as well as sustainability during the design-build process.

The second moment of risk is when the design (demand in terms of images, potential for sustainable construction, spatial and functional performances and estimation of building costs) is to be matched by the construction documents (supply in terms of technical descriptions, drawings, administration and building costs calculations)
this is when the selected method of monitoring, once applied in the design phase, can easily proceed in interpreting the desired design quality into technical documents, relying on the existing expertise and the role of the architect in the traditional building process

The third moment of risk is when the execution takes place on the basis of the construction documents. Once the design is mirrored consistently in the construction documents, the quality procedures for safety, sustainability and execution in situ should cover most of the risks for mismatch at the moment of delivery.

Nevertheless attention should be paid to the relation between the performance of materials, the execution quality and the predictable sustainability and service life.

The fourth moment of risk is when delivery has taken place and the period of use starts. The after-care services do not cover the risks of a mismatch in terms of fitness for (sustainable) use.
Therefore the phenomenon of performance - guarantee- assurances becomes increasingly the trend in the real estate branch and subject for research as to protect the client from unexpected blows and liabilities.

As these moments include risks for a mismatch between demand and supply monitoring should provide -methods, models and skills that can cover these risks. In behalf of monitoring sustainable design and construction an advanced system of expressing environmental matters in financial terms will be presented by Marcel Dewever and Dr. Michael Haas.
Marcel Dewever is the Chief Inspector on Environmental Affairs with a special mission to empower the GBA-management by implementing sustainability in their decisions. For that purpose he developed a three-step arithmetical model in cooperation with Michael Haas for quantifying the environmental effects of buildings (“The TWIN-model, an environmental calculation method as performance concept”) and for expressing these effects in financial terms.

Collecting systems for waste return in the building industry: combining political, logistical, economical and environmental aspects

A.M. Schuurmans-Stehmann
Environmental Department
INTRON BV, the institute for quality assessment in the building industry
Sittard, the Netherlands

J.M. J.M. Bijen
Department Civil Engineering
Technical University of Delft
Delft, the Netherlands

The amount of building and demolition waste is a growing concern. Recycling techniques have been developed for many materials. However, the building and demolition waste must be returned from the building site to the recycling plant to have the waste recycled. A system for collection and return of waste must be available for this purpose.

For the development of such a system, a multi-disciplinary approach is necessary: political and logistical aspects have to be accounted for: optimisation can take place by economic and environmental analyses of several options for the system.

This contribution clarifies the use of the above mentioned disciplines for the development of a “return system”. Two cases are dealt with: TRESPA cladding panels and expanded polystyrene insulation material.

Keywords: building waste, economy, life cycle analysis (LCA), logistics, policy, returning system, TRESPA, EPS

1. Introduction

Since the Brundtlandt report ‘Our common future’ we know the word ‘sustainability’. Sustainable means that social and economical processes fit within the limits set by nature, now and in the future. Several countries have environmental policy plans nowadays aiming at a sustainable development.

In the Netherlands we have the National Environmental Policy Plans (NEPP1 1989, NEPP+ 1991, NEPP2 1993, NEPP3 1997), a product policy (‘Product and environment’, 1993) and a special policy on sustainable building (‘Sustainable building’ 1991, Plan of action Sustainable Building 1995, Plan of action Sustainable Building 1997). These policies have three main topics as a foundation:

- Integral chain management
- Energy extensivation
- Quality improvement.

Especially the first topic focuses on recycling: product chains have to be closed. This closing, however, must not shift environmental problems to other environmental compartments. This means that we have to analyse the environmental impacts in an integral way: analysing all stages in the chain and looking at all relevant environmental impacts.

Recycling in the building sector got a lot of attention in the past years. Building and demolition waste is one of the largest waste streams in the Netherlands (approximately 14 Mtons a year). In 1988 this waste stream was appointed as a priority. In 1993 the first Implementation Plan for building and demolition waste was published. In this Plan actions were mentioned aiming at a reduction of 5% reduction in growth of the waste stream and maximising the recycling (90% in 2000) and a minimisation of disposal and incineration (maximum 10% in 2000). A very important action was a legislative ban on disposal that was introduced in 1996: Nowadays it is not allowed to dispose waste that can be incinerated or recycled. Furthermore the costs for disposal and incineration are strongly increasing.

This Dutch attention for recycling is not unique in Europe. We all know that recycling is a hot topic in all European countries and in the EU policy.
But how do we collect the building and demolition waste? How do we return the waste to the place of recycling? Who is responsible for the collection? Many questions for the

producers of building materials who are more or less responsible for their materials wastes.

In this contribution I give two examples of producers who have answered these questions and have introduced a return system. You will find the following in this contribution:

- in chapter 2 you find an overview of return systems for building materials in the Netherlands
- in chapter 3 we explain the return system of TRESPA cladding panels
- in chapter 4 the case of EPS insulation material is described
- in chapter 5 we draw some conclusions about the introduction of return systems.

2. Return systems in the building industry

In the early nineties the first of many initiatives to return building and demolition waste to the original producers started. Some examples from the Netherlands are:

- Dutch Association of Plastic pipe Manufacturers (FKS) introduced in 1991 a return system for plastic pipes. The plastics are reused in two production sites for new three-layered sewerage pipes;
- The Association of Plastic Facade elements (VKG) also started early research. In 1997 a return system is introduced;
- Rockwool introduced big-bags for mineral wool building waste;
- For PVC-roofing and modified bituminous roofing options for returning and recycling exist;
- Producers of EPS-insulation material are looking for efficient ways of returning and recycling;
- Building Recycling Netherlands (BRN) takes initiatives to co-ordinate the collection of building materials;
- TRESPA introduced in 1996 it's return system for TRESPA cladding panels.

The return and recycling of stony materials has been very successful in the Netherlands (and also in other countries). Special containers for stony waste are obligatory placed on the building or demolition site and returned to the sorter and crusher. A special certification system is introduced (Korrelmix) to ascertain the quality of the aggregate. The introduction of such systems for the smaller waste streams is, however, much more difficult.

3. The return system of TRESPA cladding panels

TRESPA METEON is a large-size, flat panel based on thermo-setting resins homogeneously reinforced with wood-fibres and manufactured under high pressure and temperature. TRESPA METEON is used for outdoor applications in the building sector, for example as a cladding panel, for roof eaves, balconies, street furniture, etc.
TRESPA waste material is released at the production of the plates, during pre-fabrication of the plates (residual waste) to saw the plates on the sizes needed for the building (sawing losses) and during demolition.

In this chapter I explain a feasibility study of TRESPA International and the introduction of a return system. In paragraph 3.1 you will find a short introduction of TRESPA's motivation. In paragraph 3.2 the choice for a logistical feasible system is described, in paragraph 3.3 and 3.4 the environmental aspects and the economics are described and in paragraph 3.5 I explain the considerations and final introduction of the return system.

3.1 TRESPA and product responsibility

TRESPA is one of the pioneers in feeling responsible for the environmental aspects of her products. In the period 1992-1994 several LCA-studies have been carried out. In 1995 a feasibility study for a return system has been conducted and an implementation scheme was developed. Both studies were subsidised by the Dutch Research Program for the Reuse and Recycling of waste materials, the NOH, on behalf of the national government.
The feasibility study indicated that a return system for residual waste was feasible through the dealers network. From internal research and a small scale production pilot it was concluded that reuse of the returned waste in the production of new cladding panels was very well possible.

A return system for demolition waste was not feasible (see below) TRESPA decided to introduce in 1996 a return system for TRESPA residual waste in the Netherlands, Germany and Belgium. In 1997 this return system is extended. TRESPA also started production scale experiments for the recycling of returned TRESPA material in new cladding panels. For this purpose a new installation is built.
The implementation scheme is finished in 1997.

3.2 Logistics

In the feasibility study several options have been studied. After discussions with relevant parties, some options seemed not feasible. The feasible options have been worked out:

For saving wastes

I Return system by dealers

For demolition wastes

II Return system by demolisher

III Return system by sorter

IV Return system by demolisher and sorter (combined)

In the model II, III en IV three variations are possible:

- Variation 1: Returning material to TRESPA, identification by a certificate, material is recycled;
- Variation 2: External incineration
- Variation 3: Returning material to TRESPA, no certificate, incineration in TRESPA kiln

In table I the assessment of these models and variations on management control, influence and recycling is shown.

Table 1 Feasibility of the TRESPAs returns system according to management control, influence and recycling

	Management Control	Influence	Reycling
Model I	+ returning by dealers, limited number	+ via agreements with dealers	+
Model II	- numerous potential demolishers	numerous unorganised demolishers	small amounts per collector leads to long storage periods
Model III	+ small group of sorters	+ organised sorters	+ small group of qualified professional collectors of waste streams
Model IV	- numerous potential demolishers and sorters	0 partly organised, partly unorganised	+ large direct flows, residual by professional collectors
Variation 1	idem model II, III and IV	idem model II, III and IV	idem model II, III and IV
Variation 2	worse for all models, flow is invisible for TRESPA	worse for all models due, flow is invisible for TRESPA	irrelevant
Variation 3	idem for all models	idem for all models	irrelevant

Source: [NOH,1996]

Model I was assessed to be feasible.
Model III is the most feasible system for demolition waste, preferably in combination with variations 1 or 3.

Model I is introduced. Model III not yet since the amounts of demolition are still rather low for this young product. Moreover, the introduction of a certificate is not easy and returning waste for incineration means that international agreements have to be made with other laminate-producers.

Model I is introduced as follows: Together with the cladding panels so-called LIKO pallets are delivered for the collection of residual waste. The returning of the LIKO pallets is combined with a follow up delivery. Therefore no additional transport is needed for the return system. To prevent additional sorting out of the returned material the appliers receive special collection instructions together with other product handling information. These 'playing rules' are imbedded in the Quality System of TRESPA.

3.3 The environment

Within the scope of the feasibility study a life cycle analysis (LCA) is carried out to elaborate the environmental consequences of different scenarios to operate the return system. In Figure 3.1 you will find the environmental profiles of five scenarios.

No preference could be made between reuse and incineration with heat recovery. By reuse less waste is produced but incineration has a better score for the energy use. In comparison with disposal, both reuse and incineration are better off, or at least have equal environmental performances.

Compared to the pre-return system daily practice, the incineration of combustible building waste, incineration at TRESPA produces less emissions and waste
A critical parameter in the LCA is the transport distance. The turning point lies at approximately 750 km.

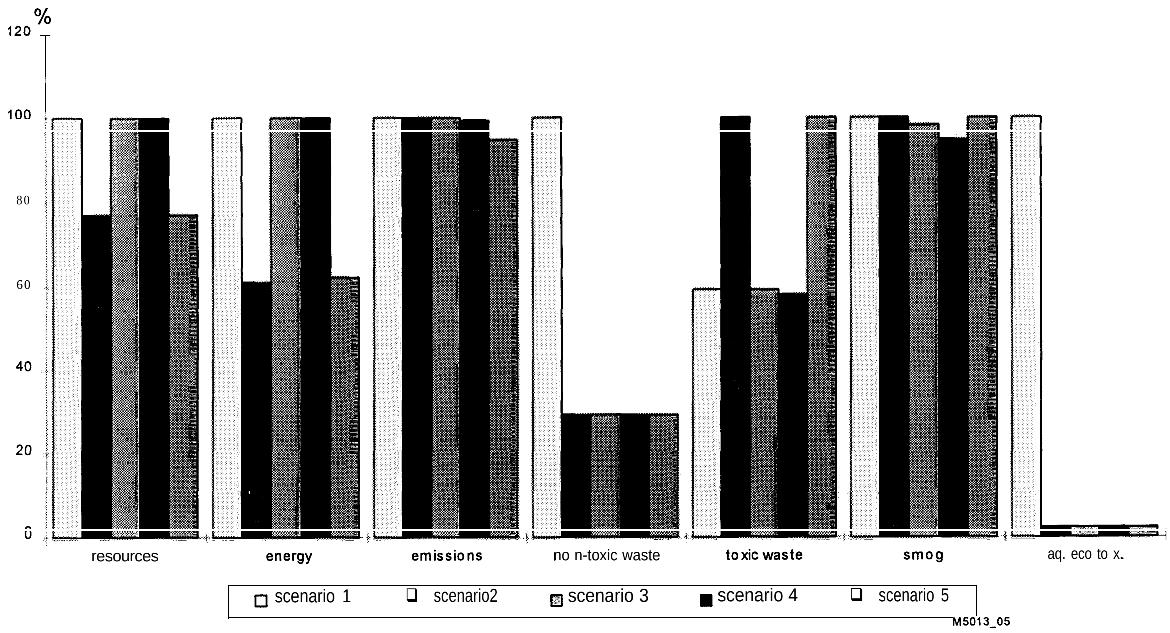

Figure 3.1 Five scenarios for the TRESPA return system: the environmental profiles

Scenario 1: reference situation: landfill after service life;
Scenario 2: thermorecycling at TRESPA;
Scenario 3: reuse in new cladding panels, 5% substitution of virgin material;
Scenario 4: reuse in new cladding panels, 10% substitution of virgin material;
Scenario 5: thermorecycling in a general incineration plant (AVI).
Source [NOH,1996]

3.4 Economics

The return system has three main costs: the investment and operation of the recycling installation, the use of LIKO pallets and the transport back to TRESPA. With the introduction of the return system no contribution was asked off the appliers. Since July 1997 TRESPA asks a contribution from the participating appliers to balance the costs of the return system.

In the feasibility study, the costs of the models have been estimated (table 2)

Table 2. Cost estimation of models

		1996	2005	2010	2015	2020
Model I	without variation	f 230,--	f 225,--	f 225,--	f 225,--	f 225,--
	variation 3	f 155,--	f 155,--	f 155,--	f 155,--	f 155,--
Model II	variation 1	irrelevant	f 275,--	f 235,--	f 230,--	f 225,--
	variation 2	irrelevant	f 230,--	f 230,--	f 230,--	f 230,--
	variation 3	irrelevant	f 205,--	f 165,--	f 160,--	f 155,--

	variation 3	irrelevant	f 140,--	f 140,--	f 140,--	f 140,--
Model IV	variation 1	irrelevant	f 225,--	f 215,--	f 210,--	f 210,--
	variation 2	irrelevant	f 390,--	f 390,--	f 390,--	f 390,--
	variation 3	irrelevant	f 135,--	f 135,--	f 135,--	f 135,--

3.5 The return system of TRESPA

Based on the logistical, environmental and economical aspects, TRESPA has chosen to combine both ways of recycling in her return system: reuse, as it is technologically possible, together with an optimal recovery of the caloric value of the remaining returned material. Because of the importance of the transport distance the system is introduced in the Netherlands, Germany and Belgium.

4. The return system of EPS insulation

Expanded polystyrene (EPS) is a well-known insulation material in the building industry. It is applied in house-building, in office-building and in road construction.

Recycling of this material is feasible and results in environmental yields. Recycling of production waste is commonly carried out since years. However, the building and demolition waste is not returned to the producers but is collected with other materials and incinerated. The Association of EPS producers (Stybenex) therefore decided to carry out a feasibility study for a return system [2]. In this study, the logistics, economics and LCA of several routings are analysed.

This feasibility study showed that two routings are feasible to collect EPS waste material form the building site:

- a routing via the producers: they take the collected material back when they are delivering new EPS. Usually there is so much transport that this takes no more than 20-50 km. extra.
- a routing via sorters: EPS is collected in bags that are transported to the sorter on top of a container. The sorter serves as a depot.

These combined routings can close the EPS insulation chain for approximetaly. 80%. The feasibility of the routings will be tested in pilots in 1998.

Managing Sustainability in Urban Planning Evaluation

P. L. Lombardi
Department of Urban Planning, University of Architecture of Venice, Italy

Abstract
Spatial planning evaluation has been recently reviewed as an activity characterised by a communicative-learning approach rather than a technical-rational one. This change has been given particularly emphases by the issue of sustainability, including ecological considerations, ethical aspects and the principle of public participation in urban planning.

In technical terms, an evaluation of urban sustainability needs an understanding of all the interdependencies between aspects and the effect that action in one aspect might have in others. Sustainability indicators should reflect these interdependencies in order to guide decision making toward the achievement of a sustainable urban development. However, current indicators which has been suggested at national and international level are quantitative in nature and specifically refers to the availability of specialist knowledge on some aspects. The elevation of these aspects and consequent imbalance and ignoring of others may result in unsustainable decisions in the long term and a less then sustainable environment.

An improvement in current decision making in the built environment, based on better communication and more effective negotiation between stakeholders on the actions to be taken, may lead to more sustainable decisions and the building of a common understanding of local sustainability. This requires clear information on urban environmental problems and robust communication channels between experts and citizens. They all need to be able to communicate at a sufficiently deep level and the earning of sustainability must be clear and agreed.

The paper investigates this problem, considering the lack of adequate infrastructures toward a common understanding of urban sustainability and illuminating the need to keep a systemic and pluralistic approach. It postulates a multi-modal thinking approach for establishing an integrated, meaningful and holistic framework for guiding the evaluation of urban sustainability in planning.
Keywords: multi-modal system thinking, planning evaluation, urban sustainability.

1 Introduction

An application of scientific logic in planning evaluation is usually adopted for clarifying consequences of different choices and planning options. It generally focuses on analysis, requiring a comparison of all the characteristics of various choice-possibilities in an explicit and systematic manner [1]. This means the separation of facts from values and basing experts judgement on quantitative indicators and on formalised methods for problem solving.

Traditional and 'formal' techniques, such as cost benefit analysis, assume to be able to assess the impacts of a policy proposal for all relevant variables of the proposal, in an empirical manner. The evaluation is understood as a demonstrative verification, which is based on formal rules of inference. Consequently, it addresses everyone who has the knowledge to understand the language used with the aim of stimulating an intellectual agreement.

This approach has raised a number of critical issues, such as the following: it does not include human values in the decisions, putting great emphasis on the known object and avoiding diversity, multiplicity and conflicts; it does not understand complexity, leading to a danger of reductionism in the analysis; it refers to an ideal public interest which is assumed as an external factor. A strong theoretical tradition has, therefore, emerged in recent years which views urban planning as a process of mediation between competing interests rather than the elusive pursuit of the public interest [2].

The new argumentative-communicative approach in planning evaluation reflects this shift from a comprehensive planning model to an incrementalist attitude in planning. The role of planning evaluation becomes to increase information and knowledge, improving public participation in environmental decision making. Evaluation is understood as a learning process which provides the factual basis of the issues for decision, focusing on language and on co-operation between parties [3].

One of the problems with this ideology in relation to urban sustainability is that no external reference point is acknowledged or even allowed, so there is no certainty that planning according to these wishes will in fact lead to sustainability in the longer term. In addition, when the wishes and views of different people or groups appear inconsistent there is no standard by which to arrive at consensus or to a final synthesis. Furthermore, it tends to ignore those who have no voice in the public arena with the danger that in practice those who shout loudest get heard. Therefore while less reductionist than approaches based on a comprehensive 'rational' model, there is still no guarantee of sustainability [4].

According to other authors [5] the fundamental question is 'how best to organise the form of discourse, to develop inclusionary argumentation and to build interrelations'. This calls for a framework which bring unity within diversity and an integrating mechanism or tool which can bring together the diversity of interests necessary to assess built and natural environmental impacts.

Urban sustainability is theoretically characterised as "a process of balancing and of synergetic integration (or co-evolution) between sub-systems, i.e. social, economic, physical (including the built heritage) and environmental" [6]. This process generally includes the conflicting requirements of sustaining the environment (environmental quality) and at the same time sustaining the flows of production and consumption necessary for the reproduction of the human species (quality of life) [7]. A common understanding of this concept should involve the consideration of a broad range of aspects both determinative (technical, based on empirical observations) and normative (non-technical, based on social values) which need to be simultaneously addressed in decision-making where problems are not always technically amenable to experts solution [8].

Following a multi-modal system thinking approach [9], the paper suggests a new methodological framework, a mechanism that brings unity within diversity with the aim to enlarge the actual network of social actors in decision-making, building an homogeneous vocabularv and a unique language of sustainable urban development.

2. Infrastructuring a common understanding on urban sustainability

2.1 The multi-modal system approach for integration of aspects

The multi-modal system thinking approach is based on the Cosmonomic Theory of Herman Dooyeweerd [10] who proposed a pluralist ontology, in which temporal reality has fifteen aspects (dimensions or level of information), as follows: Numerical, Spatial, Kinematics, Physical, Biological, Sensitive, Analytic, Historical, Lingual, Social, Economic, Aesthetic, Juridical, Ethical, Credal.

The modal aspects (each of which has a kernel meaning) are irreducible to each other. However, there are definite relationships between them, which allows an entity to function in a coherent rather than fragmented manner. These relationships are of three kinds.

1. *Dependency*. The laws of later aspects depend on and require those of earlier ones. Thus, biotic laws require those of physics, which require those of movement, etc.
2. *Functioning.* An individuality structure (entities and systems) functions in each aspect either as subject or obiect. This functioning individuality structure serves as an integration point for the aspects.
3. Analogy. Components of each aspect are mirrored, echoed in others. Such analogy is the basis for symbolic representation of knowledge on a computer [9]

Following this framework of laws, an integrated list of factors, functions and institutions which are relevant for the true long term sustainability of any built environment and its community has been developed from literature review and international reporting [11]. Table 1 illustrates this list of aspects, classifying them in accordance to the modal aspects and their core meanings.

This classification system is quite different from the traditional systems and it specifically refers to the *dependency* and the *functioning* relationships provided by the laws framework of modal aspects. It make the link between the modal aspects explicit, helping to understand how an action on one aspect needs to consider the laws of all the others, at different degree. For example, an improvement in the communication (acting in the lingual aspect) usually requires some historical processes for achieving an adequate level of technology to be employed and/or of creativity, and in less degree, all the other modal aspects from the analytical down to the numerical. This improvement may bring better social relationships and cohesion within the community, which in turn lead to a more sustainable leaving.

In other words, this framework does not tend to reduce the complexity of the problem, suggesting rigid ways for analysing urban sustainability. On the contrary, it forces you to think in an holistic and systemic manner, by integrating all aspects of reality, both determinative (empirical observations) and normative (social values).

Modal Aspects	Kernel Meaning	Examples of factors and institutions for urban sustainability
Numerical	Awareness of 'how much' of things	population, amount of various resources, number of species, accumulation
Spatial	Continuous extension	layout, shape, density, location, proximity, terrain shape
Kinematics	Movement	mobility, accessibility, wildlife movement, viability, transportation, roads, infrastructures
Physical	Energy, mass	prosperity, energy for human and for biotic activity, structure of ground on which to build
Biological	Life function	food, air, water and soil quality, hygiene, pollution, waste, green areas, biodiversity, habitat diversity, shelter, health and health services, gyms
Sensitive	Senses, feeling	comfort, noise, feeling of well-being, feelings engendered by living there, security, counselling service, asylums
Analytic	Discerning of entities, logic	diversity, functional mix, quality of analysis for planning, knowledge, education services, research centres, universities
Historical	Formative power	built heritage, technology employed, creativity, museums, archives
Lingual	Informatory, symbolic representation	communication, collaboration and networks, advertising, the media, monuments
Social	Social intercourse, social exchange	social relationships, social climate, cohesion, competitiveness, social register, clubs and societies, recreational places
Economic	Frugality, handling limited resources	efficiency, attitude to finance, use of land and of resources, signs offices, banks, stock markets, industrial plants, property-market interests
Aesthetic	Harmony, beauty	beauty, harmony, architectonic style, decoration art galleries, theatres
Juridical	Retribution, fairness, rights	democracy, rights, political structure, tribunals, administrative offices legal institutions, regulations and other policy instruments, laws, ownership,
Ethical	Love, moral	equity, solidarity, sharing, participation
Credal	Faith, commitment, trustworthiness	shared vision of what we are and of the way to go, effectiveness, equilibrium, churches, synagogues

Table 1. The list of modal aspects and their correspondence meaning in urban sustainability.

In planning and the built environment threats to sustainability, usually, come from ignoring the laws of one or more aspects [12]. This framework provides a guide for managing the process of evaluating urban sustainability, improving both technical and communicative evaluations in planning.

From a technical point of view, it helps to consider "*if*" an action is in line with the laws of all aspects in an integrated and balanced manner over the long term. Within a communicative ideology, it offers a basis for building a common understanding of the decision making problem by helping the process of getting information both, technical and non-technical. This information can be mapped onto a decision support matrix, such as the one illustrated in Figure 1.

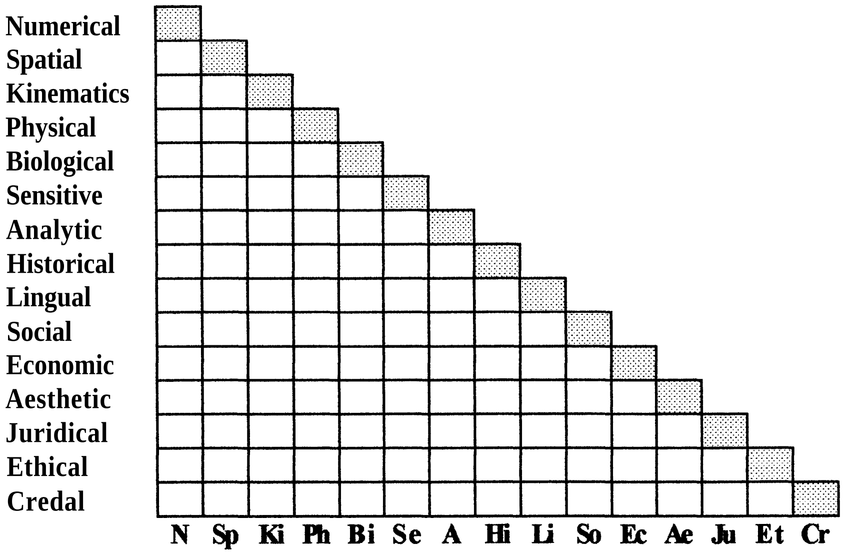

Figure 1. The decision support matrix for organising the information

Each entry of this matrix can be organised as a potential data-base which would include all the information and point of views for decision making specifically related to the links between two modal aspects. Gaps in, and the limitations of, available information on urban sustainability can be immediately highlighted, as specifically illustrated in the application in the following section.

Finally, the matrix takes into account the ***analogy*** relationship between the modal aspects by considering each of them as a source for all the information which can be produced and organised by row. This means that the second half of the matrix does not need to be considered [4]

An illustration of the multi-modal framework may illuminate the benefits of using it in planning evaluation.

2.2 An application of the multi-modal framework for illustration

In this application, the multi-modal framework will be applied to the available technical information on urban sustainability, highlighting the gaps and the main limitations of current scientific knowledge on this subject.

An effective representation of current technical information on urban sustainability is given by the lists of sustainability indicators developed by different international organisations such as OECD [13], United Nations [14], EU Expert Group[15] and European Environment Agency [16].

The aim of all these indicators is to illustrate current environmental problems, identifying their causes and effects, in order to improve decision making processes and assist local administration in finding possible solutions and correct strategies for environmental and social problems [17]. Sustainability indicators should represent both a fundamental vehicle for improving communication within the local community and an efficient technical tool for supporting decision making process.

In accordance with Agenda **21** [18], the selection of indicators should be operated through a bottom-up approach where citizens play a crucial role in identifying the more appropriate ones. However, many European countries has adopted a top-down approach, leaving to experts the responsibility of this choice.

A detailed analysis of the lists of sustainability indicators suggested at European and International levels [**13, 14,** 15, 16] leads to the following results [4,12]:

- The focus on the environment rather than sustainability. Mostly of the selected indicators are related to a description of the environment as such, without identification of the multiple effects this state has on human and natural resources. This often leads to immediate and short term solutions rather than to a prevention of negative effects.
- The unique utilisation of quantitative measures for describing sustainability in the built environment. All the selected indicators are quantitative and statistical in nature. This is a very narrow way to represent the problem which leaves uncovered a large number of fundamental aspects, putting more emphasis on certain issues than others.
- The failure in their aim to integrate all the dimensions of urban sustainability, i.e. environmental, social and economical. One reason of this problem may be that rigid and definite classifications usually leads to difficulties in defining interactions and relationships between sub-systems. A second reason is related to a difficulty in defining sustainabiljtv in substantive terms. **This** assumes different meanings in relation to a ***bottom-up*** approach, based on public participation, or a ***top-down*** approach, based on expert opinions.

These results are made particularly explicit by using the framework of Table **1** and the decision support matrix of Figure **1** for classifying the selected lists of sustainability indicators, as illustrated respectively in Table 2 and Figure 2.

Table 2 reports most of the selected indicators according to the fifteen modal aspects. It uses the numerical dimension as *an idiom* (the only one) for representing all the other aspects of reality, in accordance with the ***analogy*** relationship between the modal aspects. In other words, Table 2 can be considered as a base for developing the first column, i.e. the numerical, of the decision support matrix in Figure1.

Figure 2 shows the disharmonies in the distribution of numerical indicators along the modal aspects, illuminating the ignoring and unbalance in our scientific understanding of urban sustainability. Major information is included in the kinematics, biotic and economics while the aesthetics and the credal are empty. This lack of homogeneity in the information included within each dimension corresponds to some gaps in current technical knowledge.

A technical explanation of this lack is that the effectiveness of an aspect as an idiom, varies and the degree of correspondence declines as the distance between one aspect and another increases. Thus, the numerical aspect is not a very suitable idiom for the more soft and normative aspects, such as the aesthetical, the juridical ones, and very few quantitative indicators may be found in this area. Closer aspects, such as the ethical, are more useful for explaining juridical aspect [8].

Modal Aspects	Numerical indicators suggested by European and International Organisations
Spatial	urban land-cover (total area; total built-up area; open area; transportation network); derelict areas; urban renewal areas; population density; etc.
Kinematics	modal split; commuting patterns; traffic volume; transportation of goods; proximity to urban green area; percentage of streets according to pedestrian accessibility criteria, number of trips pro capita in average length per mode, percentage of population living close to public transport; length of pedestrian streets; length of cycle-roads; percentage of public transport of goods (ton/km); number of private cars; length of fast motor-way; length of rail-way; length of public transport; number of people using public transport (millions); percentage of transport network on the total urban area, percentage of people moving in the town over the total urban population; etc.
Physical	energy consumption; energy production plants; surface water; percentage of listed natural areas water consumption pro capite related to different uses; hectares of ground for agriculture; etc.
Biological	mortality rate, population growth rate, number of inhabitants; production of special waste; percentage of enterprises for recycling; amount of recycled material over the total waste, waste treatment and disposal; biodiversity (e.g. number of bird species); presence of green areas (e.g. percentage of people owning a garden); air quality (long term SO2 + TSP, short-term concentration: 03, S02; TSP); quality of drinkable water; tons of white water; quality of water where to swim, quality of water on and under ground; wastewater, soil quality; contaminated lands; etc.
Sensitive	level of noise; noise exposition up fixed level of decibel; mitres square of living space for person; average floor area per person; percentage of housings without domestic infrastructure (gas, electricity, water); criminal rate, racism's actions rate, rapes rate, percentage of people feeling unsecured to go out at night, fatalities and causalities from traffic accident; etc.
Analytic	alphabetisation rate, library use rate (number of consulted books); number of research centres in the area; etc.
Historical	number of listed buildings; percentage of buildings needing a restoration; etc.
Lingual	number of principal phone-lines every 100 inhabitants; presence of information knowledge database
Social	percentage of population participating to neighbourhood activity; percentage of population using recreational services (artistic manifestations); etc.
Economic	distribution of income pro capite; rate of GNP growth pro capite; relation between housing price and rent, percentage of people living in a state of poverty; exported goods and services; imported goods and services; energy consumption pro capite per year; fuel consumption in £; energy consumption per sectors and sources; employment rate percentage of employment opportunities in the top-ten enterprises; real unemployment;; average distance from work; percentage of recycled paper in public offices; number of enterprises having environmental permission; public expenditure and private investment for the environment; percentage of expenditure for environmental protection on the GNP; percentage of government funds deriving from taxes and subsides; etc.
Aesthetic	
Ethical	number of younger participating in voluntaries activities and community services; etc.
Juridical	percentage of population voting in the administrative elections; number of juridical actions and advising for violation of environment regulations; percentage of control on economic activities without contravention, etc.
Credal	

Table 2. A multi-modal classification of quantitative sustainability indicators

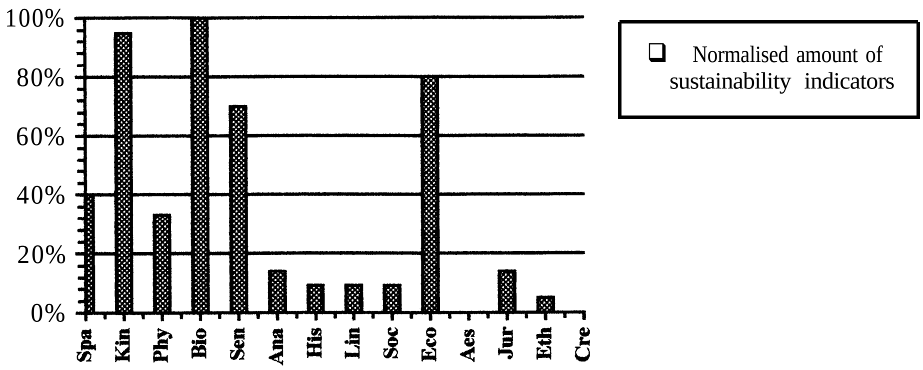

Figure 2. Distribution of sustainability indicators along the modal aspects

3 Conclusion and further research

The multi-aspect nature of urban sustainability requires an improvement of current approaches in planning evaluation, both technical and communicative, and the integration of the artificial (but time-honoured) separation of subject (human system) and object (physical system)]. .

The main advantages in adopting the multi-modal system thinking for evaluation are the following: a) it links all relevant evaluation criteria and indicators in a holistic manner, nesting them in an ordered manner; b) it considers different levels of information, avoiding ignoring and imbalance among them; c) it provides structure and continuity for the evaluation, helping discussion among the parties concerned.

This approach has also been used as a classification system for sustainability indicators suggested by different European and International Organisations. This analysis of sustainability indicators has shown a vision of the problem which is only quantitative (one-dimensional) and technical, therefore partial and sectorial. In addition, it has illuminated a lack of information in many aspects of urban sustainability and the consequent need to improve both, current scientific knowledge in this field and current participatory approaches in decision making. In particular, the development and management of soft and unstructured information may be supported by interactive and communicative techniques, such as the multi-modal framework illustrated in this paper.

Further research is underway for developing a knowledge based system on the base of this study.

Productivity and Quality in Renewal of Buildings

N. H. Bertelsen
Danish Building Research Institute, Hørsholm, Denmark

Abstract
Improved productivity and quality in renewal of buildings are not in conflict with a requirement for sustaining the environment, but it requires that the building sector changes its attitude to the handling of innovation and process control. Research on the increasing Danish renewal sector has provided experiences on how to handle these changes. The research work is based on hypotheses and models on productivity documentation, and analyses and improvements are adjusted to the building sector. The practical use is demonstrated on renewal projects, and it is proposed that the principles are transferred to environment research.

Guidelines for contractors and consultants on how to document productivity on different types of projects are developed. They can be used for improving both the competitive power in the companies and in renewal projects, and they simplify the productivity documentation. A new method for step by step reducing the deviations in the productivity analyses helps to zoom in on major problems and search for the best opportunities for improvements. Examples show that efforts must be dedicated to manpower planning instead of to purchasing, and that process planning, requirements, quality and price primarily shall be specified on the different building elements and secondly on the individual contracts.

It is clear from the described examples that there is only little experience in the renewal sector on handling innovation processes from ideas to final implementation of products and processes. We also feel that there is a lack of understanding in some environment research work concerning the basic control mechanism in the building sector. It is our opinion that this has to be changed, if the building sector shall fulfil the requirement for sustaining the environment.
Keywords: Productivity, quality, renewal, roof, labour, cost

1 Introduction

When one looks at the various initiatives of development which have been carried out in the Danish building sector it is striking that the greatest efforts are made in the field of development of products based on new ideas. Only a small part of the development is to be found in the implementation of the best of the tested ideas and in the field of development of better methods and work routines. This low priority for better methods is probably a consequence of the fact that the development activities, which are the easiest to grasp, are furthered quite subconsciously, whereas the activities that are difficult to understand and which demand cooperation of various groups, subconsciously are given a lower priority.

Already in 1637 the French scientist and philosopher René Descartes wrote about this problem in *The Method* [1]: *"I started with the most simple objects which were easy to grasp and then progressed little by little to understand the most complex ones"*.

In the research on productivity and quality undertaken at the Danish Building Research Institute (SBI) we have focused on practical examples which have shown great improvements and which have or might have an influence on the sector as a whole. The research is in addition based on the following two assumptions:

- A new and better method has not been found until it is easily comprehensible and can be made into an example the end-user will choose instead of the old method
- The success of a method depends on the internal cooperation in building projects as well as on clear relations between “customer need” and requirements

The objective of the development is to find common methods which can be used to document individual solutions, to compare several projects and to point out areas which can be improved. The methods should be simple so that they, with a minimum amount of readjustment, can be used both in technological research and development, as well as in the development of the various companies in the sector.

2 Model for analysis of quality and productivity

The model has been built up based on experiences from quality control, economy control, production control and similar areas in other industrial sectors [2][3][4], and it has then been simplified to a form suitable for the practice of the Danish building sector. The model is based on the scientific traditionwhere qualitative methods often in the beginning are applied within new research areas and then later exchanged with quantitative methods which, step by step, go from the approximations of the first order to more and more complex models.

When comparing such different areas as economy control, production control, quality control and environmental control it turned out that they are all founded on the same general elements. The only difference is that different parameters are used for the control and that different areas are at a different innovation level. It is also evident that a great part of the data is mutual and has many common features. Consequently, it has been the objective of this model to make a common framework which can be used for more than analysing quality and productivity.

Relationship between customer and supplier or the customer-supplier-chain

The model presupposes that the building is to be delivered as a product from the construction parties to the customer, who may be a building owner or the end user. During the building process, it is a question of a chain of customer-supplier conditions covering deliveries of materials, workman hours, services and building parts.

In a customer-supplier relationship the customer's demands andwishes as regards the product are not always identical with what the supplier can deliver. Possibly a gap of opinion on quality and price between the two parties may occur and be visible when the building is delivered. In the same way the consultants make demands on the contractor and the contractor on the suppliers when the work is being carried out. That means that the chain of deliveries and subdeliveries are presented with a chain of demands on which the two parties may have different views and which on delivery might cause some discussion.

Basic elements in the building process

The individual building processes are described based on an input-output model as indicated in Figure 1. The input consists of working hours spent to carry out the working process and raw materials which are included in the final product, and capital including operating equipment supporting the process. The output consists of the product or services delivered from the process, conditions of delivery and the price of the product - the result of the process.

The individual building process and services can be divided into a number of sub-processes which together contribute to the execution of the total building process. In each sub-process a processing of goods and services takes place and between the sub-processes a stream of information and exchange of materials and services take place. In each sub-process and each exchange of information or materials, development or changes may occur.

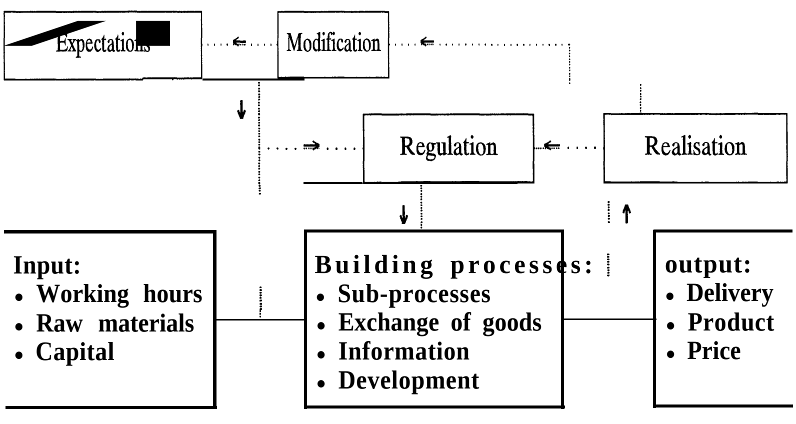

Figure 1. The simple controlling model for the design, planning and building process and also used in the analysis.

It is a prerequisite for controlling a building process that some requirements and expectations as to the result of the process are made. Towards the end of the process the accomplished values are measured and a comparison of the two values can be expressed in a deviation which, depending on size and importance, may result in the following decisions: No reaction, a regulation of the process or a modification of the expected values.

Productivity parameters of the control

The parameters included in the control of a building process cover the consumption of resources spent in the process and the final result. If these two main parameters are set in proportion to each other you get the parameter model for productivity which in this context describes the building process viewed from the side of the building sector and not from that of the client. In this relation a decreasing consumption of resources will give a rising productivity and an increasing building process result will also give a rise in productivity.

The consumption of resources is further divided into the three parameters of resources: Time consumption, building products and operating capital. The numerator of the parameter model which describes the result of the building process is also divided into three parameters: Date of delivery and duration, standard & quality as well as volume and quantity. Under standard & quality the functions and properties as well as architectural and aesthetic qualities and environmental standard are described, and they are probably the most difficult parameters to handle.

3 Methods for comparison of building elements of several projects

As mentioned in the previous section, the model presupposes that a building can be divided into a number of coherent building processes, and measured by the productivity parameters the individual building project in its entirety can be described. These two items are further described in the subsequent description including how in practice product- and process-key-figures for the individual building processes are fixed and are to be used for instance for benchmarking.

Division a project into building parts and contract parts

In Denmark it has for many years been the practice that the various building projects are divided into contracts and often the activities of the contracts have been subdivided according to SfB-classification [5]. In recent years this practice has undergone some changes as several consultants today also use a division of the building project into elements as a base.

The division into building elements is the general and stable division focusing on delivery in close connection with the end user, whereas the division into contract parts focuses on the cooperation between parties in the building process. At the moment a common division into building elements is demonstrated on new building and on renovation of small building properties. Building elements takes place in units which are visible to the building and shall be clearly limited geometrically, so it is possible to locate them in the project under the following main areas:

- *Property and land* of the building as well as surrounding areas and installations and small buildings outside the housing property
- *Building*, its outer structures, the load-carrying structures and installation elements for distribution and supply in the building
- *Flats* and ***rooms*** of the building such as living-rooms, stairs and common rooms complete with installations
- ***General activities*** regarding the building project which do not belong to the other items, but concern design, administration and financing of the project.

Product- and process key figures for benchmarking

A central task for the reseach on productivity and quality development, i.e. to render it visible, and a means to make the sector visible is to work out various key figures which the sector can refer to - also called benchmarking. A key figure system is based upon the fixed quality and productivity parameters with reference to the individual building elements and in relation to the different uses and purposes of the buildings. There are two types of key figures - product-related key figures and process-related key figures. The product-related key figures relate to end user and their communication with the consultant attached to the design and delivery of the building, whereas the process-related key figures relate to the construction parties to further the improvement of contract parts.

As an example, the process-related key figure for the entire roof construction can be expressed in proportion to the size of the roof area, whereas the product-related key figure is expressed in proportion to the total floor area. That means that for a one-storey house these two figures will be the same, but the higher the number of floors of a building, the lower the product-related key figure will be.

Minimizing ***deviations in analysis of key figures***

The key figures are mean figures of similar types of buildings. In order to render the results of the analysis and the development even more visible the deviations between the individual buildings are set down. This can be done by means of an SBI-method called "Stepwise Minimizing of Deviations" (SMOD).

The principle is well-known within quality control and production control, but also within various sports, e.g. shooting. Through an analysis of a number of measurements, the average and standard deviation are to be calculated and put in proportion to the goal. Then a search for different factors which can reduce the standard deviation and the distance to the desired goal is the next step. If such an important factor is found it has to be eliminated and one can start a new round of minimizing of deviations.

Table 1. *Stepwise* ***minimizing of deviations*** *(SMOD)* ***in the analysis on 88 roof constructions in Copenhagen*** *[6].* ***The values are expenses on direct construction work in*** *DKK-*
kroner *excl.* ***VAT and in*** *1995-prices.* ***General activities will add 44*** *%* ***to these expenses.***

Type of renovation	Number of projects	Process-related key figures for roof Expenditure per roof area in kr/m²		
		Average	Standard deviation	
1. Minor repairs	7	256	55	21 %
2. Repairs, min.	2	560		
3. Repairs, max.	2	1.455		
4. Renewal, min.	18	1.755	575	33 %
5. Renewal, max.	53	3.190	944	30 %
5.1 Non-utilized attic	27	2.759	704	26 %
5.2 Utilized attic	26	3.637	964	27 %
Sub-total for 82 projects	82	2.518	1.278	51%
Projects not included:				
Atypically expensive projects	4	from 5.187 to 6.946		
Projects without renewal	2	0		
Total for all 88 projects	88	2.615	1.485	57 %

The stepwise minimizing of deviations has been applied in analyses of 88 renewal projects in Copenhagen [6] and an illustration of the method on roof construction can be seen in Table 1. The standard deviation for all 88 projects is 57 %. The first step is to remove atypically expensive projects and projects where no renovation has been done one comes to 82 projects with a standard deviation of 51 %. The second step is to divide the renovation into 5 types, and the standard deviation for each type is calculated to 21 - 33 %. One type is very large and consists of 61 % of the remaining 82 projects and with a total standard deviation of 30 %. The third step divides the 53 projects into two sub-groups - one for buildings with non-utilized top floor and one for buildings with utilized top floor, and the standard deviation for the two new and even groups was reduced from 30 % to 26 % and 27 %.

4 Method for comparison of activities in a project

The method has been applied to a 4-storey building property with 9 flats in Odense, which were totally renovated in 1995 [7]. In the test it was the wish to examine the quality of the design process and to find important areas where it would be advantageous to start improvements or initiate further investigations.

Relative deviations in the planned workman hours

The project was divided into 8 building elements and 5 contracts and into many different activities within each of these. Out of the 40 combinations of building elements and contracts, work was only carried out in 27, and for each of these, expected and realised data were collected for each productivity parameter. On this basis the relative deviation for each combination and parameter has been calculated by means of the following expression:

Relative deviation = (Realised - Expected) /Expected

Table 2. *Relative deviation for workman hours in the test project in Odense [7]. The deviations in bold are the most important ones, which should be submitted to improvement.*

Building elements	Contracts in the renewal projects					Contract total
	Mason	Carpenter	Painter	Plumber	Electrician	
1. Roof	-5 %	**119 %**	*	-27 %	*	33 %
2. Facades	10 %	10 %	(1380 %)	*	*	-1 %
3. stairs	18 %	93 %	-33 %	*	-20 %	33%
4. Bath and toilet	12 %	-61%	-10 %	-47 %	-70 %	33%
5. Kitchen	-1 %	20 %	76 %	0 %	-28 %	17 %
6. Heating	*	*	-20 %	**90 %**	*	83%
7. Living-room	*	-37 %	308%	(115 %)	335%	120%
8. Building site	*	*	*	*	(160 %)	160 %
Elements total	-4 %	-36 %	71%	-6%	17 %	16 %

Note: '*' no work has been carried out, '()' small numbers of hours

In Table 2 an example is given of how the result can be presented for the calculated relative deviations. The presentation points out areas where improvement efforts probably would be of most value by finding the greatest deviations for the combinations of a considerable size. 5 areas have been pointed out, which are marked in bold, and these cover a total of 37 % of the total number of workman hours.

That means that if it is possible to find the reason and limit the deviation in these 5 areas, a marked improvement of the result of the design and planning will take place as far as future projects are concerned. In the same way all the other parameters have been studied one by one to find possibilities of improvement and the same presentation has been used to make it easier for the parties to find the most important areas of future efforts.

Potential cost reductions concerning labor cost compared to building products

If, on the contrary, one has to compare one productivity parameter with another to find out where future efforts are best applied, a comparison of various divisions can be made by means of the same data. As an example, the difference is shown between the labour cost and the expenses for building products.

In the renovation project in Odense [7] the labour cost amounts to 47 %, the expenses for building products amount to 49 % and operation cost amounts to 4 % of a total realised workman expense of 2.690.670 DKK-kroner. That means that improvement efforts regarding the consumption of resources should either focus on labour cost or on building product expenses. If one looks at the relative deviations for both labour cost and building product expenses it is possible to set up two distributions which can be compared, Figure 2 and Figure 3. In each distribution the deviations for the individual building elements, contracts and activities are weighted in proportion to their share of the total expenditure.

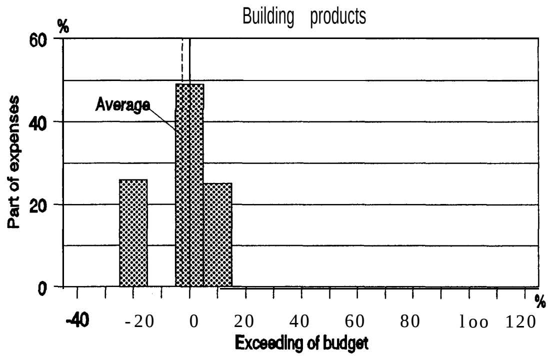

Figure 2. Distribution of budget-exceeding for buildingproducts (49 % of the total workman-expenses).

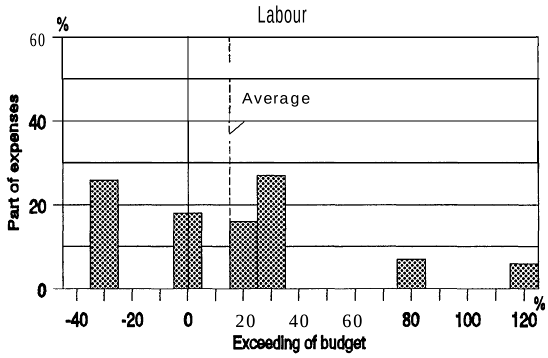

Figure 3. Distribution of budget-exceeding payroll expenditure for labour (47 % of the total workman-expenses).

As far as building products are concerned, the average is seen to remain at a lower consumption of 3 %. For 49 % of the expenses for building products the expected values have hit the realised values, and the largest deviation is -20 %. Conversely, the average of the labour cost seems to be in excess of 15 %, and the deviation is large. For instance 5 % of the expenses have an excess of up to 120 %. Comparing the two distributions it is evident that labour costs are the most difficult ones to plan, and that it will be here that the possibility of improvements will be the greatest. The interesting aspect of this conclusion is that it is in clear contrast to the efforts spent on development, the largest efforts normally being spent on the field for products.

As shown in the above example, the important effort areas are pointing at areas where the deviations are the largest. The procedure of the improvement work and of better analyses is to try to minimize deviations.
